**Bridge C:** The aggregate was a quartz gravel of gneissic origin, showing signs of strong deformation. The quartz crystals in the aggregate particles showed strongly patchy extinction. Stress lamellae are evident in the quartz crystals, which also show sutured boundaries. Some microcrystalline quartz was noted at quartz crystal boundaries. These petrographic features indicate that the aggregate is susceptible to AAR. In fact, AAR gel was clearly observed around the reacted aggregate particles in hand specimens of cores

**Figure 4- Views of representative cores from different bridges**

#### **4.2 SEM/EDX examination of cores**

The SEM/EDX examination was conducted on specimens coated with evaporated carbon. All the cores examined from the three bridges contained various forms of AAR products, but the amount of products varied amongst the cores even in each bridge.

Figure 5 shows examples of AAR products in Bridge A. Both elements contained AAR gel, which was found around reacted aggregate particles, as well as some crystalline AAR products that forms within the aggregate periphery. The number of reaction sites was larger in the cores from the crosshead than that from a pier column. This reflects the more extensive cracking noted in the crosshead. Some of the products appeared depleted in alkali and enriched in Ca, which is due to contact with cement paste over prolonged exposure to wet conditions.

Figure 6 shows representative SEM views of AAR products in pier column of Bridge B. Generally, AAR was stronger in Bridge B than Bridge A, as also indicated from the appearance of the cores, where

internal cracking of aggregate particles and AAR rimming of aggregate particles were evident in Bridge B cores. AAR gel was present in many sites. Some highly Na-rich fibrous products were present in the concrete, which also contained Al, indicating that in addition to the silica minerals, feldspar minerals may also have reacted with Alkali. The concrete from the abutment crosshead showed similar but even larger amounts of AAR products, indicating that AAR was probably stronger in the crosshead than in the pier wall. This probably resulted from higher cement content of concrete in the crosshead, as indicated by higher compressive strength (see later).

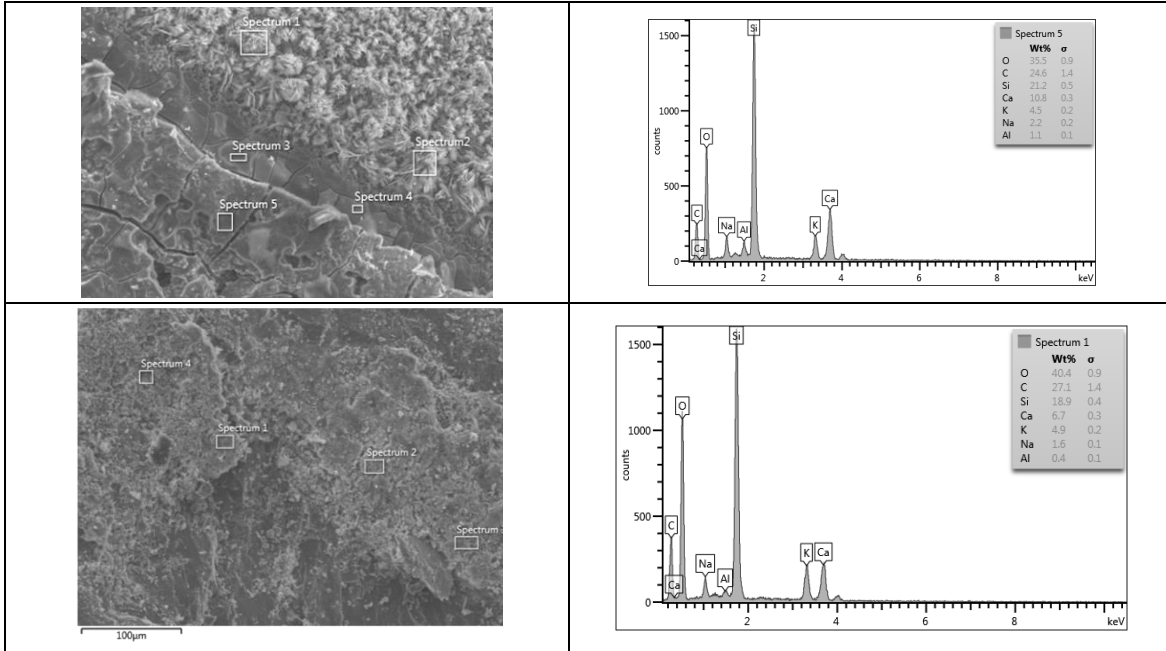

Figure 5- SEM views of AAR products in Bridge A. Top: AAR gel & Rosettes in pier column; Bottom: AAR Rim at aggregate periphery in crosshead

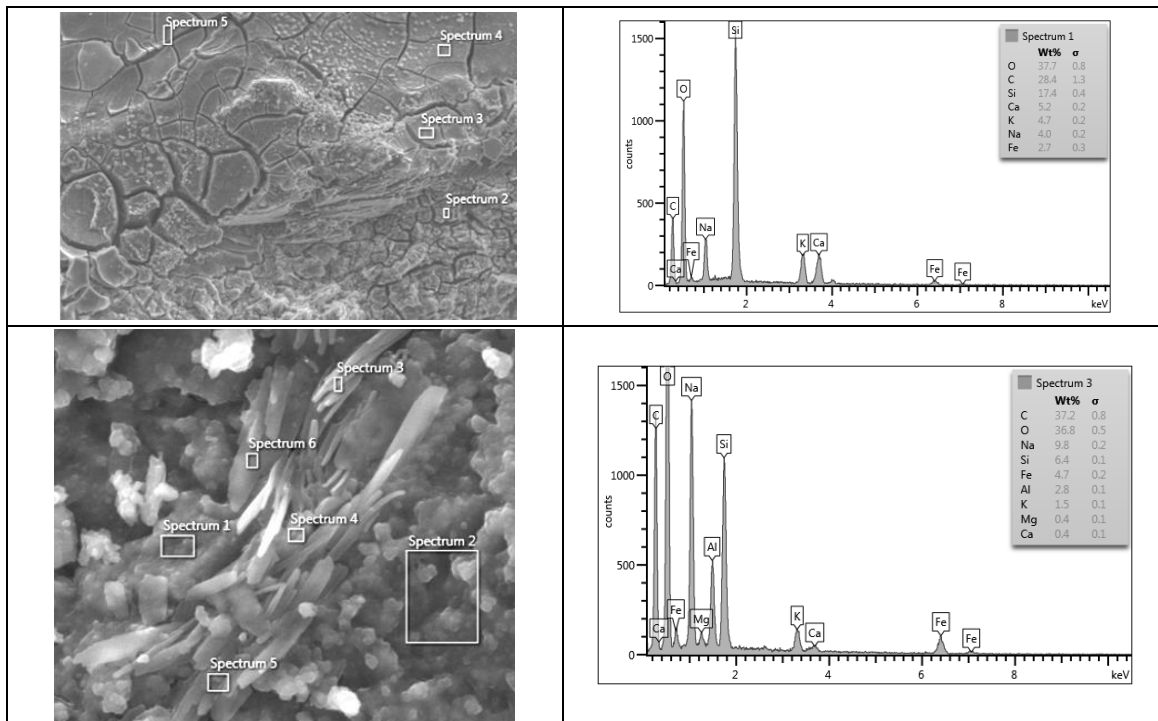

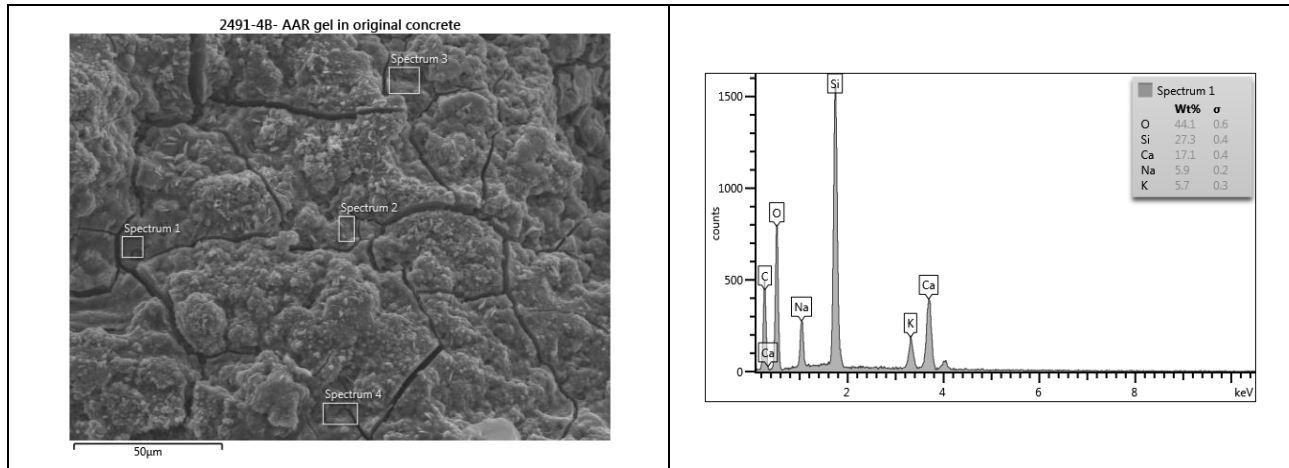

Figure 6- Representative SEM views of AAR gel around reacted aggregate and Na-rich fibrous crystals formed in reacted aggregate, both in pier wall of Bridge B

Figure 7 shows a representative SEM view of AAR gel in Bridge C. AAR products were present in all the concrete elements examined, except in one of the two jacket concrete from one of the columns (Core C13/2491-4A). The reasons for the difference in the concrete of the two jackets examined are not known, but may relate to the alkali content of the original mix. The concrete in the pile-cap exhibited more extensive signs of reaction than in other elements, and this is reflected in the larger extent of cracking reported for pile-caps. Both the concrete jackets, with and without AAR, have exhibited cracking. It was found that the relatively thin concrete jackets did not contain steel reinforcement, and the reason for the cracking of the jacket concrete that has not exhibited AAR may have been lack of reinforcement and low resistance to drying shrinkage.

**Figure 7- Representative SEM view of AAR gel in pier column of Bridge C. Note high Na content of the AAR gel, indicating high Na in original cement**

### 4.3 Compressive strength and Modulus of Elasticity

Table 4 presents the results of compressive strength tests conducted on the cores in accordance with AS 1012.14. The average values of compressive strength for the different elements in each bridge are also presented. Generally, the various elements exhibit adequate compressive strength. For Bridge A and Bridge B the crossheads showed higher strength than columns, whereas for Bridge C, columns showed the highest strength. These strength values may overestimate the actual strength of the elements concerned, as cores are usually drilled in sound portions of concrete, away from cracks, whereas the element itself would include a considerable number of cracks and microcracks. Nevertheless, the compressive strength of concrete could have been reduced by AAR. This is because, strength values of around 40 MPa indicate that the original concrete may have been VR400/40 grade (VicRoads Specification Section 610- Structural Concrete), and those of around 30 MPa of VR330/32 grade. Sound concrete of these grades should have had strength values of 50 MPa and 40 MPa, respectively, at the age of these bridges.

It is known that the compressive strength of concrete is less sensitive than other strength properties, such as tensile and flexural strength and modulus of elasticity, to the effects of AAR (17-19); therefore, the strength values given in Table 4 may not reflect the AAR-induced damage in the elements concerned. A number of cores were subjected to modulus of elasticity testing, in accordance with AS 1012.17-1997. In these tests, the compressive strain measurements were recorded by two bonded 120-Ohm strain gauges attached at 180° along the central 60mm of the cylinders, which were installed between the platens of a calibrated universal testing machine. Load was applied up to a stress of about 40% of the nominal compressive strength, and at this point the load was released and the loading –unloading cycle repeated twice more. A fourth load cycle was then applied to failure. The testing was conducted under controlled temperature and humidity conditions of 23°C and 50% RH.

The results are summarised in Figure 8 for Bridges A& B and in Figure 9 for Bridge C. The values of elastic modulus are also given in Table 4. The lowest modulus values were obtained for the pile-cap of Bridge C and Crosshead of bridge B, both of which had shown more extensive AAR products than other

elements. The AAR-induced internal microcracking significantly reduces the stiffness of the affected elements, which is reflected in the low values of elastic modulus. The stiffness of other elements is probably also somewhat reduced as the largest value of elastic modulus was 27 GPa, whereas concrete of VR400/40 would be expected to have an elastic modulus of around 35 GPa.

**Table 4- Strength properties of concrete in various elements of Bridges**

Bridge	Element	Core ID	Compressive Strength (MPa)	Elastic Modulus E (Gpa)
A	Pier column P2C2	C14/2633-2	35.18	-
	Pier column P1C1	C14/2633-3	33.5	29
	Pier wall P2C1	C14/2633-5	32.19	-
	Abutment Crosshead	C14/2633-6	36.19	-
	Abutment Crosshead	C14/2633-7	44.02	-
	Abutment Crosshead	C14/2633-10	43.2	29
B	Pier wall	C14/2634-1	43.08	-
	Pier wall	C14/2634-4	37.65	-
	Pier wall	C14/2634-5	36.8	27
	Abutment Crosshead	C14/2634-7	42.87	-
	Abutment Crosshead	C14/2634-9	50.3	19
	Abutment Crosshead	C14/2634-10	41.33	-
C	Pile cap	C13/2491-2	28.3	17.3
	Pile cap	C13/2491-3	36.5	-
	Cross- head	C13/2491-6	36.7	25.3
	Cross- head	C13/2491-8	36.5	-
	Column	C13/2491-9	40.0	-
	Column	C13/2491-11	42.3	29.1
	Column	C13/2491-12	41.1	-
Column	C13/2491-13	42.8	31.5	

It should be noted that the higher cement content in VR400/40 concretes could have favoured stronger AAR development than in VR330/32 grade, due to higher alkali content.

Overall, these results indicate that the strength properties of concrete in the various elements have deteriorated due to AAR.

#### 4.4 Residualalkali Content of concrete

The residual alkali content was determined on pulverised specimens of concrete for Bridges A & B only, as Bridge C is a coastal structure, being subjected to contamination by tidal salt water and salt spray. Instead, chloride ion penetration was investigated in Bridge C, as this is the major cause of chloride induced corrosion of steel-reinforced concrete.

Table 5 presents the results of determination of water-soluble, residual alkali content of concrete.

Figure 8- Stress strain curves for cores from different elements

Figure 9- Stress strain curves for cores from different elements in Bridge C

**Table 5 --Residual Alkali Content of concrete**

Bridge	ID and Component	Alkali per volume of concrete (kg/m <sup>3</sup> )		
		Na <sub>2</sub> O	K <sub>2</sub> O	Na <sub>2</sub> O eq.
Bridge A	C14/2633, Pier Column	1.68	1.71	2.81
	C14/2633, Abutment Crosshead	1.91	1.60	2.97
Bridge B	C14/2634-3', Pier	2.51	1.92	3.78
	C14/2634-8, Abutment Crosshead	2.01	1.59	3.06

For Bridge A, the alkali contents in the cores from the pier column and the abutment crosshead were 2.81 kg/m<sup>3</sup> and 2.97 kg/m<sup>3</sup>, respectively. The corresponding values for the concretes from the pier wall and the abutment crosshead of Bridge B were 3.78 kg/m<sup>3</sup> and 3.06 kg/m<sup>3</sup>, respectively. Some of the measured alkali could have been released from the pulverised aggregate phase of the concretes; an artefact which would not occur in the structure, and needs to be corrected for. However, this would need fresh samples of the same aggregate, which were not available. In the case of Bridge A, which contained the quartz gavel the correction for alkali content would be small (around 0.1 kg/m<sup>3</sup>), whereas it could be considerably larger for Bridge B, which contained aggregate derived from igneous rock (perhaps around 0.5-0.7 kg/m<sup>3</sup>). However, in the latter case, there is also the possibility that the aggregate may release alkali into the concrete and increase the extent of AAR (21).

It is generally accepted that an alkali content of about 3 kg/m<sup>3</sup> is required to initiate AAR in concrete. Given that AAR has already occurred, the amount of available alkali could be sufficient to sustain further AAR in concrete elements concerned, particularly if the aggregate phase releases alkali into the concrete. The measurement of residual expansion would clarify the extent of remaining AAR potential.

#### 4.5 Chloride content of concrete in Bridge C

Chloride ion content in concrete was determined on pulverised concrete samples obtained at incremental depths from the concrete surface of selected elements in Bridge C, following AS 1012.20, which determines the total acid soluble chloride content. The chloride content required for corrosion initiation in reinforced concrete is related to the hydroxyl ion concentration in the pore solution of concrete, which varies depending on cement type and concrete quality. The Australian Standard AS 5100.5- Section 4 (Concrete durability) gives a limit of 0.6 kg/m<sup>3</sup> as the maximum acceptable chloride content in reinforced concrete structures. For medium strength concrete, this threshold value would correspond to about 0.1% chloride ion by mass of cement. It is considered that corrosion activity is very likely at chloride content of 0.4% by mass of cement, which would equate to 0.07% chloride by mass of concrete.

The results of chloride content determination in different columns, both at the water mark and at 1.5m height above pile-caps, showed that the chloride content at the depth of reinforcing bars (design cover thickness of about 89 mm) was high enough to cause steel corrosion, as illustrated in Figures 10.

The chloride profiles in the jacket concrete indicate that the surface coating had little resistance to chloride penetration, unless the coating was applied long after the installation of the jacket concrete, which was intended for scour protection rather than being as a chloride barrier.

The chloride content at the reinforcement depth at the base of columns, i.e. behind the jacket, is well in excess of the corrosion initiation threshold, which would have occurred before the installation of the jacket concrete. Therefore, the reinforcement is subjected to active corrosion in the columns and surface treatments (further jacking or coating) would be ineffective in preventing corrosion. In this situation, it is common to install a cathodic protection (CP) system, before corrosion damage becomes significant.

However, in the case of Bridge C, which includes reactive aggregate phases, care should be exercised in the application of CP because the CP current, particularly impressed current, could aggravate the AAR situation in the concrete (20) and cause further expansion and cracking.

**Figure 10- Chloride ingress profiles in concrete jackets and in columns**

#### 4.6 Residual Expansion of concrete

The results of residual expansion measurement, conducted on cores from various elements of the three bridges, under the storage conditions of 38°C and 100% RH, are presented in Figure 11 in the form of expansion curves. The initial, relatively rapid rise in expansion over the first couple of weeks is attributed to moisture absorption by the concrete and/or existing AARgel, and subsequent expansion due to continued formation of new reaction products.

**Bridge A:** Core C13/2633-1 from the column, which has exhibited the weakest manifestation of AAR, showed the lowest expansion and reached a plateau of 0.015%, including the initial expansion due to moisture absorption, which is considered insignificant. Core C13/2633-8 from the crosshead, which has exhibited a stronger case of AAR, showed larger expansion of 0.026%. The plateau indicates that the amount of alkali in the concrete is insufficient for further reaction. It is likely that leaching of alkali from the core, under the storage conditions of the test, could have contributed to the depletion of alkali.

**Bridge B:** Cores C13/2634-3 and C13/2634-6 from the pier wall and crosshead, respectively, showed larger residual expansion potential (0.045% and 0.086%, respectively) than cores from bridge A. These

levels of expansion indicate that further expansion and cracking may occur in these elements in the future, particularly in the crosshead. However, previous work (22) has shown that the expansion level that concrete elements can achieve under field exposure conditions in Australia would be around only 50% of the expansion experienced by cores which are cured at 38°C, 100% RH. Therefore, it would be expected that additional expansion of 0.043% could occur in the crosshead, which would probably lead to further cracking. These elements should be monitored to verify whether or not additional cracking occurs.

**Bridge C:** Large variations were measured in the residual expansion potential of cores from the pile-cap (C13/2491-1), lower part of column (C13/2491-10) and abutment crosshead (C13/2491-10), as illustrated in Figure 11.

The low expansion results for the pile-cap and lower part of column probably arise from alkali leaching effects, and the fact that these elements are often submerged in saltwater, would not induce further potential for AAR (23). It appears that only the crossheads could exhibit deleterious expansion in the future. However, if impressed current cathodic protection (CP) is applied to suppress reinforcement corrosion, then the other elements may also develop deleterious AAR-induced expansion (22).

#### 4.7 Possible treatments to protect various elements

The level of intervention required to reduce the rate of deterioration of AAR-affected elements depends on the impact that AAR had had on the condition of the elements concerned, their residual strength, as well as their current residual expansion potential. As noted above, the compressive strength of concrete appears to be adequate for all the elements examined. However, some elements exhibited reduced stiffness (low modulus of elasticity), which may also indicate deterioration of tensile and flexural strength of the respective elements. Such elements may need strengthening, e.g., post-tensioning or application of epoxy-bonded CFRP (carbon fibre reinforced polymer). Other elements would need lower levels of intervention, largely to suppress the rate of AAR expansion. Mitigation of chloride-induced corrosion of reinforcement in Bridge C, requires special attention due to the combined presence of AAR in the concrete.

On the basis of the above argument, the treatments recommended below could be applied to the various elements of the three bridges. This assumes that the elements tested are representative of other similar elements in each bridge.

**Bridge A:** Application of an appropriate penetrating silane product to the aerial parts of columns and crossheads, would reduce the water content of concrete and, consequently, further suppress that AAR potential. For elements which are prone to flooding, silane products may not be effective, and application of a heavy-duty surface coating (e.g., anti-carbonation acrylic coating) could prove more effective.

**Bridge B:** The exposure conditions for this bridge are benign and application of an appropriate silane would probably reduce the rate of expansion. In addition, application of appropriately designed epoxy-bonded CFRP system could, at least partially, restore the reduced strength and stiffness of the element.

**Bridge C:** Due to the fact that chloride-induced corrosion of reinforcement has already started in some elements, and the AAR-affected nature of the concrete, as well as low modulus of elasticity of pile-caps, three types of protection are required for the bridge elements, as follows:

- 1- Crack injection for the wide cracks noted in the pile-caps, and patch repair of corrosion-induced cracks in lower parts of columns, followed by an appropriate heavy duty surface coating to protect the repaired areas from chloride ingress.
- 2- Application of a cathodic protection system at low levels of impressed current or a sacrificial anode CP system, knowing that the aggregate is reactive and concrete expansion would need to be monitored. Application of an appropriate protective surface coating could be useful in limiting both the availability of oxygen and further chloride penetration.
- 3- Application of an appropriate silane to the crossheads and columns (above tidal zone) to allow the internal moisture of the elements to escape, without allowing moisture ingress, thereby reducing the rate and extent of expansion. The silane should be applied after a dry summer period to allow sufficient penetration. Once the concrete is drier, a heavy duty anti-carbonation coating could also be applied which would also reduce further chloride penetration.

- 4- With respect to strengthening to counter the effects of AAR, only parts of the pile caps may need attention.

Figure 11- Residual expansion curves for cores from the three bridges, under storage conditions of 38°C and 100% RH

## 5. Conclusions

This work has confirmed the presence of AAR in all the concrete elements examined from the three bridges, arising from the reactive aggregate types used in these bridges. The severity of AAR varied in different bridges and amongst different elements of the same bridge. AAR was mild in Bridge A, and stronger in elements of Bridge B than those of other bridges. In bridge C, the pile-cap examined exhibited the greatest impact of AAR in the form of wider cracks. Cracking in the concrete jackets, which were unreinforced, was probably due to drying shrinkage effects than AAR.

The compressive strength of concrete in all elements appears to be adequate, although the stiffness of some elements has significantly deteriorated due to the effects of AAR. Such elements may ultimately need strengthening.

The measured residual expansion of concrete in most elements appears to be small, i.e., low potential for further reaction and cracking. The potential for further deleterious expansion is moderate for the crossheads of bridge B and Bridge C.

Recommendations for protection against corrosion and AAR have been made, taking into account the results of various tests.

# Effectiveness of Traditional and Alternative Supplementary Cementitious Materials in Mitigating Alkali-Silica Reactivity

Daniel Pospischil<sup>1</sup>, Vute Sirivivatnanon<sup>1</sup>, Uthayakumar Sivathasan<sup>2</sup> and Kevin Cheney<sup>2</sup>

<sup>1</sup>University of Technology, Sydney, Australia

<sup>2</sup>Hanson Construction Materials Pty. Ltd.

**Abstract:** With occasional disruptions in the supply of quality fly ash, and the global move towards sustainable means of power generation, it is timely for the Australian construction industry to examine the use of alternative Supplementary Cementitious Materials (SCM's) in various concrete applications. In this study, Metakaolin, Ground Granulated Blast Furnace Slag and Fly Ash were used to partially replace traditional Portland cement in mortar mixtures. The influence of these SCM's on the workability and early age strength development of mortars was examined, along with their effectiveness in mitigating the alkali-silica reactivity (ASR) of aggregates, which was evaluated using the new Australian Standard ((AS1141.60.1) (1)) for the Accelerated Mortar Bar Test (AMBT). Both the type and dosage of the two SCM's were studied.

**Keywords:** Accelerated mortar bar test (AMBT), alkali silica reactivity (ASR), supplementary cementitious materials (SCM).

## 1. Introduction

SCM's are not only widely used in concrete applications due to the range of benefits that such materials provide to the fresh and hardened properties of concrete, but also due to the range of environmental benefits associated with their use. With many SCM's being the by-product of existing and necessary industrial processes, the greenhouse gas emissions associated with the production of SCM's such as Fly Ash and GGBFS is considered to be negligible (Rubenstein (2)). The greenhouse gas emissions and energy requirements associated with the production of SCM's are attributed to the process from which the materials are wrought, and as such the use of certain SCM's is considered to be environmentally sustainable (Rubenstein (2)). In contrast, it is accepted that the production of 1 tonne of Portland cement results in emission of approximately 1 tonne of carbon dioxide alone, and as such, there is impetus within the construction industry to augment the use of blended cements and SCM's, which provide greater environmental sustainability (Rubenstein (2)).

Fly Ash and GGBFS are two of the most widely used and commercially available SCM's in Australia's construction industry, with Silica Fume also used in certain applications (Cement Australia 2014). With ongoing emphasis placed on the growth of sustainable energy production industries in Australia and on a global scale, it is estimated that the supply of Fly Ash to the Australian construction industry could halve by 2050 (Morrison, Graham et. al. (4)). In light of the popularity of the use of Fly Ash as a SCM, this paper seeks to present the effect that varying dosages of Fly Ash, GGBFS and an alternative SCM (Metakaolin) have on select fresh and hardened properties of mortars. This is crucial, as the findings of the report may deliver recommendations regarding types and dosages of SCM that can be used, should supply of traditional SCM's (namely Fly Ash) be constrained in the future.

The objectives of the reported work are as follows:

- To determine the impact of various dosages of Fly Ash, GGBFS and Metakaolin on early-age compressive strength of mortar, fresh properties (flow and air content) of mortar, and mitigation of mortar expansion due to alkali-silica reactions.
- If applicable, to propose types and dosages of SCM that can be used in concrete applications in place of Classified Fly Ash, (a commonly used SCM), should supply of Classified Fly Ash to the construction industry ever be constrained.
- To relate the mitigation of expansion of mortar bars due to alkali-silica reactions, to the physical and chemical characteristics of SCM's incorporated into mortars.
- To discuss variations in the compressive strength and workability of mortar specimens, in light of the physical and chemical properties of SCM's incorporated into mortars.

## 2 Scope and Experimental Procedures

With regards to the materials specifically used, two types of aggregate were tested:

- Dacite aggregate, denoted by 'DA'.
- Rhyolite aggregate, denoted by 'RH'.

These aggregates were used for the purposes of testing expansion of mortar due to ASR. For the determination of mortar air content and compressive strength, Sydney Sand was used as the fine aggregate; however, this is not denoted in the abbreviations used to identify such mortar mixtures.

Three types of SCM were tested: Fly Ash ('FA'), GGBFS ('SL') and Metakaolin ('MK').

Control mixtures, lacking any SCM, were also mixed and tested (denoted by the abbreviation, 'C').

### 2.2 Experimental Methodology

Expansion of mortar bars due to ASR was tested and determined in line with AS1141.60.1-14 (1).

Flow of fresh mortar was measured in accordance with ASTM C1437-13 (5).

Air content of fresh mortar was measured in line with ASTM C185-08 (6).

Compressive strength of mortar cube specimens was determined in line with ASTM C109/C109M-13 (7).

Experimental conditions and methodologies which are referenced in the aforementioned standards, were followed where applicable.

### 3.0 Results and Discussion

#### 3.1 Alkali-Silica Reactivity

Figure 1: Average ASR expansion of mortar bars- Dacite aggregate.

Figure 2: Average ASR expansion of mortar bars- Rhyolite aggregate.

Figures 1 and 2 above indicate that the expansion due to ASR of mortar bars containing Fly Ash increases at a decreasing rate with time, regardless of the type of aggregate used. It is expected that expansion of mortar bars containing Fly Ash as partial replacement of Portland cement would continue to increase with time in the accelerated mortar bar test. This is due to the saturation of mortar bars with sodium hydroxide solution, which provides an abundance of alkalis able to penetrate into the mortar mixture to facilitate alkali-silica reactions (Thomas (8)). However, the decreasing rate of expansion of mortar bars containing Fly Ash is attributed to the pozzolanic reaction associated with Fly Ash. An abundance of experimental work and literature exists, which outlines the efficacy of Fly Ash in consuming calcium hydroxide within mortars, thus reducing the alkali content of the mortar and mitigating the alkali-silica reaction (Kandasamy & Shehata (9); Shafaatian, Akhavan et al. (10)). Not only does the pozzolanic reaction allow Fly Ash to bind alkalis via this chemical reaction, but it also results in the formation of secondary C-S-H gel, which prevents the dissolution of soluble calcium

hydroxide with free water in the mortar mixture (Kandasamy & Shehata (9)). Dissolution of calcium hydroxide would otherwise increase the alkali concentration within the mortar mixture, facilitating the alkali-silica reaction (Kandasamy & Shehata (9)). Whilst effects of the pozzolanic reaction are noticeable after the age of 28-d, (and sometimes do not become prevalent prior to 90-d) (Sumer (11)), Figures 1 and 2 above indicate that at an age as low as 14-d, the rate of expansion of mortar bars containing Fly Ash begins to visibly decrease (evident as the gradient lines showing the mean expansion of each mortar bar begins to plateau).

The results indicate that the efficacy of GGBFS in mitigating expansions due to ASR became more prevalent with time, a likely indication of the pozzolanic reaction of GGBFS beginning. As Figures 1 and 2 demonstrate, at the early age of 3-d, the use of 40% GGBFS to replace Portland cement (using the Dacite aggregate) was not as efficacious in mitigating expansion of mortar bars due to ASR as mortars containing any dosage of Fly Ash, 50% GGBFS or 15% Metakaolin. Figures 1 and 2 also show that at the early age of 3-d, the use of 30% GGBFS to replace Portland cement was ineffective in curtailing expansion due to ASR, with all other mortar mixtures recording smaller expansion values, with the exception of the control mixture and the mixture containing 7% Metakaolin (when the Dacite aggregate was used). When the Rhyolite aggregate was used, mortar mixtures containing both 30% and 40% GGBFS were ineffective in curtailing expansion due to ASR at 3-d, with these mixtures recording the same expansion as the control. It is postulated that any initial benefits (or lack thereof), of GGBFS in mitigating expansion due to ASR can be attributed to the dilution of alkalis in the pore solution of mortars, associated with the use of GGBFS. At the early age of 3-d, the pozzolanic reaction associated with GGBFS has not had time to initiate, and thus, mitigation of expansion due to ASR associated with GGBFS mixtures, results from a reduction in the net quantity of available, soluble alkalis in the mortar pore solution (Kandasamy & Shehata (9); Kwon (12)). Regardless of the aggregate used, results indicate that incorporation of 50% GGBFS into a mortar mixture is able to sufficiently reduce the quantity of alkalis present in the mortar pore solution. However, the use of 30% and 40% GGBFS in mortar mixtures is less efficacious in achieving this end.

Being an artificial pozzolan, Metakaolin consumes portlandite and calcium hydroxide contained within the pore solution of cement paste, producing secondary C-S-H gel (Ramlochan, Thomas et. al. (13)). In doing so, the Metakaolin directly consumes alkalis, removing them from the pore solution of the cement paste, thus minimising the quantity of available alkali which is able to react with reactive silica introduced into the mortar mixture (Thomas (8), Ramlochan, Thomas et. al. (13)). When the Rhyolite aggregate was tested, the use of 15% Metakaolin was also highly effective, with only the expansion of mortar bars containing 15% Fly Ash, 25% Fly Ash or 50% GGBFS being less at 21-d. It is clear that as the dosage of Metakaolin used to partially replace Portland cement increases, the mitigation of expansion due ASR in mortar bars is enhanced. Not only is the retention of alkalis significant in the mitigation of ASR, but in the case of Metakaolin, so too is the retention of calcium, freely present in the pore solution of mortars. When alkali-silica gel forms, its expansion is widely attributed to the consumption of calcium (in the form of calcium hydroxide) (Thomas (8); Aquino, Lange et. al. (14)). Rather than forming an alkali-silica gel of low viscosity, which permeates into mortar pores with little expansive pressure, the consumption of calcium hydroxide creates a hygroscopic alkali-silica gel, which absorbs free water, expanding in the process (Thomas (8); Aquino, Lange et. al. (14)).

As shown in Figures 1 and 2 above, the use of 7% or 10% Metakaolin to partially replace Portland cement was relatively ineffective in mitigating ASR expansion, regardless of the type of aggregate used. Regardless of the aggregate used, the use of 10% Metakaolin in mortars recorded expansion lower than only the control mixture, and the mortar containing 7% Metakaolin. At the age of 28-d, the 10% Metakaolin mixture recorded expansion which was less than that of mortar containing 30% GGBFS, and equal to that of mortar containing 10% Fly Ash, an indication of the pozzolanic reaction of Metakaolin taking effect. The use of 7% Metakaolin was the most ineffective mortar mixture (with regards to the type and dosage of SCM used), as it recorded expansion values greater than those of all mortar mixtures, with the exception of the control mixture (regardless of the aggregate used). Ramlochan, Thomas et. al. (13) have shown experimentally, that the incorporation of less than 10% Metakaolin into a mortar mixture results in the formation of additional portlandite between the ages of 14-28-d (Ramlochan, Thomas et. al. (13)). This results because, once all the available Metakaolin has experienced the pozzolanic reaction, further calcium hydroxide ions are produced from subsequent hydration reactions in the mortar (Ramlochan, Thomas et. al. (13)). With time, this portlandite is able to leach alkalis into the mortar pore solution, facilitating the formation of expansive ASR gel (Ramlochan, Thomas et. al. (13)). Although this investigation did not seek to determine the alkali concentration of mortar bars containing dosages of various SCM's, let alone the portlandite content of such mortars, the ASR expansion results obtained for mortar bars containing 7% Metakaolin would seem to support the findings of Ramlochan, Thomas et. al. (13). The lack of efficacy of 7% Metakaolin

in mitigating ASR expansion can likely be attributed to its high reactivity (its high alumina content, relative to Fly Ash, GGBFS and Portland cement contributes to its pozzolanic properties). Consequently, Metakaolin is unable to effectively mitigate the formation of portlandite, and expansive alkali-silica gel with time, when used in small dosages.

### 3.2 Early-Age Compressive Strength

**Table 5: Effect of SCM type/dosage on mean 7-d and 28-d compressive strength of mortars.**

<b>Mortar Mixture</b>	<b>7-d Compressive Strength (MPa)</b>	<b>28-d Compressive Strength (MPa)</b>
<b>C</b>	24.00	35.76
<b>FA10</b>	18.12	37.24
<b>FA15</b>	19.56	38.00
<b>FA25</b>	17.52	36.56
<b>SL30</b>	18.04	35.80
<b>SL40</b>	17.80	29.96
<b>SL50</b>	16.44	26.28
<b>MK7</b>	20.40	34.40
<b>MK10</b>	20.60	36.88
<b>MK15</b>	23.80	37.04

As shown in Table 5, the fact that the mortar containing 15% Fly Ash records the greatest 7-d compressive strength of all mortars containing Fly Ash is attributed to the role of the dilution and filler effects at this early age. The filler and dilution effects have greater impact as the dosage of Fly Ash increases. As such, where 10% Fly Ash is used, the filler effect has a negligible impact on compressive strength, with the 24.5% decrease in 7-d compressive strength attributed to the dilution of the total quantity of Portland cement within the mortar, via partial replacement with Fly Ash. The compressive strength of mortars containing 25% Fly Ash is also decreased, due to the precedence that the dilution effect takes, over the filler effect in contributing to (inhibiting) compressive strength (which explains the 27% decrease in compressive strength at 7-d associated with this dosage). It would seem that the use of 15% Fly Ash represents an optimum dosage, whereby decreases in strength associated with the dilution effect are counteracted by compressive strength increases attributed to the filler effect. The fact that mortars containing 15% Fly Ash recorded the smallest decrease in 7-d compressive strength compared to other Fly Ash mixtures would seem to compliment this explanation.

The lack of early-age strength development exhibited by mortar mixtures containing GGBFS is attributed to both the slow onset of the pozzolanic reaction, and the dilution effect, a phenomenon especially prevalent due to the large dosages of GGBFS used to partially replace Portland cement. As GGBFS was used to partially replace Portland cement in dosages ranging from 30-50% in this investigation, the contributions that the filler effect and cementitious properties of GGBFS provided to the early-age strength development of mortar were outweighed by the dilution effect of the SCM. Due to the significant mass of GGBFS used to replace Portland cement in each mortar mixture, the total quantity of cementitious material able to contribute to the early-age strength development of the mortar decreases relative to the control mixture containing Portland cement alone (Barnett, Soutsos et al. (14)). The results shown in Table 5 above compliment this academic finding, whereby the compressive strength at both 7-d and 28-d of mortars containing GGBFS was reduced relative to that of the control mortar. Due to the dilution effect in particular, as the dosage of GGBFS used to partially replace Portland cement in mortar increases, inversely, the compressive strength of the mortar decreases (Miyazawa, Yokomuro et. al. (16)).

Metakaolin has a 'filling effect' when used in mortar, whereby, the small particle fineness and high specific surface area of the Metakaolin allows the SCM to fill voids between un-hydrated cement particles and aggregate particles in the mortar (Guneysi, Gesoglu et. al. (17)). This allows the formation of a mortar with a dense microstructure, which is relatively free of capillary pores, providing strength to the mortar. With a particle fineness approximately 40 times that of Portland cement, Metakaolin particles are able to pack the interfacial transition zone between cement paste and aggregate particles in mortar, filling voids and capillary pores. This increases the density of the microstructure of the mortar, whilst homogeneously dispersing cementitious by-products throughout the interfacial transition zone of the mortar (Wild, Khatib et. al. (18)). The filler effect that Metakaolin

provides is understood to outweigh the dilution effect associated with the SCM (Guneyisi, Gesoglu et. al. (17); Wild, Khatib et. al. (18)), allowing it to enhance the strength of mortar when used in dosages ranging from 5-15%. The results shown in Table 5 above compliment this academic finding, and in particular, explain the high 7-d compressive strength of mortar specimens containing Metakaolin, relative to mortars containing Fly Ash and GGBFS.

Being a predominately alumino-siliceous material, Metakaolin displays pozzolanic characteristics. Consequently, the material is able to hydrate and harden in the presence of moisture in mortar, consuming calcium hydroxide within the mortar pore solution to produce C-S-H gel, which contributes to the strength development of the mortar (Guneyisi, Gesoglu et. al. (17)). Despite having high contents of reactive silica and alumina relative to Portland cement (Megat Johari, Brooks et. al. (19)), the pozzolanic reactions associated with Metakaolin are most vigorous between the ages of 7-d to 14-d (Wild, Khatib et. al. (18)). This academic finding is supported by the experimental results presented in this investigation, whereby, the 28-d compressive strength of mortar specimens containing Metakaolin was found to be greater than that of the control mixture (with the exception of the mortar mixture containing 7% Metakaolin).

### 3.3 Mortar Flow

**Table 6: Effect of SCM type and dosage on fresh mortar flow.**

<b>Mortar Mixture</b>	<b>C</b>	<b>FA10</b>	<b>FA15</b>	<b>FA25</b>	<b>SL30</b>	<b>SL40</b>	<b>SL50</b>	<b>MK7</b>	<b>MK10</b>	<b>MK15</b>
<b>Flow (%)</b>	132	135	136	137	129	139	133	136	126	126

The results shown in Table 6 compliment a plethora of academic studies, which present experimental results that correlate increases in mortar flow with increasing dosages of Fly Ash. According to Sumer (11), “the morphologic effect states that there are many micro beads in Fly Ash, working as ‘lubricating balls’ when incorporated in fresh concrete” (Sumer 2012, p.531 (11)). The spherical shaped particles that constitute Fly Ash induce a ‘ball bearing effect’ regarding the fluidity and motion of mortar in the fresh state, which is manifested by way of enhanced workability (increasing mortar flow), when the Fly Ash is incorporated into a mortar mixture. This explanation is supported by Sahmaran, Christianto et. al.(20), who argue that the spherical shape of Fly Ash particles reduces friction between the particles themselves, Fly Ash and cement particles, and Fly Ash and aggregate particles in a mortar mixture, enhancing mortar flow. Consequently, when force is exerted on a mortar or concrete mixture during placement and consolidation, the decreased resistance to particle motion (aided by the lessened frictional forces acting between the cementitious paste and aggregate particles) improves the workability of the mixture. With regards to mortar, this phenomenon is manifested through a noticeable increase in the flow of mortars containing Fly Ash.

The increase in flow associated with mortars containing 40% and 50% GGBFS, as shown in Table 6, is indicative of other experimental and academic studies. As the dosage of GGBFS used to replace Portland cement was increased, so too did mortar flow. This is attributed to the smooth, glass-like texture of GGBFS, which allows the SCM to increase mortar flow, despite its angular and irregular particle shape (Sumer (11); Isikdag & Topcu (21)). A significant body of academic study indicates that GGBFS also disperses cementitious particles evenly in a mortar matrix, which enhances the flow of such mixtures (Megat Johari, Brooks et al. (19)). The improved workability that GGBFS provides to mortar (in the correct dosages) is also attributed to the particle size of GGBFS particles, which provides a micro bead effect within the mortar (Sumer (11)).

The results obtained compliment numerous academic studies, which show that as the dosage of Metakaolin used to partially replace Portland cement in mortar mixtures increases, the flow of the mortar mixtures decreases. This is primarily attributed to the water demand that Metakaolin particles exhibit, which is a combination of both the fineness and morphology of the material (Wild, Khatib et. al. (18); Siddique & Klaus (22)). With an average specific surface area of 15000 m<sup>2</sup>/kg (Megat Johari, Brooks et. al. (19)), Metakaolin has a specific surface area significantly higher than that of Portland cement (380 m<sup>2</sup>/kg). Consequently, Metakaolin exhibits a high water demand when introduced into mortar, absorbing mix water, and thus preventing the mix water from contributing to the fluidity and flow of the mortar (Wild, Khatib et. al. (18)).

### 3.4 Mortar Air Content

Table 7: Effect of SCM type and dosage on air content of mortar.

Mortar Mixture	C	FA10	FA15	FA25	SL30	SL40	SL50	MK7	MK10	MK15
Air Content (%)	3.5	4.2	4.3	4.3	4.7	4.5	4.2	4.6	4.4	3.9

As the results in Table 7 above indicate, the partial replacement of Portland cement with Fly Ash, GGBFS or Metakaolin increases the air content of mortar, relative to the control mixture. As the dosage of GGBFS and Metakaolin used to partially replace Portland cement in a mortar mixture increases, the air content of the mortar mixture decreases. This is attributed to the 'filler effect' associated with both these SCM's. The small particle size of GGBFS, and in particular, Metakaolin, relative to that of Portland cement, allows the SCM's to penetrate homogeneously throughout the microstructure of a mortar mixture, refining the size of microstructural pores within the mortar (Guneyisi, Gesoglu (17); Wild, Khatib et. al. (18); Siddique & Klaus (22)). Consequently, the volume of air retained within the pores of the mortar decreases, due to the enhanced microstructural density of the mortar which results (Guneyisi, Gesoglu (17); Wild, Khatib et. al. (18); Siddique & Klaus (22)). It is postulated that greater microstructural density and mortar pore refinement is associated with an increase in the dosage of GGBFS or Metakaolin incorporated into a mortar mixture. In turn, the air content of the mortar would be expected to decrease, a postulation complimented by the experimental data obtained.

The increase in the air content of mortar mixtures containing increasing dosages of Fly Ash (as a partial replacement for Portland cement) presents a counter-intuitive result. In line with academic findings, it was anticipated that, as the dosage of Fly Ash used to partially replace Portland cement was increased, the air content of the mortar mixtures would decrease. Such results would be attributed to the filler effect, whereby, the micro bead effect associated with Fly Ash allows the material to enhance the microstructural density of mortar, by penetrating homogeneously throughout a mortar mixture (Sumer (11)). The results obtained do not compliment current academic findings. As such, it is postulated that the particle-packing behaviour of the spherical Fly Ash particles influenced the air content of the mortar mixtures which resulted. When spherical Fly Ash particles pack within a mortar mixture, voids form between the particles, in which air can become entrapped.

### 4.0 Conclusions

Due to the need to address potential constraints regarding the supply of Fly Ash to the construction industry (for use in concreting applications), the results and discussion presented in this investigation indicate that dosages of GGBFS and Metakaolin can be used to partially replace Portland cement in concrete applications, rather than the more traditionally used Fly Ash. Furthermore, the experimental results presented in this report, outline that particular dosages of Fly Ash, GGBFS and Metakaolin can also be used to partially replace Portland cement in concreting applications, for the purposes of preventing expansion due to alkali-silica reactivity, without having deleterious effects on the early-age compressive strength, flow or air content of mortars. The following core results were found:

- 25% replacement of Portland cement with Fly Ash ought to ensure the mitigation of expansion due to alkali-silica reactivity. Whilst the use of 25% Fly Ash is not the dosage which optimises the 28-d compressive strength of mortar, this dosage will increase the 28-d compressive strength of concrete, relative to a control specimen. Furthermore, the use of 25% Fly Ash is also expected to enhance the workability of concrete in the fresh state, namely, flow and air content. Where such a dosage was used in this investigation, the air content of mortar was found to increase by 22.9%, and the flow of mortar was found to increase by 3.8%, indicating an increase in the ease with which concrete containing 25% Fly Ash can be placed and consolidated in the fresh state.
- 50% replacement of Portland cement with GGBFS ought to ensure the mitigation of expansion due to alkali-silica reactivity. It is not recommended that GGBFS be used in applications where

it is necessary to mitigate expansion due to alkali-silica reactivity, whilst also maintaining or enhancing the compressive strength of the concrete in question. This is because it is expected that using such a dosage (50%) of GGBFS, will decrease the 28-d compressive strength of concrete. Thus, concrete containing 50% GGBFS should not be used in high strength concreting applications. However, 50% GGBFS was found to enhance the workability (air content and flow) of mortars, which is desirable regarding fresh concrete. In particular, this dosage of GGBFS was found to enhance mortar air content by 20%, and flow by 0.8%, relative to the control, in this investigation.

- 15% replacement of Portland cement with Metakaolin ought to ensure the mitigation of expansion due to alkali-silica reactivity. This is ideal, as the use of 15% Metakaolin ought to maximise the 28-d compressive strength of mortar. In this investigation it was found that the use of 15% Metakaolin enhanced the 28-d compressive strength of mortar by 3.4%, relative to the control. However, the use of 15% Metakaolin has mixed effects on the workability of mortar in the fresh state. The use of 15% Metakaolin can be expected to enhance the air content of mortars (an increase of 11.4% relative to the control was noted in this investigation). However, the use of 15% Metakaolin significantly increases the water demand of mortar mixtures, and as such, decreases the flow of mortar in the fresh state.

As stated, the aforementioned dosages of Fly Ash, GGBFS and Metakaolin ought to be used in practice, so as to mitigate deleterious expansion of concrete elements due to alkali-silica reactivity. In summation, it is evident that, in the correct dosage, Fly Ash, GGBFS and Metakaolin can all be used to optimise the mitigation of ASR expansion, early-age compressive strength development, and the flow and air content of fresh mortars, and as such, these SCM's can find application in concrete practice within the Australian construction industry.

**Abstract:** The Australian Standard accelerated mortar bar test (AMBT) method, AS 1141.60.1, adopts the expansion limits at two exposure periods to classify the alkali silica reactivity (ASR) of aggregate. This was a first step toward the use of 'reaction kinetics' or 'rate of reaction' to detect and classify alkali silica reactivity. The AS 1141.60.2 concrete prism test (CPT), on the other hand, uses a single expansion limit at one year to classify ASR. This paper examines the validity of the use of reaction kinetics, evaluated from the AMBT expansion data, to gauge and classify the reactivity. This may enable a better quantification of the degrees of reactivity and a more fundamental approach to ASR mitigation.

**Keywords:** Accelerated mortar bar test (AMBT), concrete prism test (CPT), reaction kinetics.

## 1. Introduction

Alkali Silica Reactivity (ASR) is an internal reaction that can lead to deterioration of concrete. While only a small proportion of concrete suffers from deterioration due to ASR, its effects can lead to a significant reduction in service life of affected structures. Consequently, much effort has been expended in developing test methods to evaluate ASR reaction potential.

International accelerated mortar bar (NBRI method, ASTM C1260 and CSA A23.2-25A methods) and concrete prism test methods (ASTM C1293, CSA Test method A23.2-14A) have been used in Australia, together with derived test methods adopted by various statutory authorities such as RTA T363 Rapid Mortar Bar Test and Vic Roads RC376.04 Concrete Prism Test. These test methods were joined in 2014 by two new standard test methods published by Standards Australia CE-012 Aggregate and Rock for Engineering Purposes committee:

AS 1141.60.1:2014 Potential alkali-silica reactivity - Accelerated mortar bar method (AMBT) and

AS 1141.60.2:2014 Potential alkali-silica reactivity - Concrete prism method (CPT).

AS 1141.60.1 accelerated mortar bar method (AMBT) adopts the expansion limits at two exposure periods to classify the alkali silica reactivity (ASR) of aggregate, while AS 1141.60.2 concrete prism test (CPT), on the other hand, uses a single expansion limit at one year to classify ASR.

However, alkali silica reaction is a phenomenon occurring over time. These test methods do not address the issue of how much time is likely to pass before deleterious expansion occurs. Johnston, Stokes and Surdahl (2000)<sup>[2]</sup> attempted to develop a kinetic based model for better interpreting results from the ASTM C1260 mortar bar test. A literature search resulted in the selection of the Kolmogorov-Avrami-Mehl-Johnson (KAMJ) model, which describes nucleation and growth transformation reaction kinetics. A number of tests were done at various ages using extremely reactive sand and fitted into the KAMJ model. The conclusion from the research in this paper was that a kinetic based model can provide a means of interpreting the results of ASTM C1260 independent of the 14 day result.

A further study was undertaken by Johnston, Stokes, Fournier and Surdahl (2004)<sup>[3]</sup> to try to correlate the rates of reaction determined by the KAMJ model to the onset of cracking of concrete in service and large slabs and blocks stored externally. The study concluded that using the kinetic approach of the KAMJ model allows for a significant improvement in the reliability in predicting the reactivity of aggregates. Results from the study indicate that the same equation is applicable to laboratory test ASTM C1260 and slab and block concrete specimens exposed outdoors and in predicting the time to onset cracking of concrete pavements, all of which support its suitability as a model.

This paper examines the validity of the use of reaction kinetics, evaluated from both the AS 1141.60.1 (AMBT) and AS 1141.60.2 (CPT) expansion data, to gauge and classify the reactivity. This may enable a better quantification of the degrees of reactivity and a more fundamental approach to ASR mitigation.

## 2. Value of AMBT & CPT

Rocker, Mohammadi, Sirivivatnanon and South (2015)<sup>[1]</sup> reviewed international data on AMBT and CPT tests, as well as field performance of large concrete blocks.

It was found that the AMBT was a good indicator of reactivity of some aggregates. In many cases, however, the results from the AMBT disagreed with those from the CPT and the outdoor simulated field tests. In general, reactivity diagnosed by CPT was found to correlate well with reactivity in field exposure.

This mirrors the experience of Boral Construction Materials testing over many years and the requirements of some authorities that, where an aggregate is classified as reactive by AMBT, it be tested using the CPT. This often results in a non-reactive result.

While there is no agreed hierarchy of the two test methods, experience and current practice suggests the CPT has a closer correlation to reactivity in field exposure.

### 2.1 Aggregate classification based on AMBT

The non-mandatory appendix in ASTM C1260 provides guidance to the interpretation of test results with the following expansion limits: 14-day expansions of less than 0.10% to be indicative of “innocuous” behavior whereas 14-day expansions of more than 0.20% are indicative of “potentially deleterious” expansion. Aggregates with 14-day expansions between 0.10 and 0.20% are known to be innocuous and deleterious in filed performance, and supplemental information in the form of petrographic examination or identification of alkali reaction products in specimens after tests, or field service record can be used in the assessment of the performance

**Table 2.1 Comparison of ASTM and AS Mortar bar expansion limits**

ASTM C1260		AS 1141.60.1		
Interpretation	14 days	Classification	10 days	21 days
Innocuous	< 0.10*%	Non-reactive	-	< 0.10*%
“uncertain”	0.10*-0.20%	Slowly reactive	< 0.10*%	0.10*% to <0.30%
Potential deleterious	≥ 0.20*%	Reactive	≥ 0.10*% -	- ≥ 0.30%

\*The value of the lower limit for natural fine aggregate is 0.15%

The AS 1141.60.1 classified aggregates with 21-day expansion below a lower limit of 0.10% to be non-reactive, and those with 10-day expansion equal or greater than the lower limit of 0.10% or 21-day expansion equal or greater than the upper limit of 0.30% to be reactive. For aggregates with 10-day expansion below the lower limit of 0.10% but 21-day expansion equal to or exceeding the lower limit of 0.10% but not exceeding the upper limit of 0.3% to be a “slowly reactive” aggregate. Note that the lower limit applicable to natural sand is 0.15%.

### 2.2 Aggregate classification based on CPT

The ASTM C1293 tests the expansion of concrete with a cement content of  $420 \pm 10 \text{ kg/m}^3$  and a dry mass of coarse aggregate per unit volume of concrete equal to  $0.70 \pm 0.02$  of its dry-rodded bulk density with a water to cementitious material ratio (w/cm) of 0.42 to 0.45 by mass. The cement has a total alkali content of 1.25% of  $\text{Na}_2\text{O}$  equivalent by mass of cement. Specimens are placed in a container stored in a  $38.0 \pm 2 \text{ }^\circ\text{C}$ . The non-mandatory appendix states that an aggregate might reasonably be classified as potentially deleteriously reactive if the average expansion of three concrete specimens is equal to or greater than 0.04% at one year (CSA A23.2-27A-00 Table 1). It also suggests that it is reasonable to

conclude that the amount of pozzolan or slag used in combination with an aggregate is at least the minimum needed to prevent excessive expansion in field concrete if the average expansion is less than 0.04% at two years (CSA A23.2-28A-02).

The AS 1141.60.2 uses essentially the same concrete mix proportion and test method as the ASTM C1293 but classifies an aggregate with a prism expansion of less than 0.03% at 52 weeks as “non-reactive” and an aggregate with a prism expansion equal to or greater than 0.03% at 52 weeks as “potentially reactive”. The lower expansion limit is considered more conservative as it was adopted from the RMS T364 which tests concrete with a higher adjusted cement alkali of 1.38% Na<sub>2</sub>O equivalent.

### 2.3 Aggregate classification based on reaction kinetics

The current standard methods adopted by Australia in determining ASR involve the collection of information regarding whether or not deleterious expansion occurs and should be expected for the concrete in service. This process and the information gathered fails to address the time frame; that is the amount of time that passes until significant damage might occur in the concrete in question. For this reason it is desirable to develop a model and method that explores the correlation between rates of reaction, and the development of cracking in concretes in service. By implementing a kinetic-based method for interpreting AMBT or CPT test data not only can relative potential for ASR be evaluated and determined by the existing laboratory tests, but more information regarding the time frame in which damage occurs in field concrete may also be obtained and determined from these same tests.

#### 2.3.1 The Kolmogorov-Avrami-Mehl-Johnson (KAMJ) model

The study performed by Johnston et. al. (2000, p. 142)<sup>[2]</sup> was conducted to determine an appropriate model to represent ASR expansion in the C1260 test. The Kolmogorov-Avrami-Mehl-Johnson (KAMJ) model which describes nucleation and growth transformation reaction kinetics was selected as potentially applicable and has the following form:<sup>[2]</sup>

$$\alpha = 1 + \alpha_0 - e^{-k(t-t_0)^M} \quad (1)$$

$$\alpha = \alpha_0 + (1 - \alpha_0)(1 - e^{-k(t-t_0)^M}) \quad (2)$$

Johnston et. al. (2000, p. 142-144)<sup>[2]</sup> explains the equations:

$\alpha_0$  is the degree of reaction at time  $t_0$  when nucleation and growth become dominant, and  $k$  is a rate constant which combines the effects of nucleation, multidimensional growth, the geometry of reaction products, and diffusion. For expansion,  $\alpha$  is the degree of reaction and  $\alpha_\infty$  cannot exceed 1.

For the study, ASTM C1260 tests were conducted using extremely reactive sand from South Dakota, and length measurements taken at 3, 7, 11, 14, 17, 21, 25, and 28 days with data being fit into the above equations. A value of three days was selected for  $t_0$  with the corresponding expansion value used for  $\alpha_0$ . The fit was determined with linear regression using:<sup>[2]</sup>

$$\ln \ln \left( \frac{1}{1 + \alpha_0 - \alpha} \right) \text{ vs. } \ln (t - t_0) \quad (3)$$

The table 2.2 below taken from Johnston et. al. (2000, p. 145)<sup>[2]</sup> shows the expansion values and kinetic parameters for the different test conditions.

Table 2.2: ASTM results with different base concentrations<sup>[2]</sup>

*ASTM results with different base concentrations.*

Time (days)	ASTM C 1260 Percent Expansion (NaOH Normality)					
	0.5	0.6	0.7	0.8	0.9	1.0
3	0.017	0.026	0.036	0.045	0.055	0.065
7	0.025	0.041	0.087	0.122	0.156	0.196
11	0.043	0.102	0.182	0.240	0.248	0.290
14	0.071	0.162	0.248	0.303	0.303	0.336
17	0.100	0.207	0.297	0.347	0.368	0.373
21	0.129	0.256	0.343	0.391	0.384	0.430
25	0.160	0.301	0.390	0.432	0.420	0.467
28	0.174	0.324	0.407	0.454	0.464	0.488
$\ln k$	-7.1320	-6.2530	-4.4130	-3.7460	-3.3430	-2.9550
$M$	1.715	1.694	1.179	1.001	0.850	0.743
$R^2$	0.989	0.960	0.971	0.965	0.983	0.996

Where  $\ln k$  is the intercept and  $M$  is the slope of the regression line, the figure below is a plot of  $M$  versus  $\ln k$ . Figure 2.1 shows a uniform response with respect to the exponential and rate components of the kinetic parameters.

Figure 2.1: Exponent versus  $\ln$  rate constant: ASTM C1260 at different concentrations. <sup>[2]</sup>

The results of Johnston et. al. (2000)<sup>[2]</sup> conclude that an application of a kinetic model based on the KAMJ equation provides a means of interpreting the results of ASTM C1260 independent of expansion values obtained at 14 days. The use of a kinetic plot of slope  $M$ , and intercept,  $\ln k$ , obtained from a least-squares fit to the logarithmically transformed kinetic equation differentiates between reactive aggregates having  $\ln k > -6$ , and innocuous aggregates with  $\ln k < -6$ .

### 2.3.2 Analysis of Australian Data

Existing test data on 56 Australian aggregates tested for ASR in accordance with procedures detailed in AS1141.60.1 and AS1141.60.2 Table 2.3 below is an extract from that data.

Table 2.3: ASR classification results based on AMBT and CPT to Test Methods 1141.60.1 and 1140.60.2

Identifier	Aggregate type	Aggregate Reactivity Classification		AMBT Expansion	
		(AS1141.60.1)	(AS1141.60.2)	% Expansion (14 days)	% Expansion (28 days)
A1	Olivine Basalt	Non- Reactive	Non- Reactive	0.020	0.049
A2	Basalt	Non- Reactive	Not completed	0.013	0.035
A3	Basalt	Non- Reactive	Non- Reactive	0.030	0.056
A5	Pyroxene Andesite	Reactive	Non- Reactive	0.403	0.739
A6	Latite	Non- Reactive	Non- Reactive	0.012	0.055
A7	CRG	Reactive	Non- Reactive	0.230	0.462
A8	Rhyodacite Porphyry	Reactive	Reactive	0.318	0.533
A9	Hornfels	Slowly Reactive	Non- Reactive	0.081	0.217
A10	Limestone	Non- Reactive	Non- Reactive	0.008	0.011

The complete set of results for AMBT is plotted in Figure 2.2 showing expansion vs time for the AMBT test data. Also plotted are indicator lines at 0.1% and 0.3% as per the classification criteria of aggregates expansion based on AS11411.60.1.

Kinetic parameters were then calculated at 14 days and 28 days and analysed using the KAMJ model to establish any correlation between test results and a kinetic based method of interpretation. This is shown in table 2.4 below.

Table 2.4: Kinetic Parameters based on AMBT (1141.60.1)

Identifier	Aggregate type	Kinetic Parameters							
		$\ln k_{14}$	$k_{14}$	$M_{14}$	$R^2_{14}$	$\ln k_{28}$	$k_{28}$	$M_{28}$	$R^2_{28}$
A1	Olivine Basalt	-6.6494	0.001295	0.935	0.948	-7.0670	0.000853	1.165	0.969

Figure 2.2: Plot of percent expansion vs time: AS1141.60.1 data

Figure 2.3: Reactivity plot based on AMBT (AS1141.60.1 test data) – 28 days

Figure 2.4: Reactivity plot based on AMBT (AS1141.60.1 test data) – 14 days

From figure 2.3 and 2.4 above, adopting the conservative value of  $\ln k$  below which all aggregates are innocuous as -6 specified in Johnston et. al. (2000) results in a split in which most aggregates tested as

non-reactive with AS1141.60.1 fall below, and those tested as reactive with AS1141.60.1 fall above. However, for both 14 and 28 days, there are some aggregates which tested as slowly reactive using AS1141.60.1 expansion criteria that are deemed to be innocuous based on the kinetic parameters, as well as some aggregate types which are reactive falling in the innocuous category of the graph and vice versa.

When examining data points for aggregates with borderline results around  $\ln k < -6$  for 14 days ( $-6.5 < \ln k < -5.5$ ) there are 10 aggregates that fall into this area of the plot. Five (5) of these aggregates all have kinetic parameters that suggest the aggregates are non-reactive with correlating CPT classifications. While another 4 have border line reactive  $\ln k$  values, -5.8976, -5.9465, -5.9832 and -5.8292 respectively, and are classed as non-reactive by the CPT expansion criteria. This suggests that the kinetic model using AMBT data, can give classification results consistent with the 12 month CPT test, but at 14 or 28 days. In our analysis the 14 and 28 day kinetic results gave comparable results with the 14 day results having slightly better agreement with the CPT classification.

### 3. Conclusions

Using a kinetic approach, such as the Kolmogorov-Avrami-Mehl-Johnson model, can provide the potential for decision making based not only on a single expansion value, but also the rate of expansion for various aggregates.

The results of this study show that the application of a kinetic model based on KAMJ provides a means of interpreting the results of AS1141.60.1 independent of expansion values obtained at both 14 and 28 days. Using this method aggregates examined with  $\ln k < -6$  are non-reactive or innocuous, whereas those with  $\ln k > -6$  are reactive.

The literature search by Rucker et al (2015)<sup>[1]</sup> and work by Ideker et al. (2012)<sup>[4]</sup> found that the reactivity diagnosed by CPT was found to correlate well with reactivity in field exposure. In our study, reactivity classifications from the kinetic method achieved close correlation to those from the CPT at both 14 and 28 days. This suggests that the kinetic approach offers potential to determine reactivity classifications consistent with those of CPT at 14 or 28 days, rather than the 12 months required by the CPT. It also has the potential to determine the rate of expansion of the alkali silica reaction, aiding in the evaluation of potential service life of a structure.

### 4. Acknowledgement

The authors acknowledged the contribution of Messrs. Peter Clarke, Tony Thomas and Dr Ahmad Shayan who highlighted the importance of reaction kinetics and reaction rate in the assessment of potential alkali silica reactivity.

**Abstract:** Usage of industrial by-product materials in concrete is increasing because this is a sustainable way to manage the by-products and convert them into economic values. This paper presents the properties of fresh and hardened cement pastes and mortars blended with a proprietary nickel slag. Water demand slightly reduced with the increase of the slag content in determination of normal consistency. Incorporation of the slag with cement slightly prolonged initial and final setting time. The Le-Chatelier soundness test results did not show any increase in expansion for cement replacement of up to 65% by the slag though it has high magnesium content. The strength activity index of the slag was found to be 84% at 28 days when 20% of cement was replaced by the slag. Cement was replaced by the slag at rates of 20-50% in mortar mixtures having water to binder ratio of 0.5. Results show that 30% and 50% replacement of cement by the slag provided about 83% and 66% compressive strength respectively compared to that of 100% cement mortar specimens.

**Keywords:** Cement paste, compressive strength, mortar, nickel slag, soundness.

## 1. Introduction

Global warming has become a significant issue in the last decade in Australia and the researchers are embarking on programs to reduce Australia's carbon emissions [1]. Cement is the conventional binder for concrete and is known as an energy intensive material. Concrete is the most widely used material [2] for construction due to its versatile properties, availabilities of raw materials, strength and durability. It is important to reduce the environmental impact of concrete production in terms of greenhouse gas emission. Hence, construction practices are being revised by allowing increased use of industrial by-products [1]. It is necessary to increase the use of supplementary cementing materials (SCMs) within the existing performance based specifications. This will reduce the 'carbon footprint' of cement manufacture and help the reduction of greenhouse gas emissions.

Researchers are working to produce concrete with better engineering properties by using SCMs and chemical admixtures [3]. These can be used individually with Portland or blended cement or in different combinations of them. SCMs are generally added to concrete mixtures to make it more economical, durable and stronger. These materials reduce the amount of required cement and can enhance the strength, workability and durability through hydraulic and pozzolanic activities [4]. Typical examples of SCMs are fly ash, ground granulated blast furnace slag, silica fume, rice husk ash, metakaolin and natural pozzolans such as calcined clay and calcined shale which are incorporated in concrete as an addition or as a partial replacement of cement. Over the last 20 years, the use of SCMs in concrete has been steadily increased in Australia. At present, more than 90% of concrete contains at least one SCM. Detailed standards and procedures for using fly ash, slag and amorphous silica as SCMs are included in the AS 3582.1 [5], AS 3582.2 [6] and AS 3582.3 [7] Standards respectively.

In this research, suitability of using a proprietary nickel slag (NS) as a supplementary cementitious material has been investigated. The raw nickel slag was collected from the industry and then ground to a fine powder with blain specific surface area of 512 m<sup>2</sup>/Kg. Paste and mortar specimens were prepared and tested using different proportions of this slag with cement. The Magnesium Oxide (MgO) content of the slag is about 30% by mass. According to AS 3583.9 [8], the value of MgO in an SCM should be less than 15%. However, the actual effect of using the slag with cement on various properties of the product needs to be investigated. It was shown by experimental work that when 8% Magnesium expansive agent (MEA) was used, the cement paste cracked; causing unsoundness [9], but the concrete prisms showed very good surface and strength after the complete hydration of MEA. Moreover, their mechanical performance was better than that of the control prisms. In fact, the soundness of concrete needs to be determined by assessing the extent of expansion and its mechanical performance that resists the possible disruption due to expansion. Therefore, during the initial study of this research, the soundness,

consistency, setting time and compressive strength properties of cement paste and mortar mixtures containing the nickel slag as a partial replacement of cement are experimentally investigated and outlined in this paper.

## 2. Experimental work

According to ASTM C618 -12a [10], the sum of  $\text{SiO}_2$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$  should be more than 50% for class C natural pozzolans. The sum of  $\text{SiO}_2$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$  for the slag used in this research is about 65%. Hence, it can be considered as a class C pozzolan.

Several tests were conducted to assess the effects of blending of the nickel slag with cement. The test results of the nickel slag blended cement paste and mortars were compared with those of the control mixtures without the slag. Comparison was also made with the results of cement paste mixtures blended with fly ash (FA) and ground granulated blast furnace slag (GGBFS). The test results are discussed in the following sections.

### 2.1 Normal Consistency

The amount of water that brings the cement paste to a standard condition of wetness is called "normal consistency". It refers to the flow behaviour of a fresh mixture. Setting time and soundness properties need to be determined at a specified consistency rather than certain water cement ratio [11]. The nickel slag was used from 20 to 65% as partial replacement of cement. The normal consistencies of the mixtures were determined in accordance with AS 2350.3 [12] Standard. The results are given in Table 1 and plotted in Fig. 1. In the table, the paste mixtures were designated using the percentages of the slag and cement. For example, a mixture with the designation of 30NS70C had 30% nickel slag and 70% cement by mass. Thus, the mixture 0NS100C is the control mixture containing no slag.

**Table 1. Normal consistency and setting time of different mixes.**

Mixture	Consistency (% Water)	Initial setting time (mins)	Final setting time (mins)
0NS 100C	30	130	190
20NS 80C	29	130	200
30NS 60C	28	130	200
40NS 70C	27.5	140	200
50NS 50C	27	130	200
65NS 35C	27	150	230

**Figure 1. Variation of water content for normal consistency with the addition of nickel slag.**

It can be seen from the results in Table 1 and Fig. 1 that the amount of water required for normal consistency slightly decreased with the addition of nickel slag. The required water content for normal consistency of the control mixture was 30% and that of the mixtures with nickel slag varied from 29 to 27%. Therefore, the required water content decreased from 30% to 27% with the inclusion of 65% nickel slag in the paste.

## 2.2 Setting time

The knowledge of the setting time of a cementitious mixture is required in order to determine the available time for mixing, transporting, placing and compacting the concrete effectively. Setting time tests are used to characterize how a particular cement paste sets. Setting time of cement paste is affected by a number of factors including fineness of cement, water-cement ratio, the chemical content and admixtures if used. According to ASTM C150 [13] specification, the initial setting time shall not be less than 45 minutes. However, an initial setting time of at least 90 minutes is usually preferred in practice. A smaller value of the final setting time is always preferred in order to avoid large expenditures on the formwork. Setting times of the pastes were determined in accordance with AS 2350.4 [14]. The setting time results of the control cement paste and the mixtures with up to 65% of nickel slag are given in Table 1. The values are also plotted against the percentage of nickel slag in Fig. 2.

**Figure 2. Variation of setting times with the addition of nickel slag.**

It can be seen from the results presented in Table 1 and Fig. 2 that initial setting times of the mixtures varied from 130 minutes to 150 minutes. The final setting time varied from 190 to 230 minutes. No significant difference in setting times was observed due to incorporation of nickel slag with cement at a rate up to 50%. At the replacement level of 65%, the nickel slag was found to retard the initial setting time by 20 minutes and final setting time by 40 minutes.

## 2.3 Strength activity Index

Strength activity index is the ratio of the strength of 20% nickel slag-blended cement mortar to the strength of the reference cement mortar at a specific age. The pozzolanicity of the nickel slag can be quantified by its strength activity index. The strength activity index of any material depends on the surface area, particle size distribution and silica content. The strength activity index can be increased by reducing the particle size thus increasing the fineness. The granulated nickel slag was ground by using a balling mill to the Blaine's fineness of 512 m<sup>2</sup>/kg, which is similar to the fineness of commercial ground granulated blast furnace slag. The control cement mortar mixture consisted of 500g of cement, 1375g of graded sand and 242g of water. The nickel slag blended cement mortar mixture contained 400g cement, 100g nickel slag,

1375g graded sand and 242g of water. Since the water demand for normal consistency of the 20% nickel slag blended paste was same as that of the control cement paste, the water contents of both the mortar mixtures were same. Cube specimens of 50mm sides were prepared and tested in accordance with the ASTM C311M Standard [15]. After casting, the specimens were placed in the moist room at 23±2°C for 24 hours. The specimens were then demoulded and cured in lime saturated water until tested for compressive strengths at the ages of 7 and 28 days. The average compressive strengths obtained from three specimens were used to determine the strength activity index. The results are given in Table 2.

**Table 2. Strength activity index of nickel slag.**

SI No	Composition	Mean 7 days strength (MPa)	Mean 28 days strength (MPa)	Strength activity index	
				7 Days	28 Days
1	Control	31	37	74%	84%
2	20% Slag	23	31		

Table 2 shows that the strength activity index for 7 days and 28 days were found to be 74% and 84% respectively. ASTM C618-08a [16] recommends the specific minimum strength activity index of 75% for SCM at 7 or 28 days. Since the value for the nickel slag at 28 days is above 75% and that at 7 days also very close to 75%, the slag meets the requirement of the ASTM standard as a supplementary cementitious material.

## 2.4 Soundness

Chemical analysis of the nickel slag showed that its MgO content is about 30%. According to AS 3582.2 [6], the value of MgO in SCM should be less than 15%. Therefore, the high magnesium content of the slag could raise concerns. However, MgO may not always be harmful for concrete depending on how it is chemically bound in the slag. Researchers found that the delayed expansion caused by slow hydration of MgO in cement had compensated the thermal shrinkage of concrete during the cooling stage [9, 17]. MgO powder is used as an expansive agent (MEA) [9, 18-19] at a rate of 5-10% weight of cement. Besides, minerals of Dolomite, Serpentine and Magnesite containing about 20-40% MgO have been used successfully for producing MEA [20-21].

The reactivity of MgO depends on its calcination temperature. MgO can be classified in three temperature categories of calcination: a) lightly burnt MgO (850-1200 °C), hydration takes place within 180 days b) heavily burnt MgO (1500-1800 °C), hydration can be up to 1000 days and c) dead burnt MgO, Periclase (>1800 °C), hydration can proceed up to 6-8 years. The higher the burning temperature, the smaller the magnitude of early-age expansion and the longer the MgO hydration process lasts. The quenching temperature of the slag used in this study was 1200-1300 °C.

When MgO hydrates, it produces Mg(OH)<sub>2</sub> (Brucite), which has a volume of 17% higher [22]. The unsoundness caused by the excessive volume changes is usually accompanied by cracking and strength loss. The soundness of the nickel slag blended cement pastes has been evaluated using Le-Chatelier soundness test which is detailed below.

### 2.4.1 Le-Chatelier soundness test

Le-Chatelier soundness test was carried out in accordance with AS2350.5 [23]. The cement paste samples were prepared at normal consistency by replacing 0 to 65% of cement by the nickel slag. The Le-Chatelier mould was filled with the paste and submerged in water for 24 hours. After curing, it was boiled for 3.5 ± 0.5 hours and allowed to cool in the room temperature. The distance between the pointer of the mould before and after boiling is taken as the Le-Chatelier expansion. Three samples were prepared for each type of mixture and an average value of the measured expansions was calculated. The results are given in Tables 3. The values of expansion are plotted against percentage of the slag in Fig. 3. Expansions of two additional mixtures containing 40% fly ash (40FA 60C) and 40% GGBFS (40GGBFS 60C) were tested for comparison with the expansion of the mixture of 40% nickel slag (40NS 60C).

**Table 3. Le-Chatelier expansions of pastes containing nickel slag, fly ash and GGBFS.**

Proportion	Average Expansion (mm)
0 NS 100C	1.0
20NS 80 C	0.75
30NS 70 C	0.58
40NS 60C	0.45
40FA 60C	0.58
40GGBFS 60C	0.42
50NS 50C	0.49
65NS 35C	0.42

**Figure 3. Variation of expansion with the percentages of nickel slag.**

It can be seen from the results that the Le-Chatelier expansion of the mixtures varied from 0.42 to 1 mm. These values are well below 10 mm, which is considered as the limiting value of the expansion [24]. It can be seen from Fig. 3 that the values generally decreased with the increase of cement replacement by the slag. The value decreased from 1 mm to 0.42 mm when the cement replacement increased from 20% to 65%.

**Figure 4. Le-Chatelier expansions of pastes containing 40% nickel slag, fly ash and GGBFS.**

Fig. 4 shows the expansions of the mixtures containing three different SCMs at the rate of 40%. The values of the expansion varied between 0.42mm and 0.58mm for these three mixtures. It can be seen from the figure that the expansion of the mixture containing 40% nickel slag was similar to that of 40% GGBFS and less than that containing 40% fly ash. Thus, the Le-Chatelier expansion of the paste containing nickel slag up to 65% was found well below the usual limit of 10 mm and was not higher than those of the control mixture and mixtures with 40% fly ash and GGBFS.

## 2.5 Compressive strength of mortar specimens

The mortar mixtures consisted of one part of binder and three parts of standard sand by mass with a water-cement ratio of 0.50. A control mixture was prepared by mixing 450g of cement, 1350g of graded sand and 225g of water. Nickel slag was used to replace 20, 30, 40 and 50% of cement in the other mixtures. Specimens produced from fresh mortar were demoulded after 24 hours, and were then cured in water with at  $23 \pm 2^\circ\text{C}$  with  $70 \pm 10\%$  relative humidity until they were used for compressive strength tests. Tests were conducted following the ASTM C109 Standard [25] using a 2000 kN capacity machine. Three samples were tested for each mix at 3, 14 and 28 days of age. The mean compressive strength results are given in Table 4. The strength developments of the mixtures with age are plotted in Fig. 5.

**Table 4. Compressive strength of the mortar mixtures.**

Composition	Compressive strength (MPa)		
	3 Days	14 Days	28 Days
0NS 100C	23	33	35
20NS 80C	16	21	29
30NS 70C	16	23	29
40NS 60C	12	19	23
50NS 50C	11	16	24

**Figure 5. Compressive strength of cement mortars containing different percentages of nickel slag.**

It can be seen from the results that the 28-day compressive strength of the control cement mortar specimen was 35 MPa. The 28-day compressive strengths of the mixtures containing 20% to 50% nickel slag varied from 23 to 29 MPa. As seen from Fig.5, the rates of strength gain of the concretes containing nickel slag were higher during 14 to 28 days as compared to that of the control concrete. This is similar to the general behaviour of concretes containing pozzolanic materials. The results indicate that 20 to 30% cement replacement by the nickel slag resulted in about 83% of the 28-day compressive strength of the

control mortar mixture. Similarly 40 to 50% cement replacement by the nickel slag resulted in about 66% of the 28-day compressive strength of the control specimen. As shown in Fig.5, the strengths of the mixtures containing the slag show increasing trends beyond the age of 28 days. The ongoing study will determine the strength development at later ages.

### 3. Conclusion

This paper presented the properties of fresh and hardened paste and mortar mixtures containing a proprietary ground nickel slag as a partial replacement of cement. The water content required for normal consistency reduced from 30% to 27% due to 65% cement replacement by the slag. Thus, the slag did not have a significant effect of the water demand of the blended paste. There was no significant effect of the slag on the initial and final setting times of cement paste up to 50% cement replacement. The strength activity indexes of the slag at 7 and 28 days were 74% and 84% respectively. No negative effect on the expansion was shown by the slag in the Le-Chatelier soundness test. The values of expansion ranged between 0.42 mm to 1.0 mm for the mixtures containing 0 to 65% slag. These values are well below the 10 mm limit usually used for the test. Mortar specimens of 50 mm cube were cast with water to cementitious materials ratio of 0.5. The 28-day mortar compressive strength reduced from 35 MPa to 29 MPa due to 20% to 30% cement replacement by the slag. The corresponding compressive strength of the mortar containing 40% to 50% slag was about 24 MPa. Thus, the proprietary nickel slag did not show any negative effect on the properties of fresh mixtures and caused reduction in 28-day compressive strength with increasing trends at the later age. This is similar to the effect of other cement replacing materials such as Class F fly ash.

**Abstract:** This study revealed the dynamic mechanical behavior of polymer matrix having different percentage of filler contents. Epoxy resin based polymer matrix were prepared and characterized their dynamic mechanical properties such as storage (elastic) modulus, loss (viscous) modulus and tan delta (damping coefficient) as a function of temperature. The temperature was applied from 30 to 120 °C with 5 °C increment and the specimens were clamped for dual cantilever bending. A total of seven different mixes with a filler volume increment of 10% started from zero filler mix (100% resin) were casted and the glass transition temperature were evaluated for each of the specimens. Knowing this temperature is important for the polymer matrix as the mechanical properties of material can change dramatically when the specimens are subjected to a temperature beyond this point. Results showed that the gradual increase of filler materials in the polymer matrix can shift the state of materials progressively from viscous to elastic. However, a slight increase of glass transition temperature were obtained among all seven mixes which ranged from 50 to 55 °C when using storage modulus or loss modulus curve and 60 to 65 °C when using peak of tan delta. To evaluate the effect of temperature and fatigue loading on specimens during the execution of Dynamic Mechanical Analysis (DMA), the flexural properties of the invaded samples were tested using three point bending once the specimens cool down to the normal temperature. It was found that the dual action of temperature and repeated loading can reduce flexural strength and modulus significantly.

**Keywords:** epoxy resin, polymer matrix, glass transition temperature, dynamic mechanical properties.

## 1. Introduction

The Glass transition temperature ( $T_g$ ) is one of the most important thermal property for designing polymeric composite materials [1]. Different from melting point,  $T_g$  is the temperature where a polymeric material changes from a hard, rigid or glassy state to a more soft, compliant or rubbery state. Glass transition temperature of polymer composites can be determined in several methods including: (a) differential scanning calorimetry (DSC) [2], (b) dynamic mechanical analysis (DMA) [3], (c) dynamic mechanical thermal analysis (DMTA) [4], (d) inverse gas chromatography (IGC) [5] and (e) differential thermal analysis (DTA) [6]. Of these methods, DMA is typically the most sensitive method to measure the glass transition temperature of polymers [7, 8].

DMA measures force and deflection while varying temperatures and/or frequency. The basic principles of DMA can be described as applying an oscillating force to a sample and analysing the material's response to that force. This cyclic nature of the test is equivalent to a creep test [8]. In reality, if a polymer heated above the glass transition temperature, the state of materials can change from glassy to rubbery and the stiffness drops dramatically. This sudden drop of stiffness can lead to serious problems in the structure.

The modulus measured from DMA is not exactly the same as the Young's modulus of elasticity. Young's modulus measures the material's stiffness at a fixed temperature, but DMA modulus measures the stiffness at variable temperature. It is well known that the Young's modulus of elasticity is determined from the slope of a stress-strain curve in the initial linear region. On the other hand, DMA measures the dynamic or complex modulus ( $E^*$ ) which is a function of storage modulus ( $E'$ ) and loss modulus ( $E''$ ), and can be expressed by Eq. (1).

$$E^* = E' + iE'' \quad (1)$$

$$\tan \delta = \frac{E''}{E'} \quad (2)$$

where,  $i$  is the imaginary unit. The storage modulus measures the stored energy per cycle while the loss modulus measures the dissipation of energy (as heat) per cycle. The ratio of loss modulus to storage modulus is called tan delta ( $\tan \delta$ ) or damping expressed in Eq. (2) which measures how well a material

can get rid of or absorbing energy under cyclic load. DMA can differentiate the glassy, viscoelastic, elastic and liquid polymers.

The glass transition temperature of epoxy grouts composed of resin with fine or coarse filler was investigated by Shamsuddoha et al. [3] using DMA. They found the  $T_g$  ranged from 60 to 90 °C depending on the mixing proportion of epoxy grouts. Goertzen and Kessler [8] measured the  $T_g$  of carbon/epoxy composites using DMA for structural pipeline repair. They found a wide range of  $T_g$  from 60 to 129 °C measured from tan delta peak for room temperature cured and post-cured specimens. The post curing system can enhance the structural and thermal properties.

The outdoor application of civil infrastructures such as bridge, railway sleepers are frequently heated by sun and when the vehicles passes over the structures they are subjected to fatigue loading at high temperature. The dual action can affect the serviceability of structures by reducing the structural performance. This study determined the glass transition temperature of polymer matrix and the residual flexural capacity of the invaded polymer matrices were evaluated.

## 2. Materials and Method

In this study, the polymer matrix is composed with resin and filler. A DGEBA type epoxy resin (Part-A) and an amine based curing agent (Part-B) were mixed with a combination of three different fillers. The resin producer furnishes the Epoxy Equivalent Weight (EEW) of 190 gm for Part-A and Amine Hydrogen Equivalent Weight (AHEW) of 60 gm for Part-B. To make the resin mix reactive, one equivalent weight quantity of amine curative will require for one equivalent weight quantity of an epoxy resin. Therefore, 32 gm of Part-B is required to react with 100 gm of Part-A, and otherwise it will not work properly. To get the effective filler mix, three different fillers named Fire Retardant Filler (FRF), Hollow Microsphere (HM) and Fly Ash (FA) were mixed together by a certain ratio of mixing which was developed by LOC Composites Pty. Ltd. and could not be included in this paper due to the commercial in confidence. The functions of three fillers are different and their combined application can improve the structural performance and durability.

Mixes were prepared for different resin-to-filler ratio started from 0% to a maximum of 60% filler with an increment of 10% by volume (Figure 1). No further increase of filler were considered beyond 60% as because it was not workable. The mixing ratio are provided in Table 1.

**Table 1. Details of mixing proportion.**

Identity of mix	Mix-1	Mix-2	Mix-3	Mix-4	Mix-5	Mix-6	Mix-7
% Resin/Filler (by volume)	100/0	90/10	80/20	70/30	60/40	50/50	40/60
Resin Part A, (gm)	124	112	100	87	75	62	50
Resin Part B, (gm)	40	36	32	28	24	20	16
Filler (FRF+ HM+ Fly Ash), (gm)	0	30	59	89	119	148	178

(a) ingredients before mixing

(b) solid polymer matrix after mixing

**Figure 1. Polymer matrix ingredients and specimens casting.**

Specimens were casted in the plastic cups which can be demolded quite easily as because the weak bond between resin and plastic. The solid polymer matrix were then cut to the specified dimensions using a cutting machine and tests were conducted in accordance with ASTM D7028 [9]. The machine was a Q800 type of TA instruments where the motor applies a force and displacement sensors measure strain, force and amplitude in the form of raw signals recorded by the machine. Test mode was DMA Multi-Frequency-Strain and the samples clamped with Dual Cantilever system. Temperature was set between 30 and 120°C, with an increment of 5°C, during temperature scans. Two specimens in each category were tested to determine the  $T_g$  of polymer matrix as shown in Figure 2. The surface of the specimens were prepared flat, clean, straight and dry to prevent slippage from the dual cantilever grips and any effects due to moisture.

### 3. Results and Discussion

#### 3.1 Generation of heat during mixing

While mixing resin (Part-A) and hardener (Part-B) together, it generated heat and the temperature was measured by a temperature gun at 10 minutes interval. The recorded maximum temperature was 75°C for the mix containing 100% resin or 0% filler (Mix-1). However, the peak temperature was decreased in the succeeding mix with the gradual increase of filler up to 60% as shown in Figure 3.

(a) generation of temperature with time

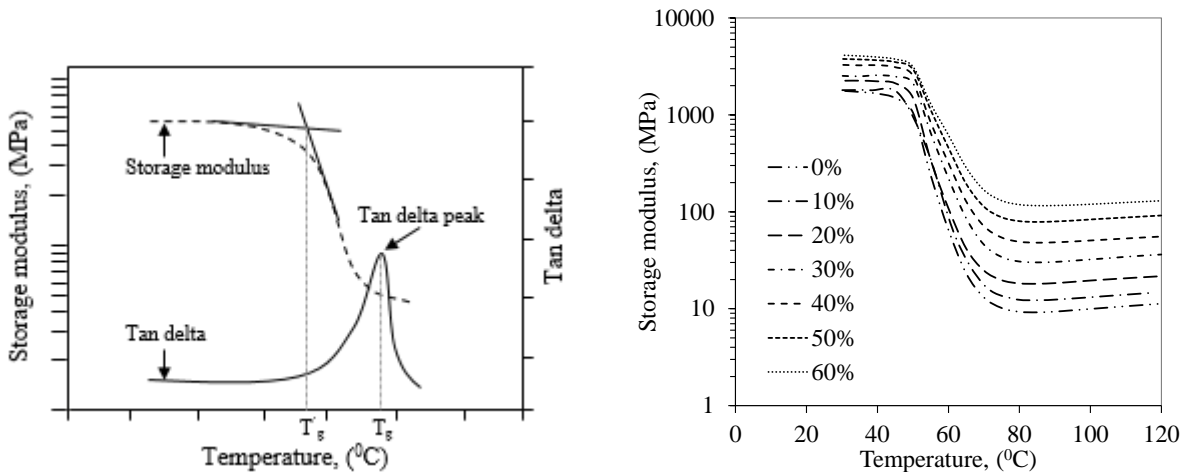

(b) variations of peak temperature with filler

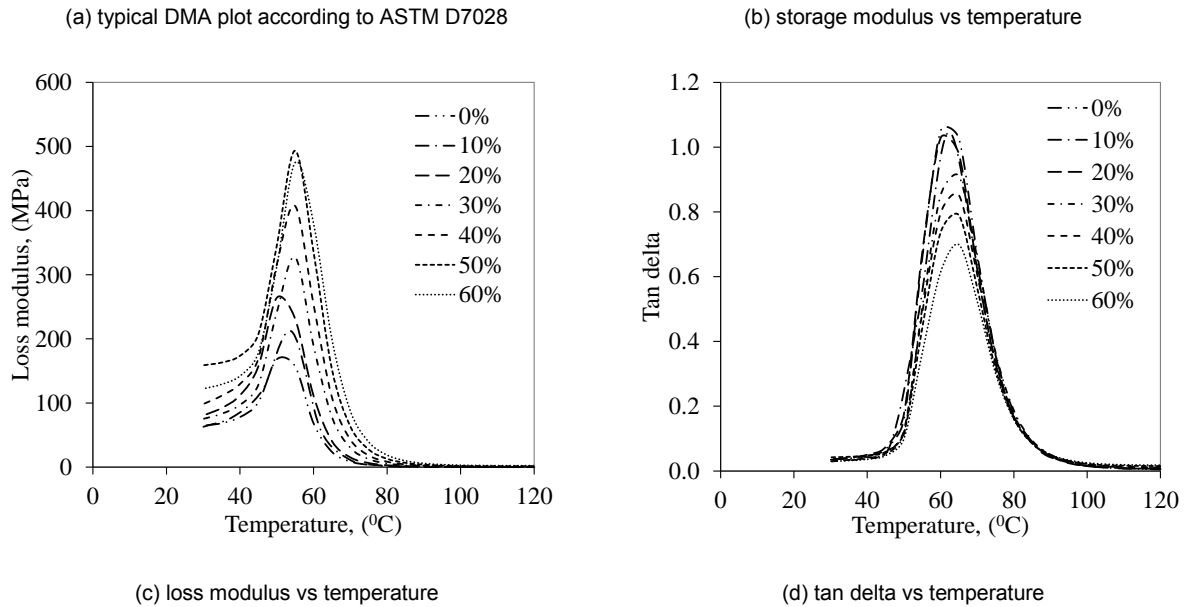

**Figure 3. Effect of filler on heat generation.**

Figure 3(a) shows that, for the mix with 0% filler, the peak temperature was obtained at 150 minutes after starting the mix and it was gradually decreased to 90 minutes for the mix having 60% filler. This indicates the exothermic reaction between resin and hardener was completed within this time period and the mixes started to lose their plasticity. A decreasing trend of heat with the increase of filler can be explained by the heat absorption capacity of filler. Filler can absorb heat and reduce the temperature to a comfortable range when 30% or more filler was added in the mix. The temperature of the mix varied between 34°C to 29°C for the addition of 30% to 60% filler which is a comfortable range of temperature to work with.

### 3.2 Glass transition temperature

The variation of storage modulus, loss modulus and tan delta with respect to temperature are presented in Figure 4(b-d). The corresponding temperature of the intersection of two tangent lines in storage modulus curve is the glass transition temperature, drawn the first tangent at a point where glass transition just started and the second tangent at the inflection point to approximately the midpoint of the storage modulus drop. The magnitude of  $T_g$  measured from storage modulus curve is slightly lower than the same measured from the peak of tan delta curve. The test standard ASTM D7028 [9] suggested to report both magnitude of  $T_g$  when using DMA. Li et al. [10], Goertzen and Kessler [8], and Shamsuddoha et al. [3] measured the  $T_g$  from the peak of tan delta curve. However, the standard practice for plastics ASTM D4065 [11] suggested to measure  $T_g$  from the peak of loss modulus curve.

**Figure 4. Variation of dynamic mechanical properties with temperature.**

In all seven mixes, the magnitude of  $T_g$  ranged from 50 to 55 °C when using storage modulus or loss modulus curve and 60 to 65 °C measured from tan delta curve. This indicates the addition of filler from 0% to 60% in the polymer matrix can only increase the glass transition temperature by 5 °C. The  $T_g$  of the polymer mix primarily depends on the resin system where the type of resin was same for all mixes. Similar observation was noticed by Shamsuddoha et al. [3] where the increase of aggregates slightly enhance the glass transition temperature. However, in this study the samples were cured at room temperature, and the post curing system of polymer matrix could probably increase the  $T_g$  significantly. The height of tan delta indicates how viscous (large tan delta) or elastic (small tan delta) the material is. The magnitude of the peak of tan delta was decreased from 1.04 to 0.7 with the increase of filler from 0 to 60%. This indicates the response of zero filler mix (tan delta peak 1.04) is more viscous than any other mix under the application of load.

### 3.3 Residual flexural strength

The flexural strength and modulus of the unaffected specimens were determined before execution of DMA. The strength was gradually decreased from 97.87 to 29.85 MPa with the increase of filler from zero to 60%. However, the flexural modulus was increased from 1.65 to 4.83 GPa with the increase of filler from zero to 60%. The strength mainly depends on the amount of resin in the mix that explains their gradual reduction. The increase of flexural modulus is due to the modulus of filler material which is significantly higher than resin. The flexural modulus can be correlated to the peak of tan delta (Fig. 4d) curve where the peak was highest for zero filler mix and lowest for the mix containing 60% filler. The height of tan delta represents how viscous or elastic the material is, under the application of load. The lowest height for 60% filler mix indicates the mix is more elastic than others and that the Fig. 5(b) illustrated with increasing trend of elastic modulus.

As it is mentioned before, the specimens were subjected to cyclic loading with high temperature during the execution of DMA. To determine the effect of temperature and fatigue loading on the flexural properties of polymer matrix, the invaded specimens were tested under three point bending. Results are compared with the unaffected control samples and it is observed that the flexural strength and stiffness for all specimens are decreased from the unaffected one presented in Figure 5.

(a) reduction of flexural strength

(b) reduction of flexural modulus

**Figure 5. Effect of temperature and fatigue loading on flexural properties.**

It is also observed that the loss of flexural strength for zero filler mix (100% resin mix) is obtained 28% which gradually increases to 40% for the mix containing 60% filler. Similarly, the reduction of flexural modulus is only 6% for zero filler mix and is gradually increased to 35% for 60% filler mix. Results have indicated that the rate of losses is increasing with the increase of filler in the mix. This phenomenon is happened probably due to the bond between resin and filler which gradually weaken with the increase of filler under the application of high temperature and fatigue loading. The rate of loss was expected similar for all mixes as the percentage loss of storage modulus after glass transition were more likely similar for all mixes presented in Fig. 4(b). However it is important to mention that, when the polymer mix is subjected to a temperature higher than its glass transition temperature, the mobility of the polymer chains increase significantly and later it cured by high temperature. This is similar to post curing system where the high resin content mix can recover flexural properties more easily than those mixes which contains low resin as the resin is temperature sensitive but not the filler, and explains why the rate of loss increases with the increase of filler.

#### 4. Conclusions

This paper presented an experimental study on thermo-mechanical behavior of epoxy based polymer matrix using dynamic mechanical analysis. The generation of heat during the mixing of resin and hardener is measured and the reduction of flexural properties after the application of high temperature and fatigue loading during DMA is evaluated from which the following conclusions are drawn:

1. The mixing of resin and hardener can generate heat which increase the temperature of fresh polymer matrix. The addition of 30% filler can reduce the temperature to 34°C from 75°C which was obtained for pure resin mix with no filler. However, a further addition of filler can decrease the temperature quite slowly, for example, the temperature comes down to 29°C when 60% filler is added.
2. Only a minor increase of glass transition temperature was obtained for the addition of filler in the mix. The  $T_g$  was increased from 50 to 55 °C for the addition of filler from zero to 60% when measured from storage modulus or loss modulus curve. However, the  $T_g$  measured from tan delta curve provided 20% higher results and ranged from 60 to 65 °C. The response of low filler matrix was found more viscous than high filler polymer matrix under the application of loads.
3. The effect of fatigue loading at high temperature is increased with the increase of filler in the polymer matrix. The combined action makes the resin-filler bond weaker with the increase of filler.

# Development of an Acid Resistant Concrete

Shamila Salek<sup>1</sup>, Bijan Samali<sup>1</sup>, Vute Sirivivatnanon<sup>2</sup>, Georgius Adam<sup>3</sup>

<sup>1</sup>University of Western Sydney, <sup>2</sup>University of Technology Sydney, <sup>3</sup>Parchem Company

**Abstract:** Modern infrastructures are designed for long service life and are increasingly being built in more aggressive greenfield and brownfield areas. Sulfate, acid-sulfate and acid resistant concrete are engineering solutions to these challenges in infrastructures without the need for additional protective membrane associated with conventional concrete. This paper presents an experimental investigation on mechanical properties of concretes made from a new acid-resistant mortar and a conventional concrete, and corresponding reinforced concrete beams, subjected to accelerated acidic environments in UTS laboratory. Concrete properties including compressive strength, modulus of elasticity, modulus of rupture, indirect tensile and drying shrinkage were examined. The load carrying capacity of companion reinforced concrete beams were also determined. The specimens were tested before and after periods of exposure to sulphuric acid solution with the concentration of 7% and changes of their properties were evaluated. The results enable an understanding of the mechanism of acid attack and the benefit of the use of acid resistant concrete. On the other hand, the effect of acid attack on reinforced concrete beams is highly dependent on the design of the reinforced concrete beams and to a lesser extent on the acid resistant property of the concrete.

**Keywords:** Acid resistant mortar, Acid resistant concrete, Acid Attack on concrete.

## 1. Introduction

Given the existence of acidic soil and acidic groundwater in acid sulfate soils, particularly in coastal areas in Australia [1], introduction of new acid resistant materials and investigation of the effect of acidic environments on performance of reinforced concrete (RC) structures is of importance. These structures could be piers, footings or foundations of different structures such as buildings and bridges [2]. Acidic environments cause the degradation of concrete and hence, decrease of load bearing capacity in these structures as well as serious durability issues.

Penetration of aggressive agents into the concrete and their chemical reaction with the cement matrix including decalcification, gypsum formation and ettringite formation causes the deterioration of concrete [3]. These chemical reactions can lead to expansion and cracking of concrete and loss of strength and elastic properties of concrete [4, 5, 6, 7].

In Australian Standard AS 3600 there are some precautions for concrete structures in acidic environments such as, some recommendations about the use of Sulphate Resistant (SR) cement in harsh environments. However, for prolonged exposure periods, SRPC does not appear to provide a better resistance to sulphuric acid attack than that provided by conventional Portland cement (OPC) [8, 9]. Some polymer modified concretes have also shown a better performance against the sulphuric acid [10]. However, they have not been mentioned as a viable solution in these environments due to implied high cost [11].

In this study a new structural concrete is developed by use of a novel acid resistant mortar (ARM) which was initially used for lining and repair purposes in Australia. For this purpose, mechanical properties of the ARM, the new acid resistant concrete (ARC) made from the ARM and a conventional concrete as the control concrete were tested before and after exposure to sulphuric acid solution (7%). Then flexural strength of reinforced concrete members made from the ARC and conventional concrete was tested before and after exposure to acid that will be presented.

## 2. Experimental Work

Experimental tests of this research include two main parts, namely, mechanical properties tests and structural tests of reinforced concrete members. The details of experimental tests will be explained in this section.

## 2.1. Test materials

### 2.1.1. Conventional concrete (CC)

The first series of specimens were cast from a conventional concrete as control concrete. The characteristics of this concrete are shown in Table 1. The target slump was  $140 \pm 10$  mm.

**Table 1. Mix design of the conventional concrete (CC).**

Nominal compressive strength (MPa)	Coarse aggregate (kg/m <sup>3</sup> )	Fine aggregate (kg/m <sup>3</sup> )	Cement (Shrinkage limited) (kg/m <sup>3</sup> )	Water/Cement Ratio	Fly ash(kg/m <sup>3</sup> )	Pozzolith 80 (liter/m <sup>3</sup> )
40	960	661	350	0.4	150	2.3

### 2.1.2. Acid resistant mortar (ARM)

The second series of specimens were made from the acid resistant mortar (ARM). The ingredients of ARM are shown in Table 2. The mean 28-day compressive strength of ARM is 30 MPa.

**Table 2. ARM Compositions.**

Ingredients	Silica sand	Fly ash	Silicates and poly silicates	Silica fume	Portland cement	Other ingredients
* Proportion	30-60%	10-30%	1-10%	1-10%	1-10%	1-10%

\* The exact amount of the ingredients of ARC has not been mentioned here due to the confidentiality agreements with the manufacturer.

### 2.1.3. Acid resistant concrete (ARC)

The last series of specimens as the main purpose of this study was made from the acid resistant concrete (ARC) which contains ARM and coarse aggregates with the coarse to fine aggregate ratio of 0.5. Water to binder ratio for both ARM and ARC was 0.4 and ARC had a slump of  $140 \pm 10$  mm. Type and grading of coarse aggregates in the conventional concrete and acid resistant concrete (ARC) were the same and the maximum size of aggregates was 10mm.

## 2.2. Test procedure

### 2.2.1. Mechanical properties tests

The mechanical properties tests included the compressive strength, modulus of elasticity (MOE), modulus of rupture (MOR) and Indirect tensile test, according to the relevant standards in Australia, namely, AS1012 [12,13,14,15,16].

To investigate the mechanical properties, 120 standard cylinders with the dimensions of 100 in diameter by 200 mm in height; 50 cylinders with the size of 150 in diameter by 300 mm in height and 80 prisms with the size of 100mm by 100mm by 400 mm were tested. For each test, three concrete specimens were tested to ensure repeatability and the reported results are the average values of these three specimens.

Each series of the specimens were kept under standard curing conditions for 28 days. Afterwards, half of the specimens were washed with water, dried to a saturated surface dry condition and were then immersed in acid solution (five folds of their volumes) and then covered to eliminate evaporation of the solutions. The density of acid solution was monitored weekly to control the acid concentration (7%). Each time the same number of specimens, not exposed to acid, was also tested to compare the behaviour of ARC with CC in the presence and absence of acid.

As this concrete is developed for structural applications, the amounts of drying shrinkage are of importance. Hence, 9 prisms with the size of 75mm by 75mm by 400 mm were cast and their ultimate drying shrinkage was measured in accordance with AS 1012.13 (1992).

### 2.2.2. Flexural strength of reinforced concrete (RC) members

Flexural strength of 15 RC beams made from ARC and CC with the dimensions of 150mm by 200mm by 2000 mm were evaluated through four-point loading test before and after four, eight and twelve weeks of exposure to sulphuric acid solution. The RC beams were designed for tensile failure. Test set-up for these tests is shown in Figure 1 a, b and c and the beams' reinforcement details are shown in Figure 1 d. Three LVDTs were used at  $\frac{1}{4}$ ,  $\frac{1}{2}$  and  $\frac{3}{4}$  of the span of the beam to record the deflections. The beams were loaded with the rate of 0.5 mm/sec by deflection control method till failure.

### 3. Results and Discussion

The results of experimental tests including the mechanical properties tests and structural tests will be presented.

#### 3.1. Mechanical Properties Tests

The results of mechanical properties tests of the conventional concrete (CC), Acid resistant mortar (ARM) and acid resistant concrete (ARC) are summarized in Table 3. All reported times in this Table are the time of exposure to acid or water after 28 days of standard curing. Another important point in this table and Figure 2 is that the test results of control concrete have not been reported after eight weeks of exposure due to degradation of the concrete samples.

**Table 3. Mechanical Properties of CC, ARM and ARC after exposure to sulphuric acid.**

Type \ Time		2 weeks			4 Weeks			8 Weeks		
		exposure to water	exposure to acid	Change (%)	Curing	Acid	Change (%)	Curing	Acid	Change (%)
CC	Compressive Strength (MPa)	46.1	44.7	-3.0%	53.8	44.2	-17.8%	-	-	-
	MOR (MPa)	5.8	6.0	3.4%	5.9	6.2	5.1%	-	-	-
	MOE (GPa)	33.0	32.0	-3.0%	37.0	35.0	-5.4%	-	-	-
	Indirect Tensile (MPa)	6.6	7.1	7.6%	6.7	8.6	28.4%	-	-	-
ARM	Compressive Strength (MPa)	31.4	31.1	-1.0%	35.1	34.4	-2.0%	37.1	32.5	-12.4%
	MOR (MPa)	5.1	4.9	-3.9%	5.3	4.8	-9.4%	5.4	4.4	-18.5%
	MOE (GPa)	26.0	26.0	0.0%	28.0	28.0	0.0%	29.0	29.0	0.0%
	Indirect Tensile (MPa)	3.9	4.1	5.1%	4.1	4.5	9.8%	4.2	4.6	9.5%
ARC	Compressive Strength (MPa)	43.0	42.3	-1.6%	44.5	41.8	-6.1%	51.6	45.0	-12.8%
	MOR (MPa)	5.6	5.6	0.0%	5.7	5.7	0.0%	6.0	5.3	-11.7%
	MOE (GPa)	32.0	32.0	0.0%	33.0	32.0	-3.0%	33.0	28.0	-15.2%
	Indirect Tensile (MPa)	3.8	4.0	5.3%	3.9	4.5	15.4%	4.4	4.5	2.3%

#### Compressive strength

Regarding the compressive strength of concretes it should be mentioned that after introduction of coarse aggregates to ARM to produce ARC, compressive strength increased from 31.4 to 43 MPa at the age of six weeks (42 days) and from 35.1 to 44.5 MPa after eight weeks (56 days) of standard curing which suggests about 30% increase of compressive strength.

As shown in Figure 2, CC had 3% and 17.8% compressive strength loss after two and four weeks of exposure to acid solution respectively, whereas, these strength loss decreased by 1.6% and 6.1% for the ARC.

**Figure 2. Compressive Strength of CC, ARM and ARC after exposure to acid.**

This decrease was 1% and 2 % for the ARM, effectively unchanged. Comparison of the strength loss of CC and ARC after two weeks and four weeks of exposure to acid solution reveals that the strength loss of ARC was about 1/3 of CC.

- *Modulus of Rupture (MOR)*

Modulus of rupture (MOR) of CC had a slight increase in acid. ARM had 3.9% and 9.4% decreases after two and four weeks of exposure to acid, respectively. This shortcoming was resolved after addition of coarse aggregates to ARC and there was no change in MOR characteristics of ARC samples after two and four weeks (28 days) of exposure.

- *Modulus of Elasticity (MOE)*

Tests of modulus of elasticity (MOE) of CC showed a slight decrease after two and four weeks (14 and 28 days) of exposure to acid solution (3% and 5.4%), whereas, ARM did not show any change in MOE characteristics even after eight weeks of exposure to acid. ARC did not have any change of MOE after two weeks and 3% decrease after four weeks (28 days) of exposure that was less than CC. In addition, comparison of the MOE test results of ARM and ARC without acid confirms the increase of MOE by addition of coarse aggregates to the ARM. This was predicted due to the role of aggregate in stability of concrete.

- *Indirect Tensile strength*

As shown, for all types of specimens, tensile strength measured by splitting test, increased after exposure to acid compared to the specimens under standard curing conditions. This unexpected increase was greater for the control concrete. For instance, after four weeks of exposure to acid CC had 28% increase compared to ARM (9.8%) and ARC (15.4%). The reason behind this increase is currently being explored through microstructural analysis in the UWS laboratory.

The same trend was initially expected for the changes of indirect tensile and flexural strength in acid. However, for MOR, the unaffected concrete at the extreme fibre of the conventional concrete is tested, whereas, for ARM and ARC the partially acid corroded extreme fibre of the ARM and ARC is tested. In indirect tensile test, the external layer that is to carry the compressive load is unaffected concrete in CC and the acid-affected layer in ARM and ARC.

- *Drying shrinkage*

Given the purpose of this project, which was developing the ARC for structural application, amounts of drying shrinkage of ARC was an important factor. ARM naturally had a high amount of drying shrinkage due to its fine nature. This issue was addressed by addition of coarse aggregate in ARC which led to the ultimate drying shrinkage of 900 micro strains which is within the acceptable range for structural concretes according to AS3600 (See Figure 3).

**Figure 3. Drying Shrinkage of CC, ARM and ARC**

### 3.2. Flexural strength of reinforced concrete (RC) beams

Two groups of RC beams were tested for flexural strength namely, CC and ARC. Figure 4 shows the load deflection of concretes before exposure to acid. As can be seen ARC had similar ultimate load but greater ultimate deflection comparing to CC, displaying more ductile behaviour.

Figure 5 shows the flexural behaviour of CC and ARC beams after exposure to acid. This reveals that after exposure to acid both types of concretes had some strength loss but there was no significant change. This loss was greater in CC beams comparing to ARC that can be attributed to reduction of the effective depth of the CC beam sections, causing the shortening of lever arm and, therefore, reducing the load capacity. This decrease of effective depth was found by measurement of the depth of the beams before and after exposure to acid. The initial depth of all beams was 200mm that decreased to 180mm and 162mm after four weeks and eight weeks (28 and 56 days) of exposure to acid, respectively. For CC the exposure to acid seems to increase the ductility of the beams, accompanied by loss of load carrying capacity from about 78 kN to about 62 kN after eight weeks (56 days) of exposure due to reasons mentioned above. The impact of acid exposure to ARC is less pronounced than CC with slightly better ductility and less loss of load carrying capacity with time of exposure.

In Figure 6 the normalized ultimate load of specimens is obtained by dividing the ultimate load of RC beams to the ultimate load of non-acid exposed beam. The normalized ultimate load of the beams predicts a dramatic decrease of flexural strength for CC in longer term dropping to 80% of the original strength after 12 weeks (84 days). This factor seems to remain almost constant (at about 90% of strength) for ARC and more resilient for long term exposure to acid. For the first 10 weeks of exposure, CC seems to display a better flexural strength, however, after 10 weeks the ARC behaves much better. Coincidentally the value at 10 weeks is about 90% for both CC and ARC. This confirms that ultimate load bearing of CC beams decrease much faster than ARC beams compared to not acid exposed beams from the same materials.

It is important to mention that despite degradation of surface layers of CC beams and loss of a considerable amount of concrete cover (20 mm loss of 25 mm concrete cover), the acid did not reach reinforcing bars after twelve weeks of exposure. However, a major loss of strength is predicted after long term exposure of CC beam to acid due to corrosion of reinforcing bars.

Figure 4. Load-deflection of ARC and CC beams in flexural test

a) Load-deflection of Conventional Concrete after exposure to sulphuric acid.

b) Load-deflection of ARC after exposure to sulphuric acid.

Figure 5. Load versus deflection in flexural test a) conventional concrete and b) ARC beams after exposure to acid.

Figure 6. Normalized ultimate load of the RC beams versus time of exposure to acid.

#### 4. Conclusion

In this study, mechanical and structural properties of a new acid resistant concrete (ARC), were investigated and compared to a control concrete in the laboratory. The results of mechanical properties tests of ARC before and after exposure to accelerated acidic conditions were promising. Drying shrinkage of ARC was also in the acceptable range for the purpose of this study. Hence, flexural strength of reinforced concrete beams made from ARC was tested for structural applications and showed that as long as the acid has not reached the reinforcing bars the maximum load bearing capacity of RC flexural members, whether from CC or ARC, does not change significantly. However, there is some strength loss because of decreasing the effective depth of RC beam sections due to degradation of concrete surface layers. Study of the history of flexural strength of RC beams after exposure to acid suggests much better performance for ARC comparing to the conventional concrete.

#### 5. Acknowledgements

The authors gratefully acknowledge the support of Parchem Company in the provision of ARM materials for testing, the UTS for provision of laboratory facilities and financial supports and the Advanced Materials Characterisation Facilities (AMCF) in UWS particularly, the director of the AMCF, Dr. Richard Wuhrer, for his wonderful support and valuable suggestions.

**Abstract:** The main cause of aesthetical deterioration of outdoor exposed building materials is the colonization by microorganisms. This phenomenon depends on factors such as geographical situation, environmental conditions and surface state of the substrate. Several researches have been devoted to the study of the effect of porosity, roughness and surface treatment on the biofouling of building materials. However, none of them has addressed the influence of cement composition. The main objective of this study is thus to highlight the influence of the composition of the material on its biocolonization by algae. The green alga *Klebsormidium flaccidum* was chosen because of its representativeness in France. It is indeed the species the most frequently identified and isolated from samples taken on sites. In order to characterize the influence of the composition of building materials on their biofouling, the behavior of mortars prepared with two types of Portland cement and two types of calcium aluminates cement is studied. The biofouling is followed by measuring the covering rate thanks to image analysis. This work is realized both on samples exposed outdoor and on samples tested in a laboratory bench. Obtained results prove that the composition of cementitious materials is a determining factor.

**Keywords:** biodeterioration, algae, mortars, Portland cement, Calcium Aluminate Cement.

## 1. Introduction

The colonization of building facades by microorganisms is the main cause of their aesthetical deterioration. The ageing of facades causes a change of the state of surface which favors the development of these species, in particular in the place where the rainwater flows and where run-outs appear. These latter are made of an association of organic particles and microorganisms called biofilm.

The main colonizing microorganisms are microalgae, fungi and bacteria (1,2,3). Barberousse (1) identified the micro-algae *Klebsormidium flaccidum* as the major microorganism developed on facades in France. *Klebsormidium flaccidum* is considered as a ground species. It is a green algae with a wide ecological amplitude (4). It can be found in the ground, on rocks, stone walls, and bark of trees. It is known for its wide presence in temperate regions (5,6,7).

The environment conditions the type of microorganism which colonizes a façade (3,8). The climate which includes temperature and moisture determines which microorganism will mainly grow. The rain and the wind favor the transport of microorganisms. The orientation of facades also impacts the biological development. An exposure toward North will be characterized by higher humidity and an absence of sun. These conditions favor the biofouling (1,9,10).

Organic materials such as paints and polymers and mineral materials such as mortar, concrete, natural stones or clay bricks are sensitive to biodeterioration. Barberousse (1) showed that the organic materials resist generally better to the colonization by algae and Cyanobacteria than mineral materials. The microorganisms observed are more diversified and more plentiful on mineral materials than on organic substrates.

Cementitious materials are heterogeneous, porous and their surface roughness can vary within a wide range. All these properties define the bioreceptivity of a material (2,11,12). Previous studies have

determined the influence of mortars' physical characteristics on their biofouling. Among them, the roughness of the surface (3,5,8,9,13) and the porosity (8,12,14) seem to be the most important ones.

Cementitious matrices partially weather because of the presence of carbon dioxide in the atmosphere. The natural carbonation of the mineral matrix leads to a decrease in surface pH and favors the microbiological colonization (8,10) and an alkaline surface pH can totally inhibit the colonization of a material by microorganisms. Indeed the pH affects the microorganisms because it regulates the ionization mechanism of metabolites (15).

The solutions developed to prevent the biocolonization of facades by microorganisms must take into account the preservation of the environment and the understanding of the interactions between microorganisms and materials is thus necessary for this purpose.

The main objective of this study is to highlight the influence of the chemical composition of the substrate on the biofouling, comparing the behavior of mortars prepared with cements of different mineralogy.

## 2. Materials and methods

### 2.1 Mortars formulation

In order to study the influence of the mineral chemistry on the biofouling of cement mortars, four types of cement were selected; two Portland cements and two calcium aluminate cements. The materials were a white Portland cement CEM I 52.5 N CE CP2 NF "SB" provided by Italcementi (coded CEMB), a grey Portland cement 52,5N-PM-ES-CP2 provided by Lafarge (coded CEMG) and two calcium aluminate cements provided by Kerneos, a white one (coded CACB) and a grey one (coded CACG). The chemical compositions obtained by X-Ray fluorescence are given in Table 1.

**Table 1 : Chemical Composition of the Cements CAC B, CAC G, CEM B and CEM G and the Siliceous Sand (%wt)**

Sample	SiO <sub>2</sub>	TiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MnO	MgO	Na <sub>2</sub> O	K <sub>2</sub> O	P <sub>2</sub> O <sub>5</sub>	LOI
CAC B	4.98	1.89	49.99	1.70	38.61	0.06	0.58	0.39	0.26	0.15	0.47
CAC G	0.25	0.38	69.8	0.18	30.61	0.03	0.46	0.18	0.42	0.12	0.56
CEM B	21.70	0.16	4.25	0.41	69.53	0.01	0.79	0.32	0.07	0.05	2.79
CEM G	22.40	0.15	2.87	2.22	69.34	0.05	0.91	0.19	0.18	0.07	1.65
Sand	97.44	0.04	1.15	0.1	0	0.07	0.15	0.39	0.53	0.01	0.2

The mortars were prepared with either CAC B, CAC G, CEM B or CEM G and siliceous sand (Sifrac DURANCE DU 0.1-0.35 with  $d_{50}=254\mu\text{m}$ ). The formulation was 30% cement, 70% sand and the ratio w/c was 0.57 for the CAC B based mortars, 0.54 for CAC G based mortars and 0.5 for the CEM based mortars, in order to obtain similar consistencies.

The dry mix was added in water in a standard mixer. The mixing time was chosen accordingly to the procedure of the NF-EN-196-1 standard. The fresh mortar was then poured into polystyrene moulds of 50x50x1 cm (LxWxH). The air bubbles were eliminated by means of a vibrating table and of a ruler. For a higher roughness, the roughcast roller was applied during the setting. The arithmetical roughness was determined with an optical profilometer CHR-150-L. The mortars were stored 7 days in 100 % of relative humidity (RH) before being cut. The final dimensions of the samples were of 8x20x1 cm (LxWxH).

Accelerated weathering of mortar was carried out in a cell under pure CO<sub>2</sub> at 20°C and 65% RH. Carbonation reaction and decrease of surface pH were thus speeded up (16).

The pH-decrease was monitored with a surface electrode (WTW Sentix Sur). When the surface pH reached 9, carbonation was stopped and the mortars chemical composition was estimated by X-ray diffractometry and thermogravimetric analysis. The carbonation time was 30 days for CEM cement based mortar and 38 days for CAC cement based mortar.

The mortar porosity was measured via mercury intrusion porosimetry (Micrometrics Autopore IV 9400) after drying 24 hours at 60°C.

## 2.2 Algal culture

The algal culture of *Klebsormidium flaccidum* requires an appropriate culture medium: the Bold's Basal Medium, according to NF-EN-15458 standard. This medium contains macro-elements such as carbon, oxygen, phosphorus, nitrogen and hydrogen as well as some mineral salts (or trace elements).

Strains were supplied by the Museum National d'Histoire Naturelle (MNHN, Paris, France). The cultures were made in batches exposed to an artificial light for photoperiods of 12 hours. Two fluorescent lamps (Fluora Osram) provided a light intensity of 20  $\mu\text{mol}/\text{m}^2/\text{s}$  PPF (Photons Photosynthetic Flux) which corresponds to a power of 30 W. This type of lamp was chosen because the light emitting spectrum matches with the chlorophyll light absorbing spectrum. Temperature and hygrometry were regulated at 20°C and 60 % RH respectively. Algal growth was followed thanks to various microbiological techniques such as cellular counting, optical density via UV-visible spectrophotometer, and determination of dry mass via algal suspension filtration. The ionic concentration was measured by ionic chromatography. These techniques were also used to characterize the algal growth in the biofouling laboratory bench.

## 2.3 Biofouling laboratory test

The system consisted of a glass chamber of dimensions 100x50x50 cm in which were settled two stainless steel supports inclined at 45° (Figure 1). The mortar samples were exposed to the same conditions of light (20  $\mu\text{mol}/\text{m}^2/\text{s}$  PPF, photoperiods of 12 hours) and temperature (20°C) as for the algal growth. The temperature was maintained with a thermoregulator. The box was filled with 50L of microalgal suspension, (concentration of 4mg/L dry mass) which was pumped and sprinkled on the top of mortar samples. The watering was made by means of a full holes banister of 2 mm in diameter, every 1 cm. The flow was set to  $26 \pm 1$  L/h. The sprinkling was carried out for 90 minutes every 12 hours and enabled to reproduce the phenomenon of colonization of a facade: microalgae were transported by the solution and had the possibility of hanging on and of adhering to the surface according to the characteristics of the mortar.

Figure 1. Laboratory bench for the colonization of mortars by streaming of algal suspension

## 2.4 Biofouling in-situ test

The in situ bench is set up at the “Ecole Nationale Supérieure des Mines de Douai” situated in Douai (North of France). The bench test on which are exposed 60 samples is constituted by a stainless steel structure (Figure 2). The angle of inclination is fixed to 45° which allows exposing samples to the weather conditions (period of sunshine, streaming, gusts of wind). Rows of samples are situated at least 1 meter above ground level, to avoid spatters phenomena. Samples are arranged so that the flow from one sample cannot contaminate the sample situated below and are spaced out by 5 cm to avoid contaminations. The site of exposure is a flat ground, distant from the traffic and close to some trees (situated at about 15 m from the bench)

**Figure 2. In-Situ bench for the colonization of mortars**

## **2.5 Biofouling evaluation**

The biodeterioration intensity was measured by image analysis. Thanks to an office scanner, the surface of sample mortars was digitized at different times. These images were then treated with the software Aphélon® which calculates a covering rate (noted  $X(t)$ ) of samples by microalgae (13). The initial RGB color space was converted in YIQ color space in order to identify easily the green algae on mortars.

The Q channel was used to quantify the number of colonized pixels after thresholding and segmentation. The colonization rate was given by the ratio of colonized area to the total surface. The different steps of image analysis are detailed on Figure 3. After segmentation the binary image represents in red the fouled area and in black the unfouled one.

**Figure 3. Example of image analysis of a specimen after 9 days test**

## **3. RESULTS AND DISCUSSION**

### **3.1 Characterization of the materials**

Results represented on Figures 4, 5 and 6 show that roughness, surface pH and porosity are not significantly different for all samples, around a value of about  $220 \mu\text{m}$  for roughness, 8.8 for surface pH and 14% for the porosity. This is an important result since it was already proven that these characteristics have a strong influence on the kinetics of biocolonization of mortars (4,5,9,12,13,14). As the physical characteristics of presently studied mortars are similar, we will thus be able to compare the effect of the chemical composition on the resistance to biofouling.

**Figure 4. Roughness of studied materials**

**Figure 5. Porosities of studied materials**

**Figure 6. Surface pH of studied materials**

### 3.2 Biofouling study in laboratory bench

The pictures of Figure 7 show the evolution of the surface of the specimens during the test period for Portland cement mortars and CAC mortars and we can thus notice that CAC based mortars were much less quickly colonized than Portland cement based mortars.

This phenomenon is fully confirmed by the evolution of the colonization rates of the specimens which is shown on Figure 8. The colonization of Portland cement based mortars both started earlier and was completed in a shorter time than the colonization of CAC based mortars.

Figure 7. Evolution of the biocolonisation of the samples during accelerated laboratory test

Figure 8. Evolution of the fraction of colonized area during accelerated laboratory test

### 3.3 *In-situ study of the biocolonization of mortars*

This part of the work was realised only with white mortars CEM B and CAC B. The samples were exposed from March 2012, at the beginning of spring. In a similar manner to what happened in laboratory tests, we can again notice that mortars containing CAC cement were more slowly colonized than the mortars which contain Portland cement (Figures 9 and 10).

On Figure 10, one can notice a decrease of the colonization rate after about 550 days and 900 days of exposure. This phenomenon was due to winter conditions which implied a detachment of algae from the material.

Figure 9. Evolution of the biocolonisation of the samples during outdoor exposition

Figure 10. Evolution of the fraction of colonized area during outdoor exposition

### 3.4 Discussion

In order to verify that the observed phenomena were not due to a difference in the alkalinity of the studied mortars, we followed the evolution of surface pH of the samples and of the pH of the algal suspension all along the laboratory test. The results are shown in Figures 11 and 12. It is quite clear that there are no significant differences between the different materials tested, which is of course consistent with the fact that all samples are carbonated.

Figure 11. Evolution of the surface pH of samples during laboratory test

Figure 12. Evolution of the pH of algal suspension during laboratory test

Lindemann et al.(17) emphasize that aluminum toxicity is known in acidic pH and highlight a slowdown in the growth of algae at neutral pH ( $\sim 6.5$ ), pH range in which aluminum hydroxide  $\text{Al}(\text{OH})_3$  is predominant. A bacteriostatic effect of hydrated alumina gels formed by mild acid attack in sewage pipes is also proposed to explain the durability of aluminous cements for such applications (18).

It is thus likely that species containing aluminum such as the gel of  $\text{Al}(\text{OH})_3$ , present in significant amounts in carbonated aluminates cements (19,20), possess a bacteriostatic effect at the origin of the particularly high durability of CAC based mortars with respect to the algal biocolonization.

### 4. Conclusions

In this study, we have shown, both by accelerated laboratory tests and by outdoor exposition, that aluminate cement-based mortars present a resistance to algal biocolonization much higher than Portland

cement mortars. This study was performed using mortars with similar physical characteristics (roughness, porosity, surface pH) and which do not influence the pH of their environment in different ways. We can thus conclude that this effect is mainly due to mineralogical differences. Previous studies indicate that this phenomenon might be caused by a bacteriostatic effect of aluminum hydroxide. We plan to continue this study and verify this hypothesis by additional tests on the interaction between  $\text{Al}(\text{OH})_3$  and microorganisms.

# Expansive Behavior of Mortars Containing Surf Clam Shell Powder at Early Age

Akio Watanabe<sup>1</sup> Kazumi Hirokawa<sup>2</sup> and Takashi Kondo<sup>1</sup>

<sup>1</sup> Associate Professor of Civil Engineering, Tomakomai National College of Technology

<sup>2</sup> Professor of Civil Engineering, Tomakomai National College of Technology

**Abstract:** Reuse of surf clam shell has been of great interest in Japan, especially in fishing areas. The authors have investigated properties of concrete containing the clam shell powder, and they found that the clam shell powder could be used as an admixture of concrete. In this study, early age expansion between mortars with and without the surf clam shell powder was compared. Length changes of mortars at early ages were measured in accordance with ASTM C1698. As a result, regardless of the incorporation of the clam powder, the authors found them shrunken in the first few hours after mixing. However, subsequent behavior of mortars was quite different between them. It was observed that the mixed mortar, in which approximately 10 percent of the cement were replaced with surf clam shell powder, remarkably expanded by 10mm in length. This expansion may be related to formation of calcium hydroxide. The clam shell powder can be used as an effective expansive admixture for concrete.

**Keywords:** surf clam shell, ASTM C1698, Ca(OH)<sub>2</sub>, expansion.

## 1. Introduction

The enterprising use of industrial waste is required in the concrete structures. In Japan, approximately 480 kg of industrial waste, including blast furnace slag, fly ash, municipal solid waste incineration ash, and sewage sludge, is currently used per tonne of cement, and this proportion is increasing year by year. In Hokkaido, northern Japan, it is desired that waste generated as a result of processing seafood is also used as a construction material. This fishery-related waste includes approximately 200,000 tonnes of shells every year, but establishing methods of using these shells is a challenge. Research into the use of shell in concrete is being conducted in South Korea, where oyster shell is being studied as a concrete aggregate<sup>1</sup>. Furthermore, some scallop shells (of which there is also an abundance in Japan) are also being used as concrete aggregate.

However, surf clams, which are a specialty of Tomakomai City in Hokkaido, are caught in small quantities—6,000 tonnes in Hokkaido (of which 800 tonnes are caught in Tomakomai)—and so the amount of surf clam shells available is lower than that of scallop shells, and most are disposed of through methods that do not allow for recycling. Because large amounts of shells are required, using them in aggregate is thus an unsuitable method for utilizing waste surf clam shells. One idea is to use a mixture of scallop and surf clam shells, but it is best to avoid mixing the shells because their compositions are different. Whereas the surf clam shells are made of aragonite-type calcium carbonate, scallop and oyster shells are made of calcite-type calcium carbonate, and so the hardness and other properties of the shells differ. A mixture of shells of different quality could cause a decrease in the quality of the concrete. Therefore, a different method of use to that of scallop and oyster shells must be devised for surf clam shells.

Rather than using the surf clam shells as aggregate, the present research examines the use of the shell as an admixture that can be added in small amounts to improve the quality of concrete. The authors focused on the fact that surf clam shells are calcium carbonate and thought that by burning the shells to form calcium oxide they could be used as an expansive admixture for concrete. This paper examines the expansion characteristics of cement mortar that result from the addition of surf clam shells.

Figure 1. XRD of surf clam and scallop shell

## 2. Experiment

### 2.1 Material characteristics

#### 2.1.1 Surf clam shells

Surf clam shells are calcium carbonate-based, like scallop and oyster shells, but the crystalline structure is different. Figure 1 shows the results of powder X-ray diffraction measurements of the shells. The main peak values for aragonite-type calcium carbonate, 26.59°, 33.15°, and 38.10°, are identified in the surf clam shell, whereas the main peak values for calcite-type calcium carbonate, 29.65°, 47.57°, and 48.93°, are identified in the scallop shell. Lime made from limestone is ≥90% calcite-type calcium carbonate, and has a stable crystalline structure used in cement and steel. In contrast, aragonite-type calcium carbonate is described as being in a “metastable phase” and has a crystalline structure found only in some corals and shells. This structure is harder than the calcite-type, and its characteristics include changing into the calcite-type when burned at approximately 500°C.

The surf clam shells used in this research were ground to a grain size of 75 μm or lower, and burned for 1 hour at 1,000°C. Figure 2 shows the results of powder X-ray diffraction measurements of surf clam shell before and after burning. The aragonite-type calcium carbonate changes into calcium carbonate. Photo 1 is a scanning electron micrograph (SEM) of the shell powder. The surface of the shell powder becomes smooth as a result of burning.

Figure 2. XRD of surf clam shell before and after burning

(a) Before burnig

(b) After burning

Photo 1. SEM of surf clam shell before and after burning

#### 2.1.2 Lime-based expansive admixture

An evaluation of the expansion characteristics of the surf clam shell was carried out by comparison with a commercial expansive admixture. Expansive admixtures can be divided into those containing calcium sulfoaluminate, which cause expansion by forming ettringite ( $3\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot 3\text{CaSO}_4\cdot 32\text{H}_2\text{O}$ ), and those containing lime, which cause expansion by forming calcium hydroxide ( $\text{Ca}(\text{OH})_2$ ). Considering the composition of the surf clam shells, a lime-based expansive admixture was used in this research. Table 1 shows the chemical composition of the burned surf clam shell and the expansive admixture.

Table 1. Chemical composition of the burned surf clam shell and the expansive admixture

	Weight Percent						
	Ig.loss	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>3</sub>
Burned surf clam shell (HP)	1.4	0.05	0.03	0.19	98.0	0.08	0.24
Expansive admixture (B)	1.2	4.2	1.1	1.0	74.0	0.5	16.5

## 2.2 Mixture

A mortar (hereafter, N) comprising cement, water, and fine aggregate at a ratio of 1.0:0.5:2.0 was made using ordinary Portland cement (density 3.16 g/cm<sup>3</sup>) and river sand (density 2.77 g/cm<sup>3</sup>). Surf clam shell (HP) and expansive admixture (B) were substituted in proportions of 0.05 and 0.10 with respect to cement mass (hereafter, HP5, B5, HP10, and B10).

## 2.3 Compressive strength test

Square pillar specimens of size 40 × 40 × 160 mm were produced in accordance with Japanese Industrial Standards (JIS) R 5201. The specimens were removed from their molds 24 hours after pouring, and cured in water at 20°C. A compressive strength test was carried out at material ages of 7 days and 28 days.

## 2.4 Mortar specimen length change test

A length change test according to the American Society for Testing and Materials (ASTM) C1698 was employed as a method of measuring the expansion of the mortar, and it was decided to study the expansion characteristics of the mortar at an early age. This test was originally intended to evaluate autogenous shrinkage at low water-cement ratios, and is a method of examining length change in cement paste or mortar poured in a corrugated mold using a dial gauge based on the length when set<sup>2,3</sup>. This research enhanced the test apparatus by replacing the dial gauge with a laser displacement meter so that the length change could be measured directly straight after pouring.

Photo 2. Length change measuring device

A polyethylene corrugated mold approximately 30 mm in diameter and 425 mm in length was installed vertically on top of a shaking table, and the mortar was poured in from the top while the table was vibrated. Then, a Teflon stopper was put on to make a specimen for measuring length change. This was installed on a platform fixed at a 30° angle in a temperature-controlled room at 20°C, and length change was measured using the length change measuring device shown in Photo 2. The measurable range using this test apparatus was -10 to +10 mm.

## 2.5 Other tests

Samples were collected from the specimens after the compressive strength test, and these samples were immersed in acetone and, after the hydration reaction was halted, dried in a vacuum. Chemical analysis was carried out using thermogravimetry-differential thermal analysis (hereafter, TG-DTA) and powder X-ray diffraction. Pieces of samples were also collected from the specimens after the length change test and were examined using a scanning electron microscope (SEM).

# 3. Results and discussion

## 3.1 Compressive strength

Figure 3 shows the results of the compressive strength tests. If N is taken as the reference, the compressive strength of HP5 is slightly lower at material ages of both 7 days and 28 days. However, HP10 has a compressive strength of approximately 5 N/mm<sup>2</sup> at 28 days, which is a very low value. The reason for this is that, as shown in Photo 3, the HP10 mixture showed considerable expansion, such that a length change of approximately 10 mm in the direction of the longitudinal axis was identified, generating

many tiny cracks as a result. The cause of this expansion is considered to be calcium oxide reacting with water and forming calcium hydroxide, similar to a lime-based expansive admixture. Among the mortars in which the expansive admixture was used, the strength of B5 at a material age of 7 days was greater than N. The strength of B10 was slightly lower than N, and was at the same level as HP5.

### 3.2 Expansion characteristics

Figure 4 shows the measured results for length change. Displacement indicates length from the initial length of 425 mm. Each specimen demonstrated considerable shrinkage during the period from directly after pouring until 4 to 5 hours later. This is considered to be shrinkage due to a cement hydration reaction. Subsequently, almost no change in length was found for N, HP5, or B5. The reason why expansion was not found in specimens HP5 and B5 was considered to be that the added amount was small and the reactions that occurred were insufficient to cause expansion. However, HP10 demonstrated considerable expansion from after shrinkage until 1 day had passed, and subsequently showed almost no length change. The reason why there was almost no length change after the material age of 1 day is considered to be because the quantity of water for the reaction was limited inside the airtight space of the corrugated mold. B10 showed gradual, continuous expansion after the material age of 1 day. This is considered to be because the amount of CaO in B10 is lower than in HP and SO<sub>3</sub> is added instead, thus the reaction is controlled such that expansion occurs over a long period.

### 3.3 Formation of calcium hydroxide

Figure 5 shows the results of TG-DTA analysis at a material age of 7 days. The TG-DTA measurement conditions were an air flow of 25 ml/min. and a rate of temperature increase of 10°C/min., and the reference material was alumina. Figure 6 shows the results of quantitative evaluation of calcium hydroxide using the calibration curve method. N contains approximately 1.0% of Ca(OH)<sub>2</sub>, while HP5 contains approximately 1.5% and HP10 contains approximately 2.0% of Ca(OH)<sub>2</sub>. In other words, HP10 contains approximately twice the Ca(OH)<sub>2</sub> of the standard mortar. Therefore, the large expansion of HP10 is judged to be caused by the formation of Ca(OH)<sub>2</sub> due to the reaction of CaO in the burned HP with water. The reason why HP5

Figure 3. Compressive strength

Photo 3. Specimens (7days)

Figure 5. Results of TG-DTA (7days)

Figure 6. Ca(OH)<sub>2</sub> content of mortars (7days)

Figure 7. XRD of mortar (7days)

(a) N (×2,000)

(b) N (×10,000)

(c) HP10 (×2,000)

(d) HP10 (×10,000)

Photo 4. SEM images of N and HP10 after the length change test

did not expand is considered to be because the mixed amount of HP (CaO) was small and insufficient for Ca(OH)<sub>2</sub> to be formed.

### 3.4 Evaluation of calcium hydroxide using X-ray diffraction

Figure 7 shows the results of powder X-ray diffraction at a material age of 7 days. In HP5, the Ca(OH)<sub>2</sub> peak is roughly the same as in N. However, in HP10, the Ca(OH)<sub>2</sub> peak at 18° is very large compared to N, B5, and B10. The 18° peak increases in size according to the crystal orientation of Ca(OH)<sub>2</sub>. In other words, given that the content of Ca(OH)<sub>2</sub> in HP10 and B10 is roughly the same in the TG-DTA, it can be inferred that the cause of expansion is determined not just by the formation of Ca(OH)<sub>2</sub>, but also by the crystal orientation of the Ca(OH)<sub>2</sub>.

### 3.5 Electron microscopy of mortar fracture surface

Photo 4 shows SEM images of N and HP10 after the length change test. Some needle-like crystals of approximately 1 µm in length, considered to be ettringite, are visible in the SEM image of N. On the other

hand, in the SEM image of HP10, a large amount of rod-like crystals are found, and these crystals are of a size ranging from 5 to 10  $\mu\text{m}$ , making them visible even at a magnification of  $\times 2,000$ . These crystals are thought to differ from typical ettringite because of their large size.

Looking at the results of the powder X-ray diffraction measurements in Figure 7, ettringite peaks (e.g.,  $9^\circ$ ) are not visible in any of the specimens, and so it is unlikely that large amounts of ettringite were formed. However, the rod-like crystals are observed in large quantities, and so are considered to be relevant to mortar expansion. If these crystals originate in the  $\text{Ca}(\text{OH})_2$  detected using TG-DTA and powder X-ray diffraction, this could explain the size difference between the  $18^\circ$  peaks (Figure 7). In other words, although the cause is unclear, the results suggest that the powder X-ray diffraction peak may have increased in HP10 due to the thickness to which the crystals grew. The identity of this crystal requires investigation.

#### 4. Conclusion

This research investigated the expansion characteristics of a mortar in which the powder of burned surf clam shells was substituted for a portion of the cement, with the aim of using surf clam shells as an expansive admixture. The summarized results are as follows:

- (1) The surf clam shells change from  $\text{CaCO}_3$  to  $\text{CaO}$  as a result of burning at  $1,000^\circ\text{C}$ .
- (2) Mortar in which approximately 0.1 or more of the cement is replaced by burned surf clam shell demonstrates considerable expansion, and the formation of  $\text{Ca}(\text{OH})_2$  is increased.
- (3) In length change tests using a corrugated mold, all mortar specimens demonstrated shrinkage during the period from directly after pouring until setting. Subsequently, HP10 demonstrated considerable expansion until a material age of 1 day.
- (4) The cause of this expansion is considered to be the formation of  $\text{Ca}(\text{OH})_2$  due to  $\text{CaO}$  in the powder of burned surf clam shells reacting with water.
- (5) The intensity of the powder X-ray diffraction peak of  $\text{Ca}(\text{OH})_2$  at  $18^\circ$  was increased in HP10. Also, large amounts of rod-like crystals were observed in SEM images of pieces of the HP10 specimen.
- (6) These results show that mortar incorporating powder of burned surf clam shells causes expansion, and suggest that the powder of burned surf clam shells can potentially be used as a substitute for lime-based expansive admixtures. However, as there are points that are unclear in the expansion mechanism, research aimed at expansion control remains necessary.

# The use of cementitious coatings to reinstate low nominal cover on reinforced concrete structures

Neil Wilds<sup>1</sup>

<sup>1</sup>Technical Manager, Protective Coatings laboratory

<sup>2</sup>International Paint, Akzonobel, UK

**Abstract:** Reinforced concrete is used extensively in modern construction of numerous assets including bridges, jetties, public and industrial infrastructure. Structure design lives of 50 years and often significantly longer means durability should be a critical consideration. Durability of reinforced concrete depends on a variety of factors including the surrounding environment, mix design of the concrete and construction practices. A nominal design cover, thickness of concrete over steel reinforcement bars to provide corrosion protection, will typically be specified based upon the environment and the type of concrete used. In practice whether on site or in the pre-cast yard the specified concrete cover thickness is not always achieved. This will reduce the time to first maintenance and can lead to expensive repair costs particularly in severe coastal or industrial environments where high levels of chlorides and or acidic gases are present. When this occurs it can lead to project delays, scrapping of pre-cast units, potentially re-casting concrete on site or the use of protective coatings to reinstate the cover. Advanced cementitious coatings offer an innovative solution to this problem due to their ability to be applied to new, green, concrete and act as a barrier to moisture, Chlorides and acidic gases ensuring lasting protection.

This paper explores the problem and reviews the use of advanced cementitious coatings as a cost saving solution.

**Keywords:** concrete, concrete corrosion, durability, low cover, chloride protection, concrete repair and protection, cementitious coatings.

## 1. Causes of low cover

There are lots of causes of low cover and, although mistakes can happen on the project site, problems can sometimes be traced back to the design process. With the wish to make modern concrete structures more complex and aesthetically pleasing, the design becomes more complicated, and insufficient attention may be given to the practicality of turning the concept from the designer's drawings into reality. In some cases, designers do not picture the construction sequence or envisage the difficulties on project site, and so the requirements for steel reinforcement are based upon structural needs rather than the ease of assembly as subsequent encasement in concrete. This is seen as a common problem on highway and marine structures, where the sheer density of reinforcement provides big challenges for the contractor. In these instances, insufficient consideration is sometimes given to the mix design of the concrete to enable it to be poured into confined spaces.

Another cause of low cover can be poor workmanship, with the wrong or inadequate spacers being used or inadequate fixing of the formwork. Furthermore, great care must be taken when concrete is being poured and compacted to avoid displacement of the reinforcement. It must be remembered that, if the concrete fails to meet its specified characteristic strength, the cover quality will be inadequate to maintain the required durability requirements. Poor compaction and honeycombing will again reduce effectiveness of the concrete cover and will require remedial action. Therefore, it is vital to maintain tight quality control at all times to avoid such potentially costly mistakes.

## 2. Consequences of low cover

The concrete cover must have a minimum thickness for three main reasons:

- To protect the steel reinforcement bars (rebar's) from environmental effects to prevent their corrosion.
- To provide thermal insulation, this protects the reinforcement bars from fire.
- To give reinforcing bars sufficient embedding to enable them to be stressed without slipping.

The depth and quality of the concrete is vital as the relatively thin layer of concrete has to be able to maintain a passivating alkaline layer, formed by the release of calcium hydroxide as cement hydrates, whilst still forming a barrier to ingress of chloride ions or carbonation. Typical levels of cover are given in Table 1.

Country	Concrete Code	Range of Concrete Cover (mm)
UK	BS:8110	25-50
EU	EN 1992 (EC2)	diameter +10 - 55
USA	ACI:318	40-50
Australia	AS:3600	15-78

This is especially important where concrete structures are exposed to industrial or marine environments). The premature failure of corroded steel reinforcements and the expansion of the iron corrosion products around the rebar's are one of the main causes of the concrete degradation. The minimum concrete cover will depend on the environmental conditions encountered and must be thicker when the concrete is also exposed to moisture and chloride. A high quality concrete made with a low water-to-cement (w/c) ratio will have a lower porosity and will be less permeable to water and to the ingress of corrosive species (dissolved oxygen, chloride). A thicker cover or a more compact concrete will also reduce the diffusion of CO<sub>2</sub> in the concrete, protecting it better from carbonation and maintaining a higher pH for a longer time period, increasing so the rebar service life.

### 2.1 Remedial actions

#### 5.1.1 Demolition

Demolition is a drastic measure and the last resort, however once a client finds a major defect within a new structure the first suggestion is often to demolish those sections that do not meet the specification, or in the case of precast concrete elements reject the item. This is not always practicable, as it may be sometime before the problem is found or the costs in terms of delay to the project may be unacceptable.

### 5.1.2 Recasting

An alternative to demolition maybe partial recasting, which involves removing back to behind the level or the reinforcement using high pressure water jetting to avoid damage to the adjacent structure. The formwork is the repositioned to achieve the desired cover and the concrete is recast. However, depending when the problem is discovered, there may be problems with accessing the area to carry out the work.

### 5.1.3 Rendering

It may be practicable to increase the cover by building out the face of the concrete with a polymer-modified render, although it is important to ensure adequate key removing the surface laitance and achieving a rough surface using wet grit blasting. Depending upon the protective properties of the render, it may be possible to reduce the thickness of the cover while still providing the same degree of protection.

### 5.1.4 Protective Coatings

By far the easiest and most cost effective way of enhancing cover is to use cementitious protective coatings. These will not only reinstate the cover but also provides additional aesthetic and protective properties. But when selecting a coating system care must be taken to assess the film thickness required providing the necessary protection. In addition, the coating must be compatible with the substrate and its surroundings, and the products expected lifespan should be considered. The system must also be backed up by relevant independent test data and approvals.

## 3. Chloride Attack on Concrete

To use a well-known analogy, if a chloride ion were the same size as a tennis ball, then a capillary pore within even good-quality concrete would be the size of a railway tunnel (the radius of a chloride ion is  $0.18 \times 10^{-9}$ m. The size of the smaller capillary pores in concrete is  $1 \times 10^{-7}$ m. The diameter of a tennis ball is 670mm therefore multiply this by the difference in size (100) and you get 6.7m, which is certainly the size of a railway tunnel). Therefore, when concrete structures are exposed to salt spray or submerged in saltwater, chloride ions easily penetrate the concrete, eventually reaching the steel, breaking down the passivating layer and causing corrosion, even under highly alkaline conditions. Corrosion most rapidly occurs in the splash zone where the wet/dry conditions exacerbate chloride penetration and there is enough oxygen to facilitate the corrosion process.

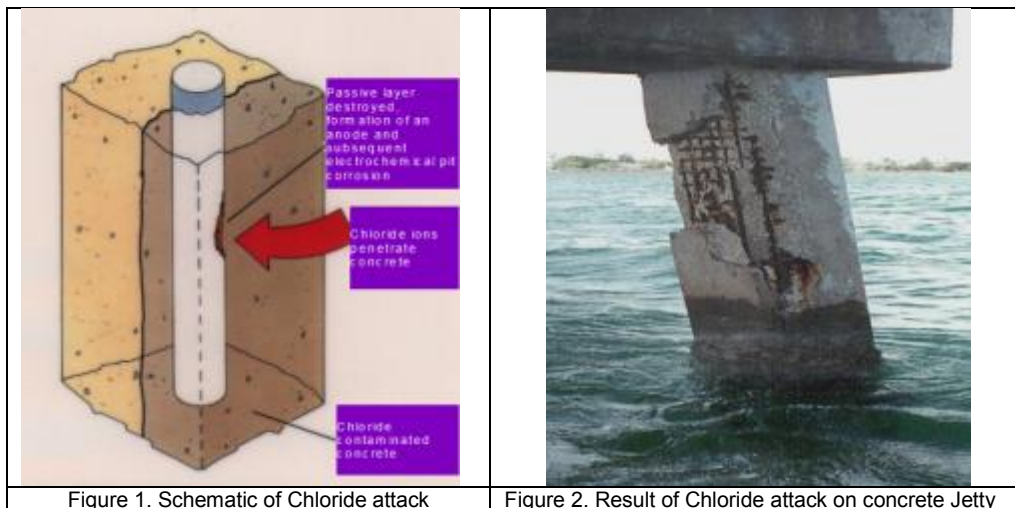

Figure 2. Result of Chloride attack on concrete Jetty

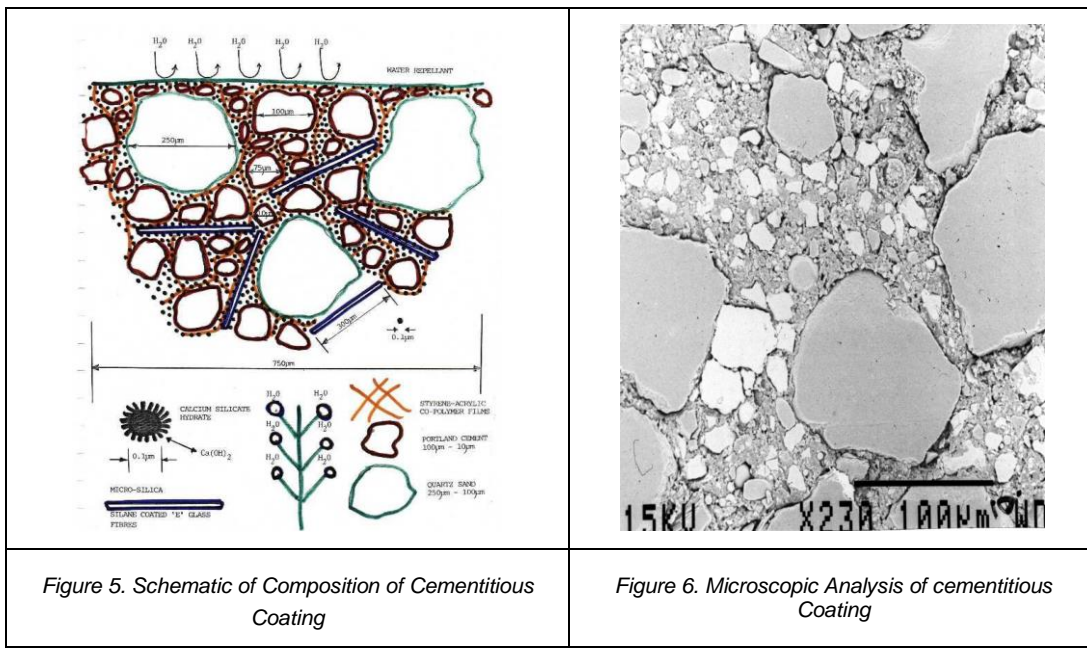

### 3. Carbonation of Concrete

The carbon steel of rebar is protected from oxidation by atmospheric oxygen by the high pH of concrete interstitial water. The rebar surface is passivated as long as the pH value is higher than 10.5. Fresh cement water has a pH of about 13.5 while evolved cement water pH ~ 12.5 is controlled by the dissolution of calcium hydroxide. Carbon dioxide present in the air slowly diffuses through the concrete and progressively reacts with the alkaline hydroxides (KOH, NaOH) and with calcium hydroxide leading to the carbonation of the hydrated cement paste. As a result, the pH of the cement drops and when its value is below 10.5 – 9.5, steel surface i.e. the rebar is no longer passivated and starts to corrode.

### 4. Cementitious Coatings a solutions for low cover

To achieve these barrier properties required to protect the rebar encased in concrete, the technology of cementitious coatings uses a number of different mechanisms to minimise both the porosity and permeability of what is essentially an ultra-thin but highly modified section of concrete. Low water:cement ratio and the use of pozzolanic materials such as fly ash, which react with the lime from the cement hydration to form further hydrates, reducing pore size, while micro-glass fibres dramatically reduce permeability. However the most influential raw material is silica fume, which is a byproduct of ferro-silicon steel production and is commonly referred to as a super-pozzolan due to its high reactivity with lime. It is 100 times finer than cement and contains material in the nano-particle range, which is capable of blocking the finest pores in the cement matrix. Many investigations have documented the dramatic reduction in the rate of chloride diffusion that can be achieved by incorporating silica fume into concrete<sup>1,2</sup>, which is largely attributed to the refinement of the pore structure. This modification in the pore structure also affects other properties resulting in 2mm film resisting water under 10 bar hydrostatic pressure (100m head of water). Gas diffusion resistance is also enhanced so that 2mm will provide the same resistance to carbon dioxide as 100mm of good quality concrete.

## 5. Performance of Cementitious coatings

As previously mentioned the two main modes of failure are carbonation and chloride attack of the rebar over prolonged exposure periods. This is obviously exacerbated with low cover issues resulting in the requirement that cementitious coatings must be shown to protect against these corrosive mechanisms. There are two relevant tests that can show this and can be used as a type of prequalification.

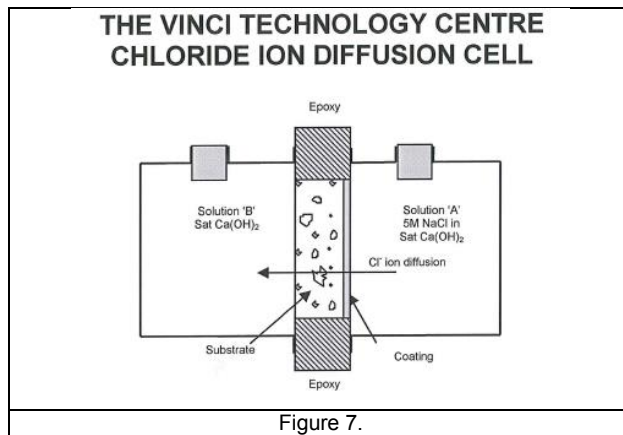

### 5.1 Chloride Diffusion Test

One such test for chloride diffusion began in 1988 initiated by Taywood Engineering (now Taylor Woodrow/Vinci construction Technology Centre).

#### 5.1.1 Test procedure

Two coats of the cementitious coating, each approximately 1mm thick were applied to one surface of a concrete slice using a palette knife. After this layer had cured for about 2 hours at 23°C and 60±5% relative humidity the second coat was applied at right angles. The coated specimen was then left to cure for 28 days under the same conditions prior to testing.

The coated specimen and an uncoated control had their top and bottom faces masked with plastic and tape respectively. They were then placed in individual moulds and the edges sealed with a cold curing epoxy resin. After allowing the resin to cure overnight, the specimens were immersed in saturated calcium hydroxide solution for 4 days. This was carried out to avoid anomalous effects due to chloride ingress by sorption rather than diffusion. Each specimen was the mounted in a diffusion cell as shown in Figure 7.

The cells were maintained at  $23\pm 2^{\circ}\text{C}$  and the chloride diffusing through the specimens was determined at suitable intervals. An aliquot of each sample was accurately pipetted into a clean oven dried glass container. Nitric acid (approximately  $50\text{--}70\text{cm}^3$ ) was added to the sample, which was then left to stand with occasional stirring. Automatic potentiometric titration with continuous stirring was used to analyse the samples. The titrator used was a Metrohm 798 MPT Tritrino and the course of the titration was monitored using a Metrohm electrode system. The accuracy of the method was checked using control samples of known chloride content ( $0.10\pm 0.01\%$ , by weight of sample).

### 5.1.2 Test Results

The following graphs Figure 8. & Figure 9. show the results from the titrations described above.

The cementitious coating has been on test for a period of 9484 days and counting (approximately 26 years). To allow the calculation of Chloride Ion Diffusion, CIDC, to be calculated, the chloride concentration must attain a steady state which is deemed when reaching  $>0.1$  mol/ltr. After 9484 days of the test, the chloride concentration was only  $0.0039\text{mol/ltr}$ , so no CIDC could be calculated. Results can be seen in Table 2 below.

Table 2. Chloride Ion diffusion Coefficient results ( After 26 years on test)		
Sample Ref	Cementitious Coating	Uncoated Control
Substrate thickness (cm)	1.414	1.465
Coating thickness (cm)	2100	n/a
Test area (cm <sup>2</sup> )	78.54	78.54
Chloride ion diffusion coefficient (cm <sup>2</sup> s <sup>-1</sup> )	n/a	1.03 x 10 <sup>-8</sup>

Although no CIDC could be calculated it can be stated that the cementitious coating on test proved a very good barrier to the ingress of chloride ions. The non – coated sample had reached a steady state after 98 days and CIDC has been calculated.

## 5.2 Carbon Dioxide Diffusion Coefficient

One such test for carbon dioxide diffusion was carried out in 2007 initiated by Taylor Woodrow Technology.

### 5.2.1 Test procedure

Taylor Woodrow Technology supplied four standard unglazed ceramic tiles 100x800mm for coating with the cementitious coating. Two coats of the cementitious coating, each approximately 1mm thick were applied to the test specimens using a palette knife. After this layer had cured for about 2 hours at 21±°C and 60±5% relative humidity the second coat was applied at right angles. The coated specimen was then left to cure for 21 days under the same conditions prior to testing. The coated samples were allowed to condition at 23±°C and ambient relative humidity at the test house prior to testing.

One coated tile was sealed in a circular steel rig such that the coated and uncoated faces were exposed. Due to the cementitious nature of the coating, oxygen at a known pressure and flow rate was passed over the coated face of the plate and helium gas was passed over the uncoated face at the same pressure and flow rate. The helium gas stream was continuously monitored by gas chromatography to analyse for oxygen. Equilibrium conditions were achieved after approximately 24 hours and the steady state flux was then calculated from the percentage of oxygen in the helium stream and the flow rate of gas.

The diffusion coefficient for oxygen (D<sub>O2</sub>) is calculated using Fick's law of Diffusion and Crank's equation.

Due to the cementitious nature of the coating, the testing was undertaken using oxygen and results converted for use with carbon dioxide using the following criteria;

$$*DC_{O_2} = 0.316 D_{O_2}$$

\*This equation has been derived from measurements of oxygen and carbon dioxide diffusion coefficients conducted with non-cementitious coating systems<sup>3</sup>

It is assumed that the relationship is valid for polymer modified cementitious materials such as that tested. This assumption is made as a direct relationship of D<sub>O2</sub> and D<sub>CO2</sub> is not available for polymer modified materials – direct measurement of DC<sub>O2</sub> cannot be carried out on such materials due to interference from the carbonation reaction.

## 5.2.2 Test Results

The results of the testing are tabulated below.

Table 3. Carbon Dioxide Diffusion Coefficient	
DC <sub>O2</sub> (cm <sup>2</sup> s <sup>-1</sup> )	8.02 x 10 <sup>-6</sup>
μ-value	1.86 x 10 <sup>-4</sup>
R (m)	39
Sc (cm)	10
Mean Dry Film Thickness (μm)	2121

Notes:

The equivalent air layer thickness (R-value) is calculated for the measured thickness of the specimen as follows;

$$\mu\text{-value} = 0.149 / DC_{O_2} \quad R\text{-value} = \mu \times \text{specimen thickness (m)}$$

DC<sub>O2</sub> and the diffusion resistance coefficient (μ-value) are calculated using the mean dft measured on a spare unused specimen.

DC<sub>O2</sub> for an uncoated plate is 1.0 x 10<sup>-3</sup> cm<sup>2</sup>s<sup>-1</sup>.

The equivalent thickness of concrete (Sc-value) is calculated for the measured thickness of the specimen as follows:

μ-mortar x specimen thickness (cm) = μ-concrete x Sc where the μ-value for an average grade of concrete is taken to be 400 (μ-concrete)

Klopfer criterion for effective anti-carbonation coating is R greater than 50 metres.

EN 1062-6 Classification C<sub>1</sub> for Carbon Dioxide Permeability requires S<sub>D</sub> value greater than 50 metres.

## 6. Example projects

### 6.1 Kwai Chung T8 Container terminal

Figure 10. Foundation coated with cementitious coating

Figure 11. Completed container terminal

Cementitious coatings were chosen to protect the supporting structure for the container terminal. The clients wanted to ensure an extended design life as any potential repairs due to chloride attack on the concrete supports would not be accessible.

## 6.2 Concrete Extension Doha Corniche

Figure 12. Application of cementitious coating system

Cementitious coatings have also been well proven in hot and humid climates, as demonstrated by the prestigious Doha Corniche project in Qatar's capital city of Doha. A waterfront promenade extending for 10km along Doha Bay, Doha Corniche was formed following extensive dredging work carried out during the late 1970s and early 1980s, which reshaped Doha's coastline; the Corniche is now popular among walkers, bikers and joggers. Protection from high seas is provided by a concrete breakwater, which suffers from erosion from wave action and chloride-induced corrosion of the steel reinforcement. When a new 500m precast concrete extension was constructed, the use of a chloride barrier was stipulated to extend the design life.

## 6.3 Link Bridge Belvedere London

Figure 13. Belvedere EfW

More recently, designer Royal Haskoning specified cementitious coatings to increase the durability on the new link bridge that forms part of the Belvedere Riverside Energy from Waste (EfW) facility in south-east London. The cementitious coating was applied to 91 precast, pre-stressed beams at Anchor Bay Wharf in Erith prior to transportation to site by barge and installation.

## **7. Conclusions**

Correctly formulated and tested Cementitious coatings present an ideal solution to non-conformance of concrete cover within specifications. Not only do they reinstate cover, they also provide structures with additional protection against carbonation, de-icing salts, water and chloride ion penetration. This ensures that the life span of the structure is both achieved and extended.

**Abstract:** The occurrence of a fire in a building raises a number of important questions regarding the post-fire or residual strength and stiffness of any exposed concrete members. Loss of residual strength and stiffness due to heating has been demonstrated by a number of previous studies, most of which have utilized experiments where unstressed specimens were heated and allowed to cool prior to testing them to failure at ambient temperature. This paper describes elevated temperature tests where the specimens were loaded during heating and cooling prior to testing them to failure at ambient temperature. This paper describes the results of such testing undertaken on eighteen identical plain concrete cylinders ( $\varnothing$  65mm  $\times$  150mm) which were exposed to temperatures of 100, 200, 300, 400, 500, and 600°C whilst they were subjected to 30% of maximum load during the heating and cooling phases, prior to testing at ambient temperature. The properties examined were residual compressive strength, residual secant modulus of elasticity and the effect on the stress-strain relationship of concrete. The exposure to high temperature decreased the residual concrete compressive strength, concrete modulus of elasticity and initial slope of stress-strain curves for the cylinders. It was found that the decrease in secant stiffness of concrete is more pronounced than the corresponding decrease in residual compressive strength. These results are compared with the findings from overseas studies which were conducted on specimens that were not loaded during heating. Finally, models for temperature-dependent residual compressive strength and modulus of elasticity are proposed.

**Keywords:** Concrete, Residual compressive strength, Residual elastic modulus, Stress-strain relationships, Elevated temperatures, Cooling, Constitutive model.

## 1. Introduction

Although concrete is considered to be resistant to heating, it is well known that the mechanical properties of concrete deteriorate after exposure to a fire and/or elevated temperatures (Lea 1922 [1]; Lea and Stradling, 1922 [2]; Malhotra, 1956 [3]; Mohamedbhai, 1982 [4]; Schneider, 1988 [5]; Phan and Carino, 1998 [6]; Khoury, 2000 [7]; Annerel and Taerwe, 2009 [8]). The degradation of mechanical properties of concrete due to short-term exposure to elevated temperature has been studied by Malhotra (1956) [3], Abrams (1971) [9], Mohamedbhai (1983) [10], Schneider and Kassel (1985) [11] and Schneider (1988) [5]. Studies have been conducted on the effect of elevated temperature on normal-strength concrete (NSC) (Castillo, 1987 [12]; Castillo and Durrani, 1990 [13]; Phan, 1996 [14]; Phan and Carino, 1998 [6]; Husem, 2006 [15]; Biolzi et al., 2008 [16]), with the specimens being tested using one or more of the following combinations of heating and loading: (a) stressed during heating and tested at high temperature, (b) unstressed during heating and tested at high temperature, and (c) unstressed during heating and tested after cooling. The unstressed residual properties of concrete after exposure to elevated temperature have been of great interest (Bazant and Kaplan (1996) [17]). In the present paper, a further combination of heating and loading, namely, stressed during heating and tested after cooling, is considered. This combination is of particular importance in the assessment and refurbishment of buildings after a fire, since it is necessary to have a sound understanding of the residual properties of concrete – i.e. the strength characteristics after cooling following heating due to a fire. In practice, all members are loaded during a fire event.

The adverse effect of extreme thermal exposure on the residual mechanical properties of concrete (i.e. combination (c)) has been demonstrated by many researchers. For temperatures less than 300°C, the reduction in residual strength is known to be small; however, the strength decreases significantly when heated above 300°C (Li and Li, 2010) [18]. NSC typically loses between 10 to 20% of its original compressive strength when heated to 300°C, and between 60 to 75% when heated to 600°C. According to the Concrete Society, (1990) [19], concrete loses 25% and 75% of its ambient compressive strength

when heated to 300°C and 600°C, respectively, following cooling. The residual modulus of elasticity decreases in a similar manner (Phan and Carino, 2000) [20].

The effect of elevated temperatures on the full stress-strain response of fire-affected concrete has been studied in the pioneering work of Furumura (1966) [21]. Later, Baldwin and North (1973) [22] attempted to establish a mathematical model for the full response using Furumura's (1966) [23] data.

There is a lack of studies where concrete members have been (i) heated under load (ii) cooled down to ambient temperature (iii) loaded to failure. This paper presents results which, in part, address the above gap in knowledge and form part of an on-going research project. The paper presents experimental results using the above sequence of loading and heating to examine the effects of heating temperature and cooling method on the residual strength of concrete. Models based on these experimental results have been developed.

## 2. Experimental Program

### 2.1 Concrete Mix and Details of Specimens

Small concrete cylinders were constructed using ready-mixed normal concrete prepared by a local supplier (Hanson Construction Materials Pty Ltd). The compressive strength ( $f'_c$ ) of the concrete was 32 MPa, the slump was 80 mm, and the maximum aggregate size was 14 mm, the properties of which are illustrated in Table 1. The test program involved 18 identical  $\varnothing$  65mm  $\times$  150mm small plain concrete cylinders, as shown in Figure 1. Of the 18 small cylinders, 2 were left as control samples and 16 were subjected to heating under stress.

The ready-mix concrete mixture was poured into small concrete cylinders followed by vibration using a vibration table for 6 minutes. The top surface of the concrete was then finished using a trowel and the specimens were left inside the molds for 24 hours to harden. After demolding, the specimens were placed in a water tank in the laboratory for curing for a further 28 days. At the end of the curing time of 28 days the specimens were removed from the water tank one day before the test and left in the laboratory to dry. Both ends of the concrete specimens were then capped using self-leveling grout (Ardex LQ 92) with a thickness of <5mm to ensure that the end surfaces of the concrete cylinders were flat in order to distribute the load uniformly. The capped specimens were air-cured until the day of heating exposure.

**Table 1. Properties of the concrete mix design per 1 cubic meter.**

Contents (kg/m <sup>3</sup> )	Quantity
Cement	158
Slag	158
Coarse sand	664
Coarse aggregate	1015
Hanson Kilmore manufactured sand	233
Water	170

**Figure 1. Identical  $\varnothing$ 65  $\times$  150mm small plain concrete cylinders**

## 2.2 Temperature Cycle and Cooling Regimes

All 16 specimens were subjected to a stress of  $0.3f_c$  at ambient temperature ( $25^\circ\text{C}$ ) during heating and cooling. Specimens were subjected to constant load by means of a 100kN capacity 8801 Instron testing machine. Specimens were heated at a rate of  $10^\circ\text{C}/\text{min}$  to a target chamber temperature for two hours after the target temperature was achieved. The specimens were then cooled to ambient by turning off the heating to the chamber and opening the door. For each of the chamber target temperatures ( $100^\circ\text{C}$ ,  $200^\circ\text{C}$ ,  $300^\circ\text{C}$ ,  $400^\circ\text{C}$ ,  $500^\circ\text{C}$  and  $600^\circ\text{C}$ ), two specimens were exposed in the environmental chamber, as shown in Figures 2 and 3. The heating inside the environmental chamber was controlled by putting one Type K thermocouple inside the environmental chamber in addition to the built-in thermocouple attached to the chamber.

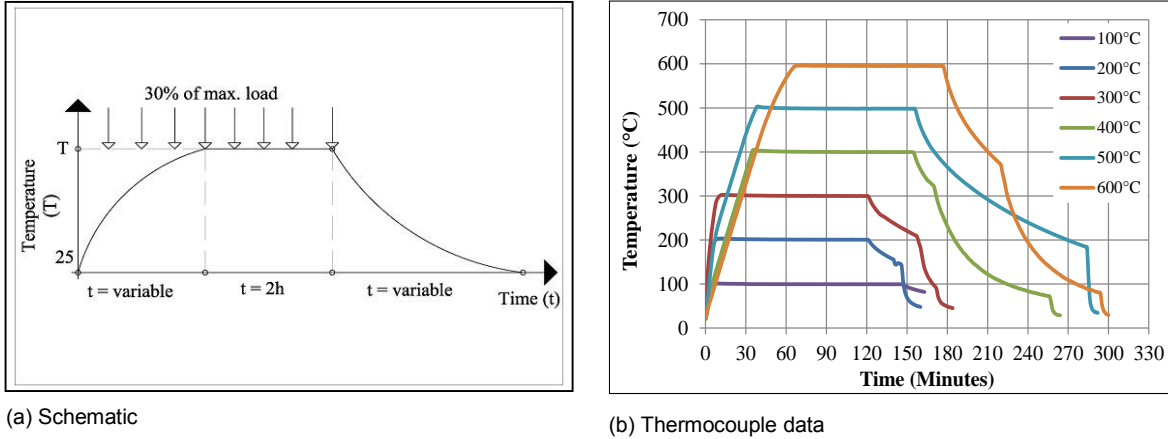

Figure 2. Heating cycles for  $\varnothing 65\text{mm} \times 150\text{mm}$  small concrete cylinders

Figure 3. Environmental chamber

## 2.3 Surface Preparation for Strain Measurement

About half of each small concrete cylinder surface area was used for strain measurement purposes using a Vic-3D digital image correlation system camera [24] on 14 specimens including 2 control samples, or a video extensometer (on only 4 specimens). For the Vic-3D system, the area of interest on each specimen was painted with a random dot pattern (speckled) for displacement calculation purposes. A layer of white paint was applied to the specimen surface followed by black speckles using a black pen. Figure 4(a) shows the process of surface preparation with the speckled pattern.

The conversion of optical images to strains is achieved as follows. Two high-resolution cameras take a picture of the pattern before loading (during image calibration stage) using the Vic-Snap software and then new images at prescribed time or load steps when the specimen is under test and subjected to external loads (Sonnenberg and Al-Mahaidi, 2007 [25]; Lee and Al-Mahaidi, 2008 [26]). With computer software (Vic-3D) the images are analyzed considering the difference between pixels of the different images and correlated to create a contour map of strains.

When using a video extensometer, the area of interest on each specimen must be painted with a layer of black paint followed by four white dots representing axial and lateral directions, as shown in Figure 4(b).

**Figure 4. Surface preparation for strain measurement**

## 2.4 Testing Technique

Residual concrete properties were determined as the mean value of the two tests per target temperature. The residual compressive strength for 14 specimens was obtained using a 1MN MTS testing machine (Figure 5) and a 100kN Instron testing machine for 4 specimens, as shown in Figure 6. A displacement rate of 0.25mm/min was used for both testing machines. The load and displacement records from the testing machines and the direct strains as determined by the Vic-3D camera or video extensometer were taken every second.

**Figure 5. 1 MN MTS machine and test set-up for Ø 65mm x 150mm small cylinders**

(b) View of sample

**Figure 6. 100 kN Instron machine and test set-up for Ø 65mm × 150mm small cylinders**

### 3. Results and Discussion

The details of the test results for the small plain concrete cylinders are summarized in Table 2. These results include those for unheated specimens and for specimens tested after exposure to heating for two hours and subsequent cooling. These specimens were loaded during heating to 30% of the ambient crushing strength.

**Table 2. Test results of small plain concrete cylinders**

Sample	Temperature °C	* Average residual compressive strength (MPa)		Strain measurement method
1	25°C	38.8		Vic-3D digital image correlation camera
2	25°C			Vic-3D digital image correlation camera
3	100°C	32.6		Vic-3D digital image correlation camera

\* The average of two 65 × 150mm small cylinders

#### 3.1 Effect of Temperature on Residual Compressive Strength

The residual strength of the small concrete cylinders is expressed as a ratio of the strength of the companion smaller concrete cylinders at ambient temperature (25°C). Figure 7(a), shows the variation of residual strength with temperature. It was observed that the cylinders exposed to temperatures ranging from 100°C - 600°C (in steps of 100°C) exhibited residual strengths of 84, 94.6, 83.3, 66, 52.1, and 42.3%

of the companion samples, respectively. It can be observed that the strength at 100°C is less than that for specimens heated to 200°C. This was also found by Li and Franssen, 2011 [27]. The reason for this is not apparent, but according to Naus, 2010 [28], it is due to cement gel layers moving closer to each other during heating. Cheng et al. 2004 [29] similarly attribute this phenomenon to general stiffening of the cement gel or the increase in surface forces between gel particles due to the removal of absorbed moisture.

Also shown in Figure 7(a), is a proposed model (Equation 1) for temperature-dependent residual compressive strength. The proposed model could be used for determining the effect of fire or other heating on the residual load capacity of concrete structures.

$$\% S = \frac{(6098 - 7T)}{10000}, \quad 25^\circ\text{C} \leq T \leq 200^\circ\text{C} \quad \& \quad \% S = \frac{(6098 - 7T)}{5000}, \quad 200^\circ\text{C} \leq T \leq 600^\circ\text{C} \quad (1)$$

### 3.2 Effect of Temperature on Residual Modulus of Elasticity

The static modulus of elasticity is defined as the slope of the concrete compressive stress-strain curve, either as a tangential slope at the origin or as the secant slope between the origin and a point on the stress-strain curve at approximately 30-40% of the peak stress. The decrease in the concrete modulus of elasticity due to elevated temperature exposure is more pronounced than the decrease in concrete compressive strength. The effect of high temperature exposure on the modulus of elasticity is shown in Figure 7(b). In general, the trend for the modulus of elasticity is that as the temperature increases, the stiffness tends to immediately decrease. However, it is clear that at lower temperatures between 100°C to 200°C, the modulus of elasticity experiences a slight increase compared to its original value at ambient temperature (25°C). From Figure 7(b), it is clear that the modulus of elasticity appears to degrade approximately linearly with temperature, particularly when  $T > 300^\circ\text{C}$ . The degradation in the elastic modulus of elasticity of concrete was 19.5%, 6%, 33.3%, 42.7, 60.5% % and 80.3% of its original value at ambient temperature (25°C) at 100°C, 200°C, 300°C, 400°C, 500°C and 600°C respectively. The reduction in the modulus of elasticity at 600°C is evidently due to micro-structural damage to the concrete with increasing temperature.

Furthermore, as Figure 7(b) indicates, a proposed model (Equation 2) for the temperature-dependent concrete residual modulus of elasticity is presented. Again, this model can be used for the evaluation of the residual modulus of elasticity of concrete structures after fire exposure or other heating.

$$\% E = \frac{(10487 - 24T)}{10000}, \quad 25^\circ\text{C} \leq T \leq 200^\circ\text{C} \quad \& \quad \% E = \frac{(6286 - 9T)}{5000}, \quad 200^\circ\text{C} \leq T \leq 600^\circ\text{C} \quad (2)$$

(b) Residual modulus of elasticity

Figure 7. Effect of heating on small cylinders

### 3.3 Stress-Strain Relationship

The residual stress-strain relationships for small plain concrete cylinders for temperatures between 25°C and 600°C are shown in Figure 8(a). It can be seen that the stress-strain relationships exhibit a linear portion, then as micro-cracking takes place, the shape of the curve becomes increasingly non-linear until it reaches the maximum stress. Beyond this point, as further cracking takes place, the curve descends until failure occurs. With the exception of the specimens exposed to 200°C, the strains corresponding to peak strengths are equal to or greater than those at ambient temperature (25°C). It is worth noting that the strains at peak strength do not necessarily increase with increasing exposure temperature. For example, the strain for the cylinders exposed to 300°C is greater than that for cylinders heated to 400°C.

Good correlation was also observed by comparing stress-strain relationships obtained using both new techniques (Vic-3D vs video extensometer), as shown in Figure 8(b).

Figure 8. Stress-strain relationships of small cylinders

### 3.4 Cracking Pattern

The observed failure patterns for tested small cylinders indicated that, prior to failure, vertical cracking started from the top of the specimens and propagated downward along the length of the specimens in the direction of loading (see Figure 9). The specimens failed by splitting as the result of excessive shear stresses. The maximum compressive load of the specimens was achieved shortly after cracks developed and propagated. The load resistance of the specimens then reduced significantly.

Figure 9. Failure mode of small cylinders

#### 4. Conclusions

This experimental study reports the results of tests on specimens that were loaded (0.3 f'c) during heating subsequent to cooling. The following conclusions can be drawn based on the results of these experiments:

1. The testing described in this paper requires careful control of both the environmental (heating) chamber and the mechanical testing apparatus over a significant time duration. This was successfully achieved.
2. Surface strains were measured using an innovative visual technique which enabled the maximum strains to be reliably determined.
3. The effect of temperatures between 100-200°C on the residual strength of the concrete cylinders is unusual, in that a lower strength was obtained at 100°C compared with 200°C. This has been attributed to the effect of moisture changes on the cement gel structure.
4. The residual strength for the concrete cylinders decreases almost linearly for temperatures of 300°C and above.
5. The decrease in the concrete modulus of elasticity, whether measured as tangent or secant stiffness, is more pronounced than the corresponding decrease in concrete residual compressive strength.
6. In general, the initial slope of the stress-strain curves decreases as the temperature increases.
7. Equations have been proposed for both residual compressive strength and residual modulus of elasticity as a function of temperature.

**Abstract:** The DuraCrete project has provided one of the guidelines for durability design and assessment of concrete structures, and is used for many large projects in Europe and other countries. In DuraCrete probabilistic method, the rapid chloride migration (RCM) test is used as bases for predicting the service life of concrete structures. The chloride migration (diffusion) coefficient is determined by RCM test at the age of 28 days, which is used to evaluate the resistance to chloride penetration of concrete. It is believed that a substantial proportion of the hydration process has taken place for Portland cement concrete with a normal w/c ratio, and over 80% of final strength is reached at 28 days. The concrete would be considered as mature. However, when Portland cement is partially replaced by fly ash, the pozzolanic reaction of fly ash in concrete is slowed down during early curing age, even at 28 days. It appears that the current service life prediction model is not reliable for fly ash concrete structures. In this paper the reference time is redefined for fly ash concrete in view of service life predictions of fly ash concrete structures. The  $D_{RCM}$  value based on the redefined reference time in practice is discussed.

**Keywords:** DuraCrete methodology, fly ash concrete, chloride migration coefficient, RCM test

## 1. Introduction

Corrosion caused by chloride ingress is assumed to be the dominant mechanism determining the service life of concrete structures in the prevailing Dutch concrete standards (1-4). Previous study shown (5) that fly ash concrete has good resistance to chloride ingress. The chloride migration coefficient ( $D_{RCM}$ ) of fly ash concrete obtained from rapid chloride migration (RCM) test continuously decreases in the period up to 3 years at moisture curing condition. The  $D_{RCM}$  value is not only used to evaluate the resistance to chloride penetration of concrete, but also used in the DuraCrete model to predict the service life of concrete structures. In the DuraCrete model, the  $D_{RCM}$  value at the reference time  $t_0$  (28 days) is normally used (6). For Portland cement concrete, it is generally accepted that when concrete is properly cured for 28 days, a substantial percentage of the cement hydration has taken place (7) and the Portland cement concrete would be considered as mature. However, when Portland cement is partially replaced by fly ash, the pozzolanic reaction of fly ash in concrete is very slow during early curing age, even at 28 days (8-9). At 28 days, the Portland cement-fly ash binary systems shows high  $D_{RCM}$  value than pure Portland cement system (5). Therefore, it is believed that fly ash concrete needs longer curing time to reach the equal maturity like Portland cement concrete at the same temperature. The predicted service life of fly ash concrete would be underestimated if 28 days is used as reference time for fly ash concretes. It is noticed that Chinese standard (10) suggests that the chloride migration coefficient determined at 84 days is used for durability design and service life prediction of concrete structure. This method has been applied in the design of Hangzhou Bay Bridge (China) and Penang Second Bridge (Malaysia).

The aim of this paper is to define a proper reference time for fly ash concrete when DuraCrete methodology is used to predict the service life of fly concrete structures. The  $D_{RCM}$  value based on the redefined reference time in practice is determined.

## 2. DuraCrete model

## 2.1 General introduction

The DuraCrete methodology was developed in 1990s in a European research project, “Probabilistic Performance Based Durability Design of Concrete Structures” (11). The aim of this methodology was to develop a durability design concept, based on realistic and sufficiently accurate environmental and material models, being capable of predicting the behavior of concrete structures (11). Defining the desired performance of the structure is the first step in the process of designing durable concrete structures (11). Figure 1 schematically shows the performance of a concrete structure when suffering from reinforcement corrosion and related damages. In this figure two main phases are defined in the development of the performance of concrete structures with time, viz. the initiation phase and the propagation phase. The initiation period is the time for an aggressive substance to reach the reinforcement and cause corrosion of the steel. During the propagation phase, deterioration develops and loss of function is observed. The propagation phase includes several kinds of damages, such as cracking, spalling and collapse, as shown in Figure 1. In the DuraCrete methodology it is assumed that the deterioration mechanism of concrete structures is caused only by chloride ingress and subsequent corrosion of steel reinforcement.

Figure 1: The performance of concrete structure with respect to reinforcement corrosion and related events (11)

## 2.2 Chloride transport model in concrete

Chloride ion transport in concrete can be driven by three mechanisms, i.e. capillary absorption, hydrostatic pressure and diffusion (12), among them diffusion is predominated. Fick's 2<sup>nd</sup> law can be used to describe diffusion-controlled chloride ion transport into concrete (13-17). When Fick's 2<sup>nd</sup> law is applied it is implicitly assumed that chloride ion penetration is primarily a diffusion process. Equation 1 was applied to calculate the chloride content at certain depth and time. In Equation 1,  $D(t)$  is the apparent diffusion coefficient, which is a time-dependent function as shown by Equation 2.

$$C(x,t) = C_s - (C_s - C_i) \operatorname{erf} \left[ \frac{x}{\sqrt{\{4k D(t)t\}}} \right] \quad (1)$$

$$D(t) = D_0 \left( \frac{t_0}{t} \right)^n \quad (2)$$

where:  $t_0$  is reference time of the concrete, normally is 28 days (18);  $D_0$  is achieved chloride migration coefficient at the reference time,  $t_0$  of the concrete (18);  $n$  is the ageing coefficient. It is theoretically range from 0 to 1 (18). It depends on the type of binder, the rate of cement hydration and environmental factors.

## 3. Materials and Methods

### 3.1 Materials

The concrete mixtures were prepared using Portland cement CEM I 42.5 N, fly ash (Low calcium), aggregate (the maximum size of 16 mm) and tap water. Table 1 shows the chemical compositions of Portland cement and fly ash. The crystalline phase of fly ash was about 41.29% determined by XRD method. The portion of mullite and quartz was 13.26% and 25.14%, respectively. The mean particle size of fly ash was about 21.46  $\mu\text{m}$  measured by Laser Method. Figure 2 presents the particle size distribution of Portland cement and fly ash. In the mixture, the replacements of cement by fly ash were 30% and 50%, respectively. Three water to binder ratios, 0.4, 0.5 and 0.6 are used. A series of samples with 50 percentages of fly ash and w/b of 0.6 were not cast because of significant bleeding.

**Table 1. Chemical compositions of fly ash and cement.**

Chemical compositions (% by mass)	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	free-CaO	Fe <sub>2</sub> O <sub>3</sub>	P <sub>2</sub> O <sub>5</sub>	K <sub>2</sub> O	MgO	SO <sub>3</sub>	Na <sub>2</sub> O
CEMI42.5N	20.36	4.96	64.4	0.6	3.17	0.18	0.64	2.09	2.57	0.14
Fly ash	48.36	31.36	7.14	-	4.44	1.90	1.64	1.35	1.18	0.718

**Figure 2: The particle size distribution of Portland cement and fly ash (by laser method).**

### 3.2 Methods

#### 3.2.1 Rapid chloride migration test

The concrete samples were cast in standard cylindrical mould with the dimension of  $\Phi 100 \times 300$  mm. After demoulding, the specimens were cured in a saturated limewater bath until preconditioning for testing in 28 days, 91 days, 180 days, 365 days, 730 days and 1095 days.

**Figure 3. The sawing plane of test specimens.**

**Figure 4. The migration set-up in laboratory.**

NT Build 492 method was used to determine the chloride migration coefficient of concrete from non-steady-state migration experiments (20). The preconditioning includes four steps, 1) cutting a  $50 \pm 2$  mm thick slice from the central portion of the cylinder as the test specimen, three specimens could be obtained from one concrete cylinder, with enough space (50mm) left at the sides to avoid any side effect; 2) placing specimen in the vacuum machine for three hours; 3) immersing saturated Ca (OH)<sub>2</sub> solution for one hour; 4) keeping the specimens in the solution for  $18 \pm 2$  hours. Figure 3 shows a sawing plane of test samples. After preconditioning, the test specimens were put in a rubber sleeve and fastened with two stainless steel clamps. The RCM set-up is shown in figure 4. The substrate surface was immersed in the anolyte solution of 0.3 M NaOH and the bottom surface was immersed in the catholyte solution of 10% NaCl. With the voltage preset at 30 V, the initial current through each specimen was recorded. The room temperature during the test was  $20 \pm 1^\circ\text{C}$  (20). Based on the initial current, a corrected voltage and appropriate test duration were chosen. After testing, each specimen were split into two pieces and 0.1M silver nitrate solution was sprayed over the freshly split section. After 15 minutes, the migration depth of chloride ion and the thickness of each specimen were recorded. The non-steady-state migration coefficient was calculated using equation 3.

$$D_{RCM} = \frac{0.0239 \cdot (273 + T) \cdot L}{(U - 2) \cdot t} \cdot \left( x_d - 0.0238 \sqrt{\frac{(273 + T) \cdot L \cdot x_d}{U - 2}} \right) \quad (3)$$

- $D_{RCM}$ : Non-steady-state migration coefficient,  $\times 10^{-12}$  m<sup>2</sup>/s;  
 U: absolute value of the applied voltage, V;  
 T: average value of the initial and final temperatures in the anolyte solution, °C;  
 L: thickness of the specimen, mm;  
 $x_d$ : average value of the penetration depths, mm;  
 t: test duration, hour.

### 3.2.2 Thermogravimetric analysis (TGA)

Thermogravimetric analysis (TGA) was performed on cement paste at atmospheric pressure in nitrogen, at heating rate 10 °C/min up to 1200 °C. The content of calcium hydration in cement paste can be calculated based on thermogravimetric curve at decomposition temperature around 460 °C.

## 4 Service Life Prediction of Fly Ash Concrete

### 4.1 Determination of reference time for fly ash concrete

In fly ash concrete, calcium hydroxide phase (CH) is consumed by the pozzolanic reaction of fly ash along with the formation of additional C-S-H gel. This has beneficial effects on the strength, permeability and the durability of concrete. Therefore, the CH content could be considered as an indicator to determine the reference time for fly ash concrete.

Figure 5. The CH content of cement paste.

Figure 6. Comparison between the  $D_{RCM}$  and the CH content.

Figure 5 shows the CH content of Portland cement paste and blended cement paste at ages from 28 days to 3 years. It can be seen that after 28 days of curing, the CH content of pure Portland cement paste change little, from 12.44% to 14.50% (see Figure 5). The CH content of blended cement paste, however, decreases greatly at ages from 28 days to 180 days. After 180 days, the CH content of blended cement paste hardly changes. It is inferred that the pozzolanic reaction of fly ash takes place dramatically after 28 days, and a relative stable structure is reached in about 180 days. The CH content with curing age can be used as an indicator to reflect the degree of the pozzolanic reaction of fly ash.

Figure 6 plots a comparison between the chloride migration coefficient,  $D_{RCM}$  of fly ash concrete (50% fly ash; w/b=0.4) and the relevant CH content of blended cement paste. As can be seen from Figure 6, the CH content and  $D_{RCM}$  show a similar trend with increasing time, decreasing significantly from 28 days to 180 days and remaining almost constant after an age of 180 days. In this study, hence, 180 days is defined as the reference time to predict the service life of fly ash concrete structures based on the DuraCrete methodology.

#### 4.2 Service life prediction

By using the redefined reference time, 180 days, the service life of fly ash concrete structures is calculated. An example of concrete mixture (50% fly ash, w/b=0.4) served under the condition of marine atmospheric (XS1) is presented. For comparison, 28 days as reference time for fly ash concrete is also presented. Based on the DuraCrete report the input parameters used in the DuraCrete methodology are summarized in Table 2. Two reference times, 28 days and 180 days are specified.

With the redefined reference time of 180 days, the calculated service life is 116 years, which is much longer than 11 years when 28 days is used as the reference time. It means that the service life of fly ash concrete structures may be underestimated if 28 days is used as reference time as Portland cement concrete.

#### 4.3 Determination of the $D_{RCM}$ value at the reference time in practice

If 180 days is used as the reference time to predict the service life of fly ash concrete structures, 180 days is required to wait for the RCM test. In practice, the  $D_{RCM}$  of concrete is typically measured at the curing ages of 28 or 90 days. If there is a way which is able to deduce the  $D_{RCM}$  value at 180 days based on the results obtained at the age of 28 or 90 days, it would promote efficiency and cost savings.

In this research, two fly ash dosages, 30% and 50% and three w/b ratios, 0.4, 0.5, and 0.6 are adopted to investigate the influence of fly ash on the resistance of concrete to chloride penetration. Figure 7 shows the  $D_{RCM}$  of each type of fly ash concrete at ages from 28 days to 180 days.

On the double logarithmic coordinate, there is a good linear relationship between the  $D_{RCM}$  values and age of the concrete, as shown in Equation 4. In Figure 7, it is clear that the slope (b) of these curves is highly related to w/b ratio.

**Table 2. Input parameters for service life predictions with the DuraCrete methodology.**

Input Items	Symbol in DuraCrete model	Value	
Reference time, <i>year</i>	$t_0$	0.0767(28 days)	0.4932(180 days)
Chloride migration coefficient, $m^2/s$	$D_{RCM}$	$15.63 \times 10^{-12}$	$2.22 \times 10^{-12}$
Chloride resistance, $year/mm^2$	$R_{cl,0}^c$	0.0020	0.0143
Ageing factor	$n_{cl}$	0.8	0.8
Curing factor	$k_{c,cl}^c$	0.79	0.79
Critical chloride concentration, % relative to binder	$c_{cr}^c$	0.2	0.2
Water to binder ratio	$w/b$	0.4	0.4
Cover depth, <i>mm</i>	$x^c$	45	45
Margin for the cover depth, <i>mm</i>	$\Delta x$	8	8
regression parameter, % relative to binder	$A_{c,s,cl}$	4.42	4.42
Environment factor	$k_{e,0}^c$	0.68	0.68
	$k_{e,c}^c$	2.9	2.9
Partial factor	$\gamma_{cr}$	1.03	1.03
	$\gamma_{c,s,cl}$	1.2	1.2
	$\gamma_{R_d}$	1.50	1.50

$$D_{RCM,T} (\times 10^{-12} m^2 / s) = b \times t + c \quad (4)$$

where: b is slope related to different type of fly ash concrete; c is a constant; t is curing age, days;

According to Equation 4 the  $D_{RCM}$  value at an age of 180 days can be directly calculated based on the  $D_{RCM}$  values measured at the curing ages of 28 days (see Equation 4). The values of b for fly ash concrete mixtures with different w/b ratios are shown in Table 3. Figure 8 shows the  $D_{RCM}$  values at different curing ages from reference (21). The value at point "x" shows the calculated result according to Equation 5 (w/b=0.53; b=-0.951).

$$\lg[D_{RCM,180days} (\times 10^{-12} m^2 / s)] = \lg[D_{RCM,28days} (\times 10^{-12} m^2 / s)] + b \times (\lg 180 - \lg 28) days \quad (5)$$

Figure 7. The  $D_{RCM}$  of fly ash concrete at ages from 28 days to 180 days.

Table 3. The value of  $b$ .

w/b ratio	$b$ (slope)
0.4	-1.055
0.5	-0.951
0.6	-0.913

Figure 8. The  $D_{RCM}$  of fly ash concrete (20) and the calculated data at an age of 180 days.

## 5 Concluding Remarks

The prediction of service life is a particularly important step during the design phase of projects. In the DuraCrete methodology, the service life is defined and predicted by taking into account reinforcement corrosion. In this paper, the input parameters are discussed for fly ash concrete structures in order to predict the service life of fly ash concrete structures more reliably. The following conclusions can be drawn:

- 1) In Portland cement-fly ash binary systems, the calcium hydroxide (CH) content is one of the indicators reflecting the rate of pozzolanic reaction of fly ash. At ages from 28 days to 180 days, the CH content of blended cement paste decreases significantly. After 180 days, the CH content hardly changes. It is inferred that the pozzolanic reaction of fly ash takes place dramatically after 28 days, and a relative stable structure is reached after 180 days. 180 days is defined as the reference time for fly ash concrete structures in the DuraCrete methodology.

- 2) By using two reference time, 28 days and 180 days, the predicted service life of fly ash concrete (50% fly ash; w/b=0.4) is 11 years and 116 years, respectively. The service life of fly ash concrete structures, in this study, is underestimated when 28 days is used as the reference time.
- 3) In order to promote efficiency and save cost in practice, the  $D_{RCM}$  value at the reference time of 180 days can be deduced based on the experimental results of RCM test performed at age of 28 days.

# EFFECT OF COMBINED FIBRES ON FIRE RESISTANCE OF LARGE SPECIMENS

Youngsun Heo<sup>1</sup> and Byungyeol Min<sup>1</sup>

<sup>1</sup>Fire Research Institute, Korea Institute of Civil Engineering and Building Technology (KICT), Republic of Korea

**Abstract:** In this study, effect of combined fibers on fire resistance of large specimens is investigated. The effect of the combined fiber technique on the level of spalling protection was experimentally confirmed by applying to large columns. Four different size of large columns were prepared for proving the effectiveness of the combined fiber technique. In addition, the authors presented the detailed procedure of the optimum fiber design for spalling protection of concrete in fire. In this design, critical parameters of fiber length, fiber diameter and the total number of fibers per unit volume were quantitatively established, so that the fiber addition can be reduced over 50% for the single type of fibers and can be further reduced for the combined type of fibers.

**Keywords:** Fire resistant concrete, Spalling, Fibers, Inter-aggregate spacing

## 1. Introduction

Normal strength concrete has been regarded as a fire-proof material because of its incombustibility and its high thermal insulating properties. However, since high strength concrete was introduced, concrete as a generic material has not existed when it comes to fire [1]. This is because the behavior of high strength concrete and normal strength concrete is at elevated temperature.

High strength concrete is at high risk of spalling when the concrete structures are exposed to fire [2-4]. The spalling is the detachment of pieces of concrete from the concrete surface, thus reducing the load-bearing cross-sectional area and capacity. It may be explosive in some cases. In extreme cases, it may result in the loss of entire cross section of a concrete member.

To mitigate the spalling problem of high strength concrete in fire, the addition of polypropylene fibers in the concrete is introduced in the open literature [5]. Since then, the effectiveness of the fibers has been proved by many researchers [6-8]. The fiber addition method has been the most widely used in concrete for the spalling protection than any other mitigating methods, due not only to the effectiveness but the simplicity and the cost effectiveness for their application to the concrete in practice.

In addition, it is expected that the use of fibers in concrete in a non-fire event has other beneficial effects on concrete such as reduction of plastic shrinkage and drying shrinkage.

In fire circumstance, the fiber addition technique can reduce the probability of spalling, or prevent it, by reducing the pore pressures that build-up during rapid heating of concrete structures in fire [9]. Polypropylene fibers initially in a form of solid phase undergo a melt phase at around 160°C. The spaces occupied by the melted fibers can provide pathways for water vapor within the concrete that can lead to pressure relief and the spalling protection of concrete.

## 2. Previous research work

In previous research, the authors have firstly proposed three critical fiber parameters providing effective pathway for water vapor in concrete in fire [10]. They are the total number of fibers per unit volume (N), the length of fibers (L) and the melting point of fibers (k). N determines the level of dispersion of fibers in concrete; L determines the level of connection of pores and k determine the commencing time of vapor evacuation. These three factors contribute an effective pore network in concrete at elevated temperature and relieve vapor pressure.

Based on the key findings from the investigations, the authors [11] have found that the addition of two types of fibers (nylon and polypropylene fibers) with selected dimensional characteristics could reduce the required fiber content up to three times less than the addition of the single type of polypropylene fibers commonly prescribed for the equal level of spalling protection of concrete in the literature. However, the findings from the previous work were drawn with small cylinders, in which a size effect may adversely affect the results.

Hence, in this current study, to further investigate the true effect of the combined fibers on the level of spalling protection, large column specimens with four different cross-sectional sizes were prepared. Finally, design of fire resistant concrete using the synthetic fibers were proposed.

### 3. Size effect of combined fiber technique

#### 3.1 Experimental outline

Table 1 shows the experimental outline. The combined fibers of 0.05% by volume and the conventional singled fibers of the same % were added in concrete. The combined fibers were nylon fibers of 0.025vol.% and polypropylene fibers of 0.025vol.%, and the singled fibers were polypropylene.

Four different sizes of columns were prepared, i.e. 300 × 300 × 1500, 500 × 500 × 1500, 700 × 700 × 1500 and 900 × 900 × 1500. The list of experimental tests conducted in fresh and hardened concretes are shown in Table 1.

**Table 1 Experimental outline**

Fiber type	Specimen size (mm)	Test conducted
Control (no fiber addition)	500 mm × 500 mm × 1500 mm	<ul style="list-style-type: none"> <li>· Compressive strength</li> <li>· Fire test (3h):               <ul style="list-style-type: none"> <li>- Spalling extent</li> <li>- Spalling area</li> <li>- Weight loss</li> </ul> </li> </ul>
Polypropylene fibers	300 mm × 300 mm × 1500 mm	
	500 mm × 500 mm × 1500 mm	
	700 mm × 700 mm × 1500 mm	
	900 mm × 900 mm × 1500 mm	
Combined fibers <sup>a</sup>	300 mm × 300 mm × 1500 mm	
	500 mm × 500 mm × 1500 mm	
	700 mm × 700 mm × 1500 mm	
	900 mm × 900 mm × 1500 mm	

<sup>a</sup> Polypropylene fibers of 0.025vol.% + Nylon fibers of 0.025vol.%

#### 3.2 Specimen preparation

The mixture proportion of the control concrete without fiber addition is shown in Table 2. Water to binder ratio of 0.25 was determined to cast high strength concrete. The binders included Fly ash of 20 % and silica fume of 10% by cement weight. A forced fan type mixer was used, and combined fibers were added for a dry mix of first 30 sec with cement, binders and aggregates, followed by mixing with water for 60 sec.

All specimens were demoulded after seven days and then placed in an atmospheric condition: temperature was 8°C - 20°C; humidity was 32% ~ 43% and wind speed was 1.4 m/s ~ 2.1 m/s. Fire tests were conducted at 91 days after casting the specimens.

**Table 2 Mixture proportion of control concrete**

W/B <sup>a</sup>	Unit water, kg/m <sup>3</sup>	S/a <sup>b</sup> , %	Weight mixture, kg/m <sup>3</sup>				
			C <sup>c</sup>	FA <sup>d</sup>	SF <sup>e</sup>	S <sup>f</sup>	G <sup>g</sup>
0.25	160	45	448	128	64	660	837

<sup>a</sup> Water to binder ratio

<sup>b</sup> Sand to coarse aggregate ratio

<sup>c</sup> Cement

<sup>d</sup> Fly ash

<sup>e</sup> Silica fume

<sup>f</sup> Sand

<sup>g</sup> Gravel

### 3.3 Materials

The Ordinary Portland cement (Density: 3150 kg/m<sup>3</sup> and fineness: 330 m<sup>2</sup>/kg) was used in this study. Fly ash (Density: 2210 kg/m<sup>3</sup>, fineness: 406 m<sup>2</sup>/kg and loss on ignition: 3.5%) and silica fume (Density: 2200 kg/m<sup>3</sup>, fineness: 20000 m<sup>2</sup>/kg and loss on ignition: 1.5%) were incorporated as mineral admixtures.

For aggregates (granite type), the combination of river sand and crushed rock (4:6) was mixed to obtain a 2.6 fineness modulus of fine aggregate. Density and absorption of the both fine aggregates were 2600 kg/m<sup>3</sup> and 0.46%. All coarse aggregates used in this study were a crushed aggregate type. Density and absorption of the coarse aggregates were 2610 kg/m<sup>3</sup> and 0.58%.

The physical properties of nylon and polypropylene fibers are shown in Table 3.

**Table 3 Physical properties of synthetic fibers**

Type of fiber	Diameter, mm	Length, mm	Density, kg/m <sup>3</sup>	Melting point, °C	Tensile strength, MPa
Polypropylene	0.040	19	910	160	560
Nylon	0.012	9	1150	220	918

### 3.4 Test methods

ASTM C 39 was conducted for compressive strength test of hardened concretes. Cylinders of size Ø100 × 200 mm were prepared and tested in triplicate for each type for this strength test. Fire tests were carried out for three hours according to the standard heating curve of ISO-834. After the test completed, the extent of spalling was visually observed, and weight loss due to spalling was examined by comparing the values before and after the test. The spalling area was calculated by using the automatic area measurement software after tracing and blacking out the contours of detached parts of heated concrete specimens on a transparent sheet.

### 3.5 Experimental test results

In this Section, experimental test results are presented. The compressive strength and spalling extent (i.e. spalling area, weight loss after fire exposure) of the concretes with single fibers and combined fibers are examined. Key findings obtained from the tests are discussed below.

### 3.5.1 Compressive strength of the concrete

Fig. 1 shows the compressive strength of the control concrete, single fiber-added concrete and combined fiber-added concrete to be placed in column specimens. Strengths of all concretes were properly developed and indicated around 100 MPa at the due date of fire tests, curing age of 91 days.

**Figure 1 Compressive strength of concrete**

### 3.5.2 Extent of spalling

Fig. 2 shows the calculated % of spalling area of concrete column specimens. It was clear that the control column without fiber inclusion had severe damage due to spalling. The spalling area of the control column was 92.4%. Fiber addition in concrete improved the spalling resistance, but a fiber type significantly affected the results.

For the specimens with a cross sectional size of 500 mm that were exactly the same size with control, the spalling area of the column with singled polypropylene fibers was 12.0%, whereas that with combined fibers was only 1.5%. The good result of the column with the combined fibers was equally observed in other larger specimens tested in this study, which provides evidence that the combined fiber technique is effective in large specimens. It is noted that the larger the size of specimens, the higher was the results of spalling area.

**Figure 2 Spalling area of concrete after fire exposure**

Fig. 4 shows the weight loss of the column specimens after fire exposure. As expected, control concrete without fiber addition lost over 40% of its original weight before fire exposure. However, the combined fiber technique was much more effective on minimizing the weight loss of the concrete in fire, compared to the addition of single type of polypropylene fibers.

**Figure 3 Weight loss of concrete after fire exposure**

#### 4. Design of fire resistant concrete using combined fibers

In the literature, it was observed that the addition of polypropylene fiber of 1.8 kg/m<sup>3</sup> and 3.0 kg/m<sup>3</sup> had a similar effect on pressure relief in heated concrete exposed to fire [6]. In other words, this means that as soon as fibers constitute a connected network, the latter is large enough to evacuate gases and vapor, thus to reduce pore pressure, in which the level of reduced pore pressure is similar to former dosage.

Hence, it is very important that the amount of fiber inclusion should be just to resist the spalling of concrete to avoid any side effects that might occur when the fiber content unnecessarily increases. In fact, it should be noted that the capability of evacuating the vapor from the concrete in fire is dependent on the level of connected pores. Since the main role of fibers is to provide the connection between un-connected pores, the length of fibers and the total number of fibers are the essential parameters for spalling protection as characterized in previous work, by which the fiber content can be minimized.

By taking these essential parameters of fibers into the design of fire resistant concrete, the optimum level of fire resistant concrete can be achieved. The detailed procedure is presented as follows.

##### 4.1 Inter-aggregate spacing

It is important to note that for a given fiber content, the essential parameters, fiber length and total fiber number, are in inverse proportion to each other [12]. The relationship is given by

$$N = \frac{4V_f}{\pi d_f^2 L_f} \tag{1}$$

where  $N$  is the total number of fibers per unit volume,  $V_f$  is the volume of fiber content,  $d_f$  is the diameter of fibers, and  $L_f$  is the length of fibers. For a given fiber content, increasing  $N$  by decreasing  $d_f$  or  $L_f$  (Eq. 1) is beneficial to obtain a well distributed pore network in concrete at elevated temperature, but unlike limited effect of  $d_f$  on spalling protection,  $L_f$  has an effect to intersect un-connected pores in concrete, so that  $L_f$

should be long enough to provide effective pathways for water vapor, which in turn should decrease  $N$  accordingly for a given fiber content.

Percolation of concrete is one of the critical factors that can determine the level of spalling. According to a percolation theory, ITZ regions are normally percolated in normal strength concrete, but not definitely in high strength concrete. To achieve the high strength concrete to be percolated, it is believed that neighboring ITZs which is not connected due to the use of high strength concrete should be re-connected by the addition of fibers with a proper length. For a given fiber content, the addition of fibers shorter than the required length will result in the lack of interconnectivity between the ITZs and the fibers, and that of fibers longer than the required length will result in a decrease of  $N$ . In both cases, the concretes would not be percolated in the optimum level. Hence, to optimize the effectiveness of fiber addition, it is the first step to determine the least length of fibers required for percolating concrete.

Since ITZ thickness in high strength concrete is very small, the distance between neighboring ITZs is referred to as inter-aggregate spacing, which is a function of the size, grading and volume of aggregates as well as other mixture proportions of concrete. It should be noted that the inter-aggregate spacing of fine aggregate is not an important parameter for spalling protection. It is the inter-aggregate spacing of coarse aggregate,  $i$ , that is important, so that the least length of fibers should be longer than  $i$  for effective spalling protection.

Briefly, in previous study, a  $C_{shell}$  model [12] has been developed based on the assumption that all coarse aggregates are spherical, and they are uniformly distributed and covered by uniform thickness of mortar shells. Based on these assumptions, it can be said that  $i$  is twice the mortar shell thickness. The procedure for calculating  $i$  (equal to the least fiber length for percolated concrete) is summarized in Table 4.

**Table 4 Procedure for the calculation  $i$ , calculated for 1 m<sup>3</sup> concrete**

Parameter description	Equation
Void volume between the dry rodded aggregate occupied by the total amounts of the coarse aggregates used, $\eta$	$\eta = \gamma - \frac{\omega}{\rho_s}$ (2)
Specific surface area of spheres uniformly distributed in the size between the mesh size (mm), $d_x$ and $d_y$ of adjacent sieves, $S$	$S = \frac{6}{(1-\eta)\rho_s\sqrt{d_x d_y}}$ (3)
Specific surface area of actual used coarse aggregate having fractions of the total mass retained on different sieves, $S_{tm}$	$S_{tm} = \sum_{x=1}^n S_x x_x$ (4)
Excess volume of mortar after filling ' $\eta$ ', $\varepsilon$	$\varepsilon = V_{conc} - (\gamma + a)$ (5)
Mortar shell thickness covering each coarse aggregates by ' $\varepsilon$ ', $T_m$	$T_m = \frac{\varepsilon}{S_{tm}\omega}$ (6)
Inter-aggregate spacing of coarse aggregates, $i$	$i = 2T_m$ (7)

$\gamma$  is the total volume of dry rodded aggregate occupied by the amounts of the coarse aggregates used

$a$  is the volume of air content measured

$\omega$  is the weight of coarse aggregate

$\rho_s$  is the density of coarse aggregate

$S_1 S_2 \dots$  and  $S_n$  is the specific surfaces of uniform spheres distributed in the different sieves [Eq. 3], and  $x_1 x_2 \dots$  and

$x_n$  is the fractions of the total mass of the actual used aggregate retained on the corresponding sieves

$V_{conc}$  is the volume of concrete used, which is equal to 1 m<sup>3</sup>

#### 4.2 Total number of fibers per unit volume

For the next stage, it is important to estimate the least  $N$  required for spalling protection. With the pre-calculated  $i$ , the estimated  $N$  has an effect on the determination of the optimum fiber length. This is because, for a given fiber content, dramatically increased  $N$  can overtake the effect of fiber length, thus decreasing the optimum fiber length.

Prior to determine the least  $N$ , the effect of the influential factors into the design of the fire resistant concrete at the material level should be carefully considered. A way of measuring fiber content as  $N$  is due to the fact that essential parameters of fibers for spalling protection is  $N$  and  $L_f$ , and  $N$  is independent of  $d_f$ .

### 4.3 The optimum length of fibers

The optimum fiber length can be calculated based on the calculated  $i$  and pre-determined  $N$ . To finalize the optimum fiber length, another contributing factor, an aggregate size in concrete, should be introduced. Because the aggregate size in concrete affects an external tangent length of adjacent aggregates, which directly affect the required length of fibers for the interconnectivity of adjacent aggregates. An average aggregate size parameter,  $d$ , can be used to represent the aggregate sizes in the concrete. This is given by

$$d = \frac{6}{S_{tm}\rho_s} \quad (8)$$

It is important to note that there is a threshold of the critical number of fibers per unit volume,  $N_c$ , that can determine a dominant fiber parameter ( $L_f$  or  $N$ ) for spalling protection. This is because  $L_f$  and  $N$  have an effect to compensate each other in terms of the pressure relief of vapor in concrete in fire. By taking this into account, the equation for the optimum length of fibers for spalling protection is given by

$$\zeta = (i + d)\left(\frac{N_c}{N}\right)^{\frac{1}{3}} \quad (9)$$

where  $\zeta$  is the optimum length of fibers,  $N_c$  is a constant, empirically determined to be 250, which is believed to be the critical boundary of a dominant factor for fiber effectiveness parameters ( $L_f$  and  $N$ ), which can be said that if  $N$  is started to be higher than  $N_c$ , the dominant factor of the fiber parameters for spalling protection is likely to be  $N$ , so that the optimum fiber length decreases to achieve increased  $N$ ; and if  $N$  is lower than  $N_c$ , the dominant factor is likely to be  $L_f$ , so that the optimum fiber length increases.

### 4.4 New measurement for fiber content

At this stage, the quantity of calculated  $N$  and  $\zeta$  is finally examined to see whether these values are sufficient for spalling protection. In the literature, the addition of polypropylene fibers has been used for spalling protection of concrete for over a decade, and its excellent performance has been verified by many researchers. For the concretes having up to 100 MPa of compressive strength, it has generally been observed that the addition of polypropylene fibers with 0.1% to 0.3% is necessary for the spalling protection of the concretes. However, it has been demonstrated that these amounts of fibers being used in the past can be reduced to over 50% [8].

As discussed in Section 2, there is a method to quantify the required fiber content for spalling protection with dimensional characteristics of synthetic fibers. The new measure for fiber content to determine the critical threshold for fiber addition for spalling protection has been established. This is given by

$$N \zeta^3 k \geq 190 \quad (10)$$

where  $k$  is a factor introducing the effect of fiber melting point which is empirically determined as  $160/t_m$ , where  $t_m$  is the melting point of fibers in degrees Celsius. It can be said if  $N\zeta^3k$  is greater than 190 where the fiber addition is optimized, there is no or minor spalling occurred in concrete in fire.

#### **4.5 Combined fibers**

As discussed in Section 3, there is a synergistic effect of combined fibers showing outstanding performance of spalling protection. By combining nylon and polypropylene fibers, concrete spalling has started to be resisted (no or minor spalling) when  $N\zeta^3k$  is more than 52, which is over 3 times less than the critical threshold, 190, mentioned above.

This is because although polypropylene fibers have low melting point, this fiber can only provide limited number of fibers per unit volume due to their large diameter. Combining other types of fibers which are small in diameter such as nylon fibers can improve the deficiency of polypropylene fibers by providing larger number of fibers per unit volume [11]. In addition, since nylon fibers have higher melting point, the concrete containing both fibers can timely provide pathways for water vapor throughout fire exposure ( in early and latter stages), which also improve the effectiveness of combined fibers as compared with the addition of a single type of fiber.

### **5. Conclusions**

This study has investigated the effect of the combined fiber technique on the level of spalling protection by applying to large column specimens and proposed the design of fire resistant concrete using synthetic fibers. The conclusions are drawn as follows.

- 1) It is proved that the proposed combined fiber technique with significantly reduced fiber content is applicable to large concrete columns.
- 2) The size of a column has an effect on the level of spalling. The larger the size of specimen, the lower is the effectiveness of the combined fiber technique
- 3) To design the fire resistant concrete by using synthetic fibers, the melting point of fibers, the length of fibers and the total number of fibers per unit volume are the important parameters. In addition, it was found that the optimum length of fibers is mainly determined by the inter-aggregate spacing and the critical fiber number per unit volume parameters.

**Abstract:** This paper presents the mechanical properties of fibre reinforced high-volume fly ash (HVFA) concretes measured at 7 and 28 days. The effects of three class F fly ash contents of 40%, 50%, and 60% by wt. as a partial replacement of cement and two types of fibres (steel and polypropylene) with three different volume fractions of 0.15%, 0.25%, and 0.50%, on the compressive, tensile and flexural strengths of HVFA concretes are studied. Test results show that the addition of fibres (steel and polypropylene) reduces the workability of HVFA concretes and the workability decreases with increase in volume fractions of fibres and increases with increase in fly ash contents. The compressive, tensile and flexural strengths of all HVFA concretes increased due to addition of steel and polypropylene fibres and the above values also increased with increase in fibre volume fractions. Among all fibre reinforced HVFA concretes, the concrete containing 40% fly ash exhibited the highest mechanical properties at both ages. The steel fibre volume fraction of 0.5% exhibited the highest compressive, tensile and flexural strengths of HVFA concretes containing 40% fly ash and the improvement was by 73%, 40% and 36%, respectively. However, in the case of polypropylene fibre the above improvements were only 44%, 29% and 20%, respectively. This can be attributed to the lower elastic modulus and tensile strength of polypropylene fibres than steel fibre. Correlations among compressive, tensile and flexural strengths of the above concretes are also established.

**Keywords:** concrete, compressive, tensile, flexural strength, high volume fly ash, fibre.

## 1. Introduction

Concrete is the most widely used construction material in the world. In line with the concept of sustainable development, concrete technology now-a-days demands the production of high-performance materials by incorporating industrial waste as supplementary cementitious materials (SCM), both with regard to environmental pollution and curbing the rise in construction costs. The most available SCM world-wide is class F fly ash (FA), a by-product of coal fired thermal power stations [1]. Several studies involving concrete containing fly ash had reported excellent mechanical and durability properties [2-4]. The incorporation of fly ash as a partial replacement of cement in concrete is a common practice for many years. Replacement of 30% or more ordinary Portland cement (OPC) by FA is termed as high-volume fly ash (HVFA) concrete [5-6]. The HVFA concrete is one example of a construction material in harmony with the concept of sustainable development: having lower environmental impact (reduced CO<sub>2</sub> emissions), judicious use of resources (energy conservation, use of by-products), and being a high performance construction material [1].

Discrete short fibres are often added in concrete to compensate its low tensile strength and brittle failure behaviour. Addition of fibres also improves the mechanical properties of concrete such as flexural strength, compressive strength, creep behaviour, impact resistance, toughness, etc. [7-8]. Conventional fibre reinforced concrete (FRC) contains mostly OPC with little or no fly ash, which is not in line with sustainable development of concrete and its application in construction industries. Therefore, the replacement of OPC with high volume fly ash in conventional FRC will make it sustainable with reduced carbon footprint. However, limited research is reported on the properties of fibre reinforced concrete containing HVFA as partial replacement of cement. Different types of fibres with different fly ash contents are used in those studies. Topcu and Canbaz [9] studied the mechanical properties of FRC containing different contents of fly ash ranging from 10% to 20% reinforced by steel and polypropylene fibres. In another study, Atis and Karahan [10] studied the properties of steel FRC containing 15% and 30% fly ash as partial replacement of cement. In both studies the length of steel fibre was 35mm. In a number of studies on fibre reinforced HVFA concretes the fibres were polymeric e.g. polypropylene [11] and polyester [12] and natural fibre [5]. Sahamran and Yaman [13] reported steel fibre reinforced HVFA concrete containing coarse fly ash and lime stone powder. The length of steel fibre was limited to 30mm in that study. Kayali [14] reported a study on fibre reinforced HVFA concrete containing 50% fly ash as partial replacement of natural fines and cement in the concretes. Steel and polypropylene fibres of 18 and 19mm, respectively long were used to reinforce the concretes.

While the above studies on fibre reinforced HVFA concretes reported better mechanical properties due to reinforcement by different fibres, however, most of them are polymeric and natural fibres which are of low tensile strength. The length of those fibres is also limited to 20mm. Moreover, the studies considered steel fibres are also limited to the length of 35mm only. Recently, longer steel fibres of about 60mm are available in the market and are used to reinforce concrete for industrial floor application, rigid pavement, etc. Approximately similar length PP fibres are also available and widely used in concrete for shotcrete applications. However, those fibres are still used to reinforce the ordinary concrete, which is mostly based on cement based binders. The partial replacement of cement with high fly ash content in those concretes will make them sustainable competitive to counterpart ordinary fibre reinforced concrete. It is also anticipated that the replacement of OPC by HVFA affects the mechanical properties and behaviour of above concretes. However, the full potential of fibre reinforced HVFA concretes is still unexploited. This paper presents a thorough study to evaluate various mechanical properties namely compressive strength, tensile strength and flexural strength of steel and polypropylene (PP) fibres reinforced HVFA concretes containing three different fly ash contents of 40%, 50% and 60% as partial replacement of cement. Three different volume fractions of steel and PP fibres of 0.15%, 0.3% and 0.5% are also considered in this study. The effects of types and volume fractions of fibres and fly ash contents on the fresh properties e.g. workability of above concretes are also evaluated. Finally, correlations among above mechanical properties are also established.

## **2. Experimental program**

### **2.1 Materials**

The ordinary Portland cement (OPC) used in this study corresponds to ASTM type I. The commercially available class F fly ash (FA) of Australian origin was used in the mixes. The chemical composition and physical properties of FA and OPC are listed in Table 1. To reduce the difficulties of mixing and to prevent the segregation of aggregates in the production of HVFA fibre reinforced concrete, the maximum aggregate size was limited to 10 mm. Fine aggregate used in this study was natural sand and crushed coarse aggregates with two different size fractions of 10 mm and 7 mm with a ratio of 2:1 by mass. Both fine and coarse aggregates were prepared in SSD condition and used in all the mixes.

Two types of commercially available fibres such as, polypropylene (PP) and steel (ST) fibre were used in this study. The PP fibres used in this study were waved form for better bond with matrix, with an aspect ratio of 75 and length of 65 mm. This type of fibre is widely used in shotcrete applications. The steel fibres used in this study were hooked-end for enhanced pull-out resistance, having an aspect ratio of 65 and length of 60 mm. Detail properties of both fibres are shown in Table 2.

Fibres generally improved the tensile properties and brittle failure of concrete. However, excessive amount of fibres adversely affects the strength if not properly dispersed in concrete due to the introduction of additional defects during processing [14]. Excessive use of fibre volume fraction (0.5 %-1.0 %) increases the air content and voids in the fibre reinforced concrete [15]. High volume fractions of fibres adversely affect their uniform dispersion in concrete and form fibre balling. Hence, the maximum amount of fibres in this study is limited to 0.50 % by volume of concrete. For each of the two types of fibres, three different fibre volume fractions of 0.15%, 0.25% and 0.50% are considered. Total cementitious materials content e.g. cement and fly ash was kept to a certain minimum level of 400 kg/m<sup>3</sup> as recommended by Malhotra et al. [11] for proper dispersion of fibres in FRC. The concrete mix proportions in this study were based on the authors' previous study [16] while for all mixes the water/binder ratio was kept constant at 0.4.

### **2.2 Preparation, casting and testing of specimens**

In a typical mixing procedure, the materials were placed in a pan mixer in the following sequence: initially, sand and gravel were dry mixed for about 1-2 min. Then cement and fly ash were added to the mixture and mixed for 3-4 min. Water was then gradually added to the mix and mixed for 3-5 minutes. Finally, the fibres were gradually added to the wet concrete and mixed for additional 3-4 minutes. The prepared specimens were kept at 25 ±3°C for about 24 h and then they were demoulded and stored in water curing tanks until the day of testing.

The experimental works were divided into two parts. The first part investigated the effect of different steel fibres contents on mechanical properties (compressive strength, tensile strength and flexural strength) of HVFA concretes containing 40%, 50%, and 60% class F fly ash by weight as partial

replacement of cement. The second part is same to the first part in every aspect except the type of fibre where PP fibre is used. Detail mix proportions of all concretes are shown in Table 3.

### 2.3 Test methods

Three cylinder specimens of 100Ø x 200 mm for each mix were cast and tested in accordance with ASTM C39/39M [17] standard for the compression test. Compression tests were conducted after 7 and 28 days of curing using a MCC8 compression testing machine with a loading rate of 0.333 MPa/sec. Three cylinder specimens of 150 Ø x 300 mm were prepared for each mix in accordance with ASTM C496/C496M [18] for splitting tensile strength test. Tensile tests were conducted after 7 and 28 days of curing using the same machine with a loading rate of 0.067 MPa/sec.

In order to evaluate the flexural behaviour of the concretes, the ASTM C1609/C1609M [19] standard was followed. The four-point bending test was conducted on 100 x 100 x 400 mm beams with a span length of 300 mm. Three specimens were considered for each mix. The specimens were tested in four-point bending using an Instron testing machine under displacement control with loading rate of 2 mm/min. The flexural strength of the fibre reinforced concretes was calculated from the ultimate load of the flexural load-deflection curve using the following formula [19].

$$f = \frac{PL}{bd^2}$$

Where:

$f$  = Flexural strength or modulus of rupture

$P$  = ultimate load

$L$  = span length

$b$  = width of the specimen

$d$  = depth of the specimen.

## 3. Experimental results and discussion

### 3.1 Workability

The effects of addition of steel and PP fibres of different volume fractions on workability of HVFA concretes are shown in Figs. 1(a) and (b), respectively. It can be seen that the workability of HVFA concretes increases with increase in fly ash contents. This can be attributed to the spherical shape of the fly ash particles and its lubricating effect in wet concrete. The same effect is also seen when either steel or PP fibres are added in those concretes. However, with increase in fibre volume fractions, this effect gradually diminished and resulted in reduction in workability. The results are in agreement with Siddique [20] who also reported reduction in workability of San fibres reinforced HVFA concretes.

Figure 1. Workability of steel (a) and PP (b) fibre reinforced HVFA concretes.

### 3.2 Compressive Strength

The effects of fibre types and their volume fractions on 7 and 28 days compressive strength of HVFA concretes can be seen in Figs.2a and 2b, respectively. The effects of replacement of cement by 40%, 50% and 60% fly ash on 7 and 28 days compressive strength of steel and PP fibre reinforced

concretes are also shown in the same figures, where the compressive strengths of above fibre reinforced concretes decreased with increase in fly ash contents. It can also be seen in Fig.2 that the inclusion of steel and PP fibres improved the 7 and 28 days compressive strength of HVFA concretes. At 7 days, the improvement of compressive strengths of both steel and PP fibre reinforced HVFA concrete is not very significant as compared to unreinforced HVFA concretes. This can be attributed to the slow pozzolanic reaction of fly ash in concrete at early age. However, at 28 days, the same concretes exhibited increase in compressive strength with increase in volume fraction of fibres and the improvement is better in steel fibre reinforced concrete than that of PP fibre reinforced HVFA concrete. The higher compressive strength of HVFA concretes provided by steel fibres than PP fibres is due to better anchorage provided by hooked ends of steel fibre and its higher modulus and tensile strength compared to PP fibre. Although the PP fibres are wave type deformed shape, which supposed to provide better bond with matrix, however the relatively lower modulus and tensile strength make them more susceptible to rupture at ultimate load, resulting in lower compressive strength. Failure behaviour at ultimate load of steel fibre reinforced HVFA concretes is also less brittle than that of counterpart PP fibre reinforced HVFA concretes due to the above reasons. The observed compressive strength results of the above concretes are in good agreement with other published results e.g. in Topcu and Canbaz [9] and Kayali [14], where researchers also observed increase in compressive strength with increase in fibre contents.

(a) Steel fibre

(b) PP fibre

Figure 2. Compressive strengths of steel (a) and PP (b) fibre reinforced HVFA concretes.

### 3.3 Tensile and flexural strengths

The indirect tensile strengths of HVFA concretes containing steel and PP fibres are shown in Figs. 3a and b, respectively. The test results show that the tensile strength of above fibre reinforced concretes decreases with increase in fly ash contents, which is consistent with that observed in compression tests. Results also show that the increase of fibre volume fractions of both fibres increases the tensile strength of the concretes and most significant improvement is observed in the case of steel fibre reinforced HVFA concretes. As expected the tensile strengths of PP fibre reinforced concretes are lower than those of steel fibre reinforced concretes due to lower modulus and tensile strength of the PP fibre than the steel fibre. The fibre end configuration of steel fibres might have also contributed to the better tensile strength of the concretes.

The flexural strengths of HVFA concretes containing steel and PP fibres are shown in Figs. 4a and b, respectively. Similar to tensile strength, the flexural strength of steel fibre reinforced concretes decreases with increase in fly ash contents irrespective of fibre volume fractions. However, in the case of PP fibre system, the concretes containing 50% fly ash deviated from this trend by showing slight increase in flexural strength. In general, the flexural strength of steel fibre reinforced HVFA concretes is higher than that of PP fibre system due to higher modulus and strength of steel fibres as well as hooks at both ends which facilitated the improved bond and better bridging of cracks during failure than that of PP fibre.

(a) Steel fibre

(b) PP fibre

(a) Steel fibre

(b) PP fibre

**Figure 4. Flexural strengths of steel (a) and PP (b) fibre reinforced HVFA concretes measured at 28 days.**

### **3.4 Correlation of compressive strength with tensile and flexural strengths**

Based on the strength properties of steel and PP fibre reinforced HVFA concretes evaluated in this study, correlation between tensile and compressive strengths and between flexural and compressive strengths are also established and are shown in Figs. 5-6. Good correlation can be seen between tensile strength and square root of compressive strength at both curing ages in both steel and PP fibre reinforced HVFA concretes. The correlation coefficient of 0.54 can be reasonably used to predict the indirect tensile strength of both steel and PP fibre reinforced HVFA concretes. In the case of flexural strength, the correlation coefficient is 1.48. It should be noted that the above correlation coefficients are based on particular types of fibre e.g. steel and PP only. Moreover, they are valid for steel and PP fibres of certain properties shown in Table 2. In order to obtain a general correlation coefficient, extensive experimental program need to be conducted by having various aspect ratios,

volume fractions, elastic modulus, tensile strengths of fibres, different fly ash contents, etc. Nevertheless, the correlation coefficient of 0.54 for indirect tensile strength of steel and PP fibre reinforced HVFA concretes is reasonable if we compare it with unreinforced concrete e.g. 0.4 in AS 3600 [21] and between 0.42 and 0.56 in ACI 318 [22]. With regard to that for flexural strength, the correlation coefficient is higher than those used for ordinary concrete e.g. between 0.56 and 0.84 in ACI code and 0.6 in Australian code (AS3600). However, it should be noted that the ratio of flexural strength to tensile strength of fibre reinforced cementitious composites can be as high as 3 according to Maalej and Li [23]. The observed ratio of correlation coefficient for flexural and tensile strengths in this study agrees well with Maalej and Li's value.

Figure 5. Correlation between tensile and flexural strengths and compressive strengths of steel fibre reinforced HVFA concretes.

Figure 6. Correlation between tensile and flexural strengths and compressive strengths of PP fibre reinforced HVFA concretes.

## 4. Conclusion

This paper presented the compressive, tensile and flexural strengths of steel and PP fibre reinforced HVFA concretes containing three different fly ash contents of 40%, 50% and 60% by wt. and three different fibre volume fractions of 0.15%, 0.25%, and 0.50%. Based on these mechanical properties at 7 and 28 days the following conclusions can be made:

- The workability of fibre reinforced HVFA concretes decreases with increase in fibre volume fractions irrespective of fly ash contents. The workability of above concretes increases with increase in fly ash contents. It is also observed that the addition of fly ash helps to disperse the fibres in the mix due to its lubricating effect.
- The compressive, tensile and flexural strengths of above concretes increase with increase in volume fraction of fibres irrespective of their types at 28 days. However, at 7 days those increases are marginal presumably due to slow pozzolanic reaction of high contents of fly ash in those concretes. The above strength properties also adversely affected due to increase in fly ash contents.
- Correlations between tensile and compressive strength and between flexural and compressive strength are established in fibre reinforced HVFA concretes. The observed correlation coefficients for tensile and flexural strength of steel and PP fibres reinforced HVFA concretes are also found to be reasonable when compared to ordinary concretes.

## 5. Acknowledgement

Authors gratefully acknowledge BOSFA, Australia for providing the steel and PP fibres and Fly ash Australia for supplying the class F fly ash in this research.

# Admixtures and Polymers

## Improving the rheology of high strength, very low W/C ratio concrete.

Gary Boon<sup>1</sup> and Tony Thomas<sup>2</sup>

<sup>1</sup>Technology Manager, Sika Australia Pty Ltd

<sup>2</sup>Chief Engineer-Concrete, Boral Concrete.

**Abstract:** The production of high strength concrete provides challenges with respect to the movement and placement of the concrete. High binder contents coupled with low water contents can give rise to concrete that is difficult to pump producing a concrete that can be classed as "sticky". The shear thickening tendency of "sticky" concrete can be measured and overcome by changing the concrete mix design. It is also important to measure and understand the thixotropy to avoid segregation.

The particle interaction and spacing has a large impact on the concrete rheology. This paper looks to evaluate the effect of the binder composition on the concrete rheology. We will show the effect of water content, binder content and composition, and the use of admixtures on the yield stress, viscosity and stress strain curve over a wide range of shear rates. The objective of this paper is to show how the binder and admixtures can be optimised to produce a more useable concrete that is easy to pump that still has the required hardened characteristics.

This paper provides experimental evidence of the role of binder composition and admixtures has on the rheology and therefore the useability of high strength concrete mixes.

**Keywords:** concrete, rheology, high strength, binder

### 1. Introduction

The rheology of concrete has been studied for many decades. There are many terms for describing the rheology of concrete, slump, workability, pumpability, flowability, compactability etc. Many of the test measurements for concrete rely on single point tests, such tests include L-box, V-funnel, slump cone, slump-flow. While fast and readily available, the single data points only provide the technician with limited information. Approximately 60 tests are available to measure various flow properties of concrete with most of these tests giving only a single parameter.<sup>1</sup> A rough way to calculate the workability of the concrete is the slump test and it can be used to prescribe the required workability for pumping, e.g. the concrete should have a slump of between 140-160mm for a pumping height of 30-60m.<sup>2</sup> A more comprehensive way to assess the concrete is to use a rheometer over a wide shear range.

When we change the mix design, the rheology of the concrete will change<sup>3</sup>. When we change the proportioning of the aggregate content, paste volume, we also change the concrete rheology<sup>4</sup>

Changing the powder content in the paste can dramatically affect the concrete rheology<sup>5</sup>.

The introduction of polycarboxylate-ether based admixtures has allowed for the increased use of high strength concrete with high fluidity. Based on the degree of fluidity achieved the concrete technology boundaries have been pushed further allowing for high strength concrete to be pumped vast distances over long working times. Therefore the study of concrete rheology has increased importance as it is how the concrete behaves under varying shear rates that will determine how it can be used in the field.

This paper explores changes in the mix design of high strength concrete using materials readily available in Australia.

How we measure the viscosity of concrete is important due to the torque required to shear the material. If the viscosity measurements are not taken at a steady state then the apparent viscosity at higher shear rates may be overestimated.<sup>6</sup>

### 2. Methodology

A concrete rheometer was utilised for the concrete rheology measurements. The rheometer was built in the Material Physics department of Sika Technology AG, Zurich. The rheometer setup is such that concrete is placed into a steel cylinder with an anti-slip cage and measurements done by rotating a double helical spindle<sup>7</sup>. The resultant shear stress was

measured vs. the applied shear rate. The shear rate was stepped downwards in a logarithmic spacing with the upper limit set to the torque limit of the device down to  $0.01\text{s}^{-1}$ , as in Figure 1.

Figure 1. shear profile used in the test

Concrete mixes were prepared with differing mix designs and the same target flow. The flow and T500 (time to reach 500mm diameter) was measured using a standard Abram cone in the upright position, the concrete was then measured in the concrete rheometer using a standard measurement protocol. The concrete was mixed briefly in the rheometer (details of profile) and then the concrete sheared up to the maximum torque the RheoMix could withstand and then sheared back down to  $0.01\text{ s}^{-1}$  in logarithmic steps. The resulting rheogram was then analysed and compared.

The mix design programme is below in Table 1.

Table 1: Mix design programme

The methodology was to change the proportions of the cement paste by changing the content of cement and supplementary cementitious materials (SCMs). The proposal was to change the psd of the fines to allow for better movement between fine particles and therefore improved rheology.

The rheograms give the continuous curve of shear stress vs. shear rate. We have taken 3 points as comparison being 0.1, 1, 10 s<sup>-1</sup>, which is an estimate of stability, flowability and pumpability. If the shear stress at 0.1 s<sup>-1</sup> is greater than the shear stress at 1 s<sup>-1</sup>, the concrete mix is likely to be stable, i.e. the aggregates will not settle to the bottom of the mix. The greater this difference the more stable the mix will be. If there is no difference or the difference is small, the aggregates will settle to the bottom of the mix and the mix is therefore unstable.

The shear stress at 10s<sup>-1</sup> is indicative if the pumpability with the higher the number, the greater pumping force required to move the material. The viscosity at high shear rates extrapolates to a linear relationship with shear rate, and is termed viscosity infinity.

### Rheograms

## 4. Discussion

The flyash series generally shows that an increased flyash replacement of the OPC gives a concrete with higher yield stress and higher shear stress at  $10\text{s}^{-1}$ . This indicates that the use of this flyash as an OPC replacement in this mix would lead to a less pumpable concrete.

Somewhat similarly, the silica fume series shows that at a low dose of silica fume, little effect is seen on the concrete viscosity, at a higher silica fume dose, a large increase in the shear stress across all shear rates is seen, the concrete is more viscous and requires more force to pump.

The use of micro-classified flyash appears to assist with reducing viscosity but variable results and seems to reduce strength significantly. The addition at  $40\text{kg/m}^3$  dose may be optimum.

Interesting that the use of Silica Fume seemed to increase the viscosity significantly as did higher levels of flyash, whereas micro-classified flyash at low doses significantly increased viscosity and this impact reduced at higher doses.

The water-cement variation series showed, not surprisingly, that increasing the water improves the pumpability of the concrete. There is a reasonable relationship between Viscosity and T500. From the data looks as if a "Viscosity Infinity" under 250 may produce a pumpable concrete. This correlates well with the previous studies showing  $200\text{Pa}\cdot\text{s}$  to give pumpable concrete.<sup>8</sup> From a practical perspective it has been found that a T500 needs to be  $<5$  seconds in order to produce commercially acceptable pumped concrete mixtures.

Overall, the 7 day strength to W/C ratio is fairly normal and so while added strength is achieved at the lower W/C ratio, the higher w/c ratio leads to better fine particle separation and so lower viscosity as expected. Unfortunately this means that very low W/C ratio is required for all of these mix binder combinations to achieve compressive strengths in excess of  $100\text{MPa}$  at 7 days. This along with the findings above underlines the importance of achieving a suitable viscosity of high strength concrete mixes to aid placement.

The admixture test series shows some useful data. The mix ADM-2 is the same as ADM-1, but additional PCE superplasticiser was added and an additional Viscosity Modifying Admixture (VMA) added to bring the initial flow back to the same as ADM-1. What we see is a rather large reduction in yield stress and a much improved concrete visually. The shape of the rheogram is changed significantly with a large dip around  $0.5\text{s}^{-1}$ . The curve increases at very low shear rates ( $0.01\text{s}^{-1}$ ) showing a stable concrete, while the shear stress at higher shear rates remain mostly unchanged indicating no improvement on pumpability of the mix. When the original PCE in ADM-1 is changed to a PCE with different chemistry (ADM-3) a large change is seen in the rheogram. Yield stress is reduced, and the concrete has lower shear stress at high and low shear rates, indicating a potential for improved ability to pump this mix at the target W/B as evidence also from the lower value of "Viscosity Infinity".

## 5. Conclusions

We can see that adjusting the proportioning of the powder in a concrete mix alters the rheological behaviour. Whilst the addition of water gives a flatter broader curve, the challenge is to reduce the water content to achieve the high target strength required. The

use of a VMA combined with a superplasticer allows the concrete technologist to modify the rheological behaviour of the concrete without changing the mix proportions.

**Abstract:** Superabsorbent polymers (SAPs) are a new and promising additive used in the building industry. They are mostly used to mitigate autogenous shrinkage. SAPs, however, have various effects on concrete properties and the most important influence is the possible change in microstructure due to internal curing. The microstructure is closely linked to the strength of the material and the microstructure is thus a key property. Dynamic water vapour sorption (DVS) may be used to characterize the change in pore structure of cementitious materials, but the technique is difficult to interpret. In the present paper, DVS measurements were performed to characterize the changes induced by SAPs in the textural and sorption properties of the material. Different models were hereby applied to study pores in the micro- (Dubinin-Radushkevich) and mesopore (Barrett-Joyner-Halenda) range and to better interpret the sorption measurements. The results show that cement pastes with SAPs and without additional water show a slight decrease in the micro- and mesopore range. The results are closely linked to a cement paste with the same effective water-to-cement ratio. Cement pastes with SAPs and with additional water show no significant difference in the micropore range and a slight increase in larger mesopore range. These new findings give insight into the effects of SAPs on the microstructure and strength of cementitious materials.

**Keywords:** Hydrogel, microstructure, water sorption, densification.

## 1. Introduction

Superabsorbent polymers (SAPs) already found their way into the medical and health-care industry due to their high absorption capacity. They are new materials to be used in the concrete industry. The polymers are able to absorb up to 500 times their own weight in fluids and are therefore useful to improve some mortar properties as they take up mixing water and gradually release it towards the cementitious matrix. These improved properties include the mitigation of autogenous shrinkage, the increase in freeze-thaw resistance, the change in rheological properties, self-sealing and self-healing, amongst others [1-4]. However, the release of water results in the formation of macropores, impairing the strength as well. Furthermore, a change in the finer microstructural properties of the material can occur.

Previous research (mercury intrusion porosimetry and (scanning electron) microscopic analysis) already showed that the water release by the SAPs resulted in continued hydration, decreasing the microporosity at later ages, not taking into account the macropores [1]. The amount of smaller capillary pores is decreased due to the filling of existing pores with hydration products and the reduction of initial micro cracks induced by autogenous shrinkage. But overall, the capillary porosity should be the same for mixtures with the same effective water-to-cement ratio (ratio of the mixing water not held by the SAPs over the cement content) [5].

Another (not widely used) technique to study the pore structure is by means of water sorption and moisture transport processes, using the moisture fixation in the concrete pore system. The technique, however, is difficult to interpret but it can give a first impression of the pore microstructure [6-7]. Two models are applied, namely the BJH (Barrett-Joyner-Halenda) method for the mesopore range [8] and the DR (Dubinin-Radushkevich) method for the micropore range [9]. In this research, the pores are classified according to micro- (< 2 nm), meso- (2-50 nm) and macropores (> 50 nm) (originally proposed by Dubinin and subsequently officially adopted by the IUPAC [10]).

In the present study, the effects of superabsorbent polymers, additional water and supplementary materials on the microstructure were investigated using water vapour adsorption isotherms. In this way, knowledge is gained on the effects of the SAPs on the sorption properties, namely the formed microstructure of cementitious materials.

## 2. Materials and Methods

### 2.1 Materials

Cement pastes with a water-to-cement ratio of 0.50, 0.46, 0.41 and 0.35 were made and cast. The cement used was CEM I 52.5 N and the standard used for the mixing procedure was EN 196-1. A varying amount of SAP expressed as mass-% of cement weight (0.5 and 1 m%) and additional water were added on top. Two types of SAP were investigated (both obtained from the company BASF). These include SAP A being a copolymer of acrylamide and sodium acrylate (particle size  $100.0 \pm 21.5 \mu\text{m}$ ), and SAP B, a cross-linked potassium salt polyacrylate (particle size  $477 \pm 53 \mu\text{m}$ ). Both SAPs are bulk-polymerized and consist of irregular crushed particles. All SAPs were vacuum dried in a desiccator with silica gel prior to testing or mixing in the cement paste mixture. The polymers are able to take up  $305.0 \pm 3.7$  and  $283.2 \pm 2.4$  g de-ionized water/g SAP,  $61.0 \pm 1.0$  and  $58.4 \pm 1.7$  g cement filtrate/g SAP and 30.5 and 8.9 g mixing water/g SAP, respectively. The aforementioned swelling characteristics were determined by means of filtration tests [4-5]. Dry SAP particles were added to the cement and were first dry mixed to ensure a homogenous dispersion in the cement. Additionally, supplementary cementitious materials were studied. All raw material characteristics are shown in Table 1.

**Table 1. Chemical composition of CEM I 52.5 N, Class F fly ash and Blast Furnace Slag**

	<i>CEM I 52.5 N</i> <i>mass-%</i>	<i>Class F fly ash</i> <i>mass-%</i>	<i>Blast Furnace Slag</i> <i>mass-%</i>
CaO	63.12	2.47	40.38
SiO <sub>2</sub>	18.73	49.34	34.35
Al <sub>2</sub> O <sub>3</sub>	4.94	24.55	11.36
Fe <sub>2</sub> O <sub>3</sub>	3.99	6.23	0.48
SO <sub>3</sub>	3.07	0.30	1.65
MgO	1.02	1.73	7.57
K <sub>2</sub> O	0.77	3.84	0.37
Na <sub>2</sub> O	0.41	0.52	0.29
Cl <sup>-</sup>	-	-	0.013
S <sup>2-</sup>	-	-	0.77
Mn	-	-	0.165

The different mixtures are shown in Table 2. The letter R states Reference, and is followed by the water-to-cement ratio. The mixtures with SAPs are first described by the type of SAP (A or B), followed by the amount relative to the cement weight (0.5 or 1 m%). If that code ends with an a, additional water was used to compensate for the loss in workability and the uptake of mixing water by the SAPs. The amount was determined by comparing the flow values. The total, effective and additional water-to-binder ratio is given as well. The amount of additional water was added in such a way that an effective water-to-cement ratio of 0.50 was obtained for all SAP mixtures with additional water. Furthermore, mixes with supplementary cementitious materials are described by the type (FA = fly ash; BFS = blast furnace slag) together with their percent replacement of the cement.

### 2.2 Storage conditions and sample preparation

After one day of storage in a relative humidity of  $95 \pm 5\%$  and a temperature of  $20 \pm 2^\circ\text{C}$ , the samples were stored in water at  $20 \pm 2^\circ\text{C}$  for a minimum period of 6 months to ensure a stable formation of the cementitious matrix and to prevent carbonation. After being stored in water for 6 months, the samples were crushed and stored again in demineralized water for a minimum of 1 hour. This ensured the polymers to swell to their full extent. Subsequently, the crushed part was wet-sieved between 500 and 1000  $\mu\text{m}$ . The SAPs were separated from the cementitious material and the paste particles were collected. The best drying technique is the solvent exchange method in isopropanol followed by vacuum drying [7]. The final collected samples were thus stored in isopropanol for one week and vacuum dried for two additional weeks in the presence of soda lime to exclude the effect of contact with carbon dioxide and the effects of carbonation. The soda lime was replaced every day.

**Table 2. Used code for the different studied mixtures, supplementary materials replacement, amount of SAPs and corresponding water-to-binder ratios**

### 2.3 Water vapour sorption isotherms

The isotherms were determined by means of Dynamic Vapour Sorption (Surface Measurement Systems, London, UK). By measuring the mass change as a function of time with changing relative humidity (RH) of the sample versus an empty reference, sorption isotherms can be calculated while the humidity is regulated by mixing humid and dry nitrogen gases. The temperature was set to 20°C, and the mass criterion to proceed to the next RH step was  $dm/dt < 0.002$  wt%/min. Dried cement pastes were first conditioned at 0% RH inside the DVS equipment followed by an adsorption-desorption cycle. The RH levels at which samples (5–10 mg) were subsequently equilibrated included 0-1-2-5-10-20-30-40-50-60-70-80-90-98% RH [7].

The used models to study the pore structure are the BJH method for mesopores and the DR method for micropores. The BJH method makes use of the Kelvin equation which relates the equilibrium vapour pressure of a curved fluid surface in a pore to the equilibrium pressure of the same fluid on a plane surface [8]. The Kelvin radius is not the actual pore radius because some adsorption occurred on the pore wall prior to condensation. The DR method is based on the change in potential energy between the gas and adsorbed phases, and the characteristic energy of the solid with the Polanyi model [9].

### 2.4 Helium pycnometry

The porosity was determined by means of Helium pycnometry. A sample (4 - 7 g) of cement paste was placed in the measuring cell of the equipment (Accupyc 1330 Pycnometer, Micromeritics, Norcross, Georgia, US). After 10 purges with He-gas the chamber was pressurized to 19.5 psig. The equilibration rate to proceed to the next step was set at 0.005 psig/min. The volume of the sample was determined ten times, and based on the average volume its absolute density was calculated. The true density was determined on bigger samples by means of weighing.

### 2.5 Statistical analysis

A statistical analysis was performed using the program SPSS® in order to compare the obtained results. Multiple averages were compared using an analysis of variance (ANOVA) test with a significance level of 5%. The homogeneity of the variances was controlled with a Levene's test. The post hoc test for data with homogenous variances was a Student-Newman-Keuls test and if no homogenous variances were obtained, a Dunnett's T3 test was used.

### 3. Results

#### 3.1 Water vapour sorption isotherms

Taking into account that water is likely to impair the mechanical properties and durability of concrete structures, water vapour sorption measurements constitute an essential tool when characterizing the properties of cement-bound materials.

The water vapour sorption curves of all studied mixtures are shown in Figure 1. Figure 1a shows all mixtures with SAP A with their respective references. Figure 1b depicts the same for SAP B. Figure 1c gives the mixtures with cement partly replaced by supplementary cementitious materials (FA and BFS).

The shape of the found isotherms provides information about the pore structure of the cement pastes. With increasing relative humidity, first the micropores will adsorb water vapour, so the lower part of the adsorption curve corresponds with the finer pores. Further increasing the relative humidity will cause a filling of the larger pores (the mesopores). The steep increase in mass due to a relative humidity higher than 50% indicates that the cement pastes mainly consist of mesopores.

All isotherms show a pronounced hysteresis loop. This hysteresis can be explained by the occurrence of cavitation or by the presence of ink-bottle pores. These isolate and constrict the larger pores when desorption occurs. The water in the larger pores will only be released when the relative vapour pressure is the one from the smaller pore constricting the larger pore. This leads to the hysteresis found with the water vapour sorption isotherms. The desorption branch will not be used later on to calculate the pore size distribution due to this negative influence. The adsorption branch is more suitable for comparing the different pore size distributions as the mesopores are filled when the relative pressure corresponds to the Kelvin radius of that pore. A larger constricted pore will also be filled at its relative pressure as water can migrate towards these pores through the already filled smaller pores.

The sorption curve is shifted downwards with decreasing water-to-binder ratio. This points to the densification of the cementitious matrix as the cement grains are packed closer together. The hydration products which are then formed cannot grow expansively and will develop a tight cluster and thus a denser matrix [11].

When using SAPs, the curves are also shifted downwards as there is densification as well. The SAPs will hold mixing water during hardening and will only provide the entrained water for internal curing. The matrix is already formed and the water released will cause a densification of the cementitious matrix in between the eventual SAP macropores. This was already found in previous research on the capillary porosity [5]. If additional water was used, the capillary porosity was comparable to the one of the reference mixture with the same effective water-to-binder ratio. Additional water thus not only compensates for the loss in workability but also counteracts the densification and the change in capillary porosity.

The water vapour sorption isotherms of fly ash systems in Figure 1c show the same overall microporosity compared to a pure cementitious matrix. Only, with increasing replacement of cement by fly ash, the amount of larger mesopores seems to increase. This is seen as the steeper rise from a relative humidity of 80% onwards for the FA50 mixture. The FA85 mixture was impossible to make as there is not enough binder available for a stable microstructure during hardening.

The same conclusion can be made considering the blast furnace slag mixtures. The amount of smaller pores seems to be slightly higher compared to the reference mixture. Again, the amount of larger mesopores is higher. The microstructure is denser in the BFS85 mixture, where not all the slag is consumed and part is acting as a filler. The isotherm remains flat but at higher relative humidity, it becomes steeper and a high amount of mesopores can be expected.

Figure 1. Water vapour sorption isotherms for specimens with or without superabsorbent polymers and additional water (a-b) and with supplementary cementitious materials (c).

### 3.2 Pore size distributions

The trends noticed in the water vapour sorption tests are reflected in the BJH mesopore size distribution calculations (Figure 2). Again, both SAP types are shown in Figure 2a and 2b, respectively, and the supplementary cementitious materials mixtures are shown in Figure 2c. All materials show an anticipated peak of narrow mesopores at 5-6 nm, which is typical for a cementitious material.

The BJH method showed an increased amount of pores with higher water-to-cement ratio. A lower water-to-cement ratio in mixtures leads to a less developed pore network with lower pore volumes, which could be expected.

Again, the densification due to the SAPs is clearly visible. The curves are shifted to the respective mixtures with the same effective water-to-cement ratio. This is for example the case for the A0.5 mixture which should be compared to the R0.35 matrix. The results show that cement pastes with SAPs and without additional water show a slight decrease in the mesopore range compared to the R0.50 reference. If mixtures with SAPs and without additional water are compared to the respective references, it is concluded that there is a slight increase in the larger mesopore range. On the other hand, the narrow mesopore range is similar. If additional water is used, the curves are shifted upwards towards the reference R0.50, which should give a matrix with the same effective water-to-cement ratio. Cement pastes with SAPs and with additional water show no significant difference in the narrow mesopore range and a slight increase in larger mesopore range.

When supplementary cementitious materials like fly ash are present, the portlandite is consumed, producing calcium-silicate-hydrates (C-S-H). They contribute to the formation of the binding phases in the cementitious matrix and thus influence the resulting pore structure. Overall, mixtures with supplementary cementitious materials show more mesopores than a cement paste with the same effective water-to-binder ratio. This could indicate pore densification when the supplementary cementitious materials' reaction causes a change of capillary pores towards gel pores. In case of fly ash, there is a decrease of the narrow mesopores. This is a property which is inherent to a cementitious matrix which is partly replaced by fly ash. For example, at early age, the pozzolanic fly ash accelerates cement hydration in fly ash systems. Then it acts as a substrate for crystal nucleation on which C-S-H phases and calcium hydroxide crystals can form preferentially. The formation of these additional C-S-H phases on the surface of fly ash particles leads to an increase in the amount of bound water relative to the cement content. Hydrates formed by the pozzolanic reaction densify the microstructure.

In blast furnace slag mixture, only a small increase in amount of narrow mesopores is found. However, in the BFS85 mixture, the amount of small mesopores is less. In this mixture, there is not enough portlandite to activate all slag (also partly the case in the BFS50 mixture). The remaining part of the slag is considered to be filler.

The micropore volumes, as determined by means of the DR method, are given in Table 3. The amount of micropores is lower than the amount of mesopores, which is typical for a cementitious material. In the table it can be seen that the use of SAPs decreases the amount of micropores and that additional water counteracts this phenomenon. However, these tendencies are less pronounced in this kind of pores.

**Table 3. Amount of micropores [ $\text{mm}^3/\text{g}$ ] calculated by means of the DR method**

	<i>DR</i> [ $\text{mm}^3/\text{g}$ ]		<i>DR</i> [ $\text{mm}^3/\text{g}$ ]		<i>DR</i> [ $\text{mm}^3/\text{g}$ ]		<i>DR</i> [ $\text{mm}^3/\text{g}$ ]

### 3.3 Porosity by means of Helium pycnometry

The results found by means of Helium pycnometry are given in Figure 3. In this figure, the theoretical amount of SAPs has been subtracted from the obtained value. The amount of macropores has hereby been theoretically determined by calculating the volume of macropores through the total uptake of water during mixing. As the water is released towards the cementitious matrix, a macropore of approximately the size of the SAP particle and water uptake volume remained. The SAP particles do not adhere to the pore walls.

**Figure 3. Amount of pores and SAP macropores [%] found by means of Helium pycnometry.**

When adding SAPs without additional water, the total amount of pores was approximately the same. This is due to the macropore formation combined with densification. Additional water even increased the total porosity due to less densification. The results show that the mixtures with SAPs and without additional water show the same porosity of the cementitious matrix as a reference specimen with the same effective water-to-cement ratio (thus after subtracting the theoretical amount of SAP macropores). If additional water is added, the total porosity is shifted upwards, but the porosity of the matrix is approximately the same as the R0.50 reference mixture. These results were already found in previous research by means of mercury intrusion porosimetry and a study on the capillary porosity by means of backscattered scanning electron microscopy [5].

The capillary porosity ( $0.2 \mu\text{m} < d < 40 \mu\text{m}$ ) changes when using SAPs. As the cementitious matrix is affected by the internal curing by the SAPs, the microstructure will be different. As the effective water-to-cement ratio is lower in specimens containing SAPs without additional water, densification of the cementitious matrix occurs as the cementitious matrix in between the SAPs is denser. The water released from the SAPs hereby stimulated continued hydration. Additional water should be used to receive a similar capillary porosity of the cementitious matrix. Mixtures with the same effective water-to-cement ratio show nearly the same capillary porosity. The amount of pores is slightly lower in SAP A mixtures and this may be due to the local use of the entrained water by the SAPs filling the already formed pores. This effect is not as clear in SAP B mixtures due to the larger particle size of SAP B compared to SAP A, masking the overall effect.

## 4. Conclusions

Superabsorbent polymers (SAPs) are a new innovative material to use in cementitious materials due to their swelling capacity. This swelling causes the formation of macropores and the release of water by the SAPs causes a densification of the cementitious matrix. This results in a material which acts with a lower effective water-to-cement ratio, unless additional water is provided together with the SAPs.

Dynamic vapour sorption proved to be a useful technique to study the porous properties of cement pastes. The microporous range could be studied by means of the DR theory and the mesoporous range by means of the BJH method.

Use of SAPs thus leads to a denser matrix as if the water-to-cement ratio would be lowered. Additional water partly counteracts the densification and results in a material with the same global matrix and properties. The amount of mesopores of mixtures with the same effective water-to-cement ratio is slightly higher in mixtures with SAPs with or without additional water.

## 5. Acknowledgement

As a Research Assistant of the Research Foundation-Flanders (FWO-Vlaanderen), D. Snoeck wants to thank the foundation for the financial support (11D7413N). The authors also want to thank the Research Foundation-Flanders for funding the project entitled 'Effect of Tunable Hydrogels on Concrete Microstructure, Moisture Properties, Sealing and Self-Healing of Cracks' (3G019012). The authors want to thank Dr. G. Herth from BASF for providing SAP A and SAP B.

**Abstract:** An experimental investigation was carried out to study the effectiveness of using hydrophobic poreblockers and crystalline admixtures to reduce the absorption, permeability, and volume of permeable voids in concretes incorporating different water-to-binder ratios (W/Bs) and binder types covering GP cement, fly ash and slag. The main prerequisite for a low permeable concrete is a dense and durable concrete matrix. This is primarily achieved by lowering the W/B of the concrete, which also correlates with higher compressive strength. Employing water-resisting admixtures in concrete can be another effective means of lowering water penetration into concrete. The use of such admixtures provides a safety margin in design, particularly where relatively high W/B concretes are specified for use. In this study, a factorial analysis was carried out to rank the effect of influencing variables such as W/B, binder type and chemical admixtures on the performance of concrete. Results indicate that water-resisting admixtures are highly effective in reducing water penetration and their effect is more pronounced in low-quality concrete having high W/Bs. The results also demonstrate that such admixtures are beneficial when used in lower W/B concretes but to a lesser degree.

**Keywords:** Water-resisting admixtures, watertight concrete, crystalline admixtures, strength, durability.

## 1. Introduction

The watertightness of an in-service concrete structure should be assessed by evaluating the properties that can cause loss of water by leakage or absorption. The main sources of water loss are cracks, joints, construction defects, and permeation through concrete matrix (1). Cracks may be caused by factors such as applied tensile stresses, restrained shrinkage, and temperature-induced expansion and contraction. Unplanned joint movements in concrete elements due to shrinkage and restraint may also lead to water leakage. Honeycombing and segregation of concrete (construction defects) are the other sources of potential leakage. However, water may also permeate through uncracked concrete by different mass transport mechanisms including adsorption, diffusion, capillary absorption, and permeability (2). Concrete cannot be completely impermeable (1), but its permeation capacity varies according to the specific properties of constituents used in the concrete as well as employed mix design that are explored in this paper.

The penetration of water through uncracked concrete is influenced by different factors. Olivier et al. (3) classified these factors into three categories, namely aggregate porosity, matrix porosity, and transition zone porosity. Hearn and Figg (4) indicated that aggregates are, by comparison, effectively impervious. When the factors controlling the matrix and transition zone porosities are considered, two factors affecting both aspects are the water-to-cement ratio (W/C) and addition of supplementary cementitious materials (SCMs), showing their importance in achieving a watertight concrete (3). Studies by Powers et al. (5) showed that the permeability of cement paste is reduced as the W/C decreases. In terms of SCMs, it is difficult to gain a clear understanding of the effect of mineral additions on permeability due to the very varied results in the literature (3). However, lower permeability of three orders of magnitude can be achieved by adding natural pozzolans, fly ash or slag to the cement paste (3). In addition, curing (method and duration) plays an important role in achieving lower permeabilities. It is believed that the reaction of FA ceases in relative humidities below 80% (6). Thus, continuous moist curing is required when FA is used in concrete (particularly in early ages). Experimental investigations carried out by Thomas showed that the concretes with SCMs achieve parity with control concretes (100% GP) sometime between 28 and 91 days. This shows the significance of long term curing and testing of concretes with SCMs.

Currently, water-resisting admixtures are also widely used to improve the watertightness and durability of concrete. These admixtures are mainly utilised to reduce the porosity in the matrix and transition zone, in addition to blocking continuous capillary pores. AS 1478.1-2000 refers to these materials as permeability-reducing admixtures. ACI 212.3R.10 (7) subdivides them into admixtures for concrete exposed to hydrostatic (PRAH) and nonhydrostatic (PRAN) conditions. Since the permeability of concrete is defined as the flow rate under hydraulic pressure, the use of permeability-reducing admixture for nonhydrostatic condition seems to be technically invalid (8).

Water-resisting admixtures for hydrostatic conditions are crystalline admixtures, which are claimed to be beneficial in accelerating the autogenous healing of concrete and blocking capillary pores and cracks up to 0.4 mm (8). These admixtures are primarily developed for use in concrete members exposed to hydrostatic pressure, such as members in tunnels and water reservoirs. In such cases, the hydrophilic crystalline chemicals react with the cement and water to increase the density of the calcium silicate hydrate (C-S-H) and generate the pore-blocking deposits. Alternatively, water-resisting admixtures for non-hydrostatic conditions (PRANs) are recommended to be adopted in any application with a head pressure of up to 4 m (9) and even up to 14 m (10), including applications such as roof slabs and concrete pavements. These admixtures contain water repellent chemicals including various soaps, oils, and long chain fatty acid derivatives. When they are added to the concrete mix, the insoluble stearate created by the reaction between the admixture and lime forms a thin hydrophobic layer on the walls of the pores and voids in the concrete matrix, leading to higher contact angles to water (8).

Researchers have reported various results when water-resisting admixtures have been used in concrete mixes (8). Experimental investigations by Dao et al. (11), Justnes (12), Rixom and Mailvaganam (10), Trinder et al. (13) and Yodmalai et al. (14) revealed improvements in the reduction of permeation capacity. In contrast, Roberts and Adderson (15) reported significant variability in the performance of hydrophobic pore blockers, with only 4 out of 9 admixtures tested showing decreasing effects on water ingress. Moreover, in an experimental study by Dao et al. (11), a tested crystalline admixture had almost no noticeable effect on the permeation capacity of concrete.

Considering the debated performance of water-resisting admixtures and the rapidly increasing demand for such admixtures in the construction industry, this paper conducts a comprehensive experimental and numerical investigation into the factors influencing the watertightness of concrete. The effects of varying W/B, binder type, the addition of water-resisting admixtures and curing are examined and compared. For this purpose, concrete mixes with three different W/Bs (0.40, 0.50 and 0.60) and three different binder types, namely general purpose cement (GP), fly ash (FA), and ground granulated blast furnace slag (GGBFS) were selected to match commercially available mix designs in Australia. Furthermore, two different water-resisting admixtures were introduced to the mixes and their performance was assessed against the control mixes devoid of such additives. To obtain sufficient data regarding the porosity of the concrete matrix as well as its mass transport mechanisms, different test methods have been employed for measuring the volume of permeable voids, absorption and permeability of concrete. Results were analysed by factorial analysis (see Section 2) to rank the importance of influencing factors as well as the interactions between these factors. Section 3 provides research methodology of the experimental and numerical studies adopted in this study. The results and related discussions are presented in Section 4.

## **2. Factorial analysis**

A series of factorial analyses of variance (ANOVA) was conducted to evaluate the importance of influencing factors on the watertightness of concrete. Factorial analysis is a statistical technique that assesses the effects of several independent variables and their interaction effects on a single dependent response (16). The use of this technique in the present study had the advantage of separating the main effects of mix parameters (W/B, binder type and the addition of chemical admixture) and their interaction on any measured property (16). The basic approach for the factorial analysis of variance is to break down the observed variance in a particular response to components attributable to different sources of variation (main effects) and to test the significance of each variance. To test the significance of each factor the F-static test is used, in which the ratio of the mean square of the variable to the error mean square is generally determined and compared with the percentile from standard tables for a level of significance decided by the experimenter (17). Factorial analysis is also a useful technique for determining the significance of the interaction between factors. An interaction between factors occurs when the change in response from the low level to the high level of one factor is not the same as the change in response at the same two levels of a second factor (17). That is, the effect of one factor is dependent upon a second factor. For instance, factorial analysis can reveal whether the effect of water-resisting admixtures in reducing permeation capacity is dependent on the W/B of the mix.

## **3. Experimental procedure**

The aim of the experimental investigation in this study was to evaluate the water penetration characteristics of the concrete specimens with different W/B, binder types, and water-resisting chemical admixtures, and rank the significance of these three factors in achieving a watertight

concrete solution. For this purpose, 45 concrete mixes were prepared and sampled with W/Bs of 0.40, 0.50 and 0.60. These mixes contained three different binder types: 100% GP, GP:FA (75:25) and GP:GGBFS (60:40). Two types of water-resisting admixtures were added to the mixes in order to evaluate their performance against the control mixes (mixes devoid of water-resisting admixtures). For reproducibility in workability, the dosage of standard water reducer was varied in the mixes to achieve the target slump of  $100 \pm 20$  mm. The dosages and mixing sequences of the admixtures conformed to the respective manufacturers' technical information. Table 1 summarises the mix designs and the levels of the investigated variables. Moreover, the effect of curing was studied by changing the curing condition of samples (with W/B of 0.50 and no water-resisting admixture) from 28-days moist-curing to 7-days moist-curing followed by 21-days air-curing. Concrete samples were moist cured in lime-saturated water tanks, whilst air-curing was carried out in laboratory with ambient temperature of approximately  $20 \pm 3^\circ\text{C}$  and relative humidity of 70%

**Table 1. Summary of mix designs and levels of variables.**

Mix design variable	Case 1	Case 2	Case 3
Target slump	100±20 mm	100±20 mm	100±20 mm
W/B	0.40	0.50	0.60
Binder content	450	350	284
Binder Type (3 levels)	GP GP/FA (75:25) GP/GGBFS(60:40)	GP GP/FA (75:25) GP/GGBFS(60:40)	GP GP/FA (75:25) GP/GGBFS(60:40)
Water content	180	175	170
Water-resisting admixture (3 levels)	None (control) HP CP	None (control) HP CP	None (control) HP CP

The raw materials used in the concrete mixes were:

- General purpose Portland cement conforming to AS 3972-2010
- Fly ash (FA) conforming to AS 3582.1-1998
- Ground granulated blast furnace slag (GGBFS) conforming to AS 3582.2-2001
- Coarse aggregate with relative density of  $2700 \text{ kg/m}^3$
- Fine aggregate with relative density of  $2650 \text{ kg/m}^3$
- Chemical admixtures conforming to AS 1478.1-2000
- Potable water

The chemical admixtures investigated in this study were a hydrophobic pore blocker (HP) and a crystalline admixture (CP). HP is a liquid hydrophobic poreblocker, which consists of active components. These active components form non-soluble materials throughout the pore and capillary structure of the concrete, sealing the concrete against penetration of water and other liquids. HP is classified as 'water-repelling substance' as per Australian Standard AS 1478.1-2000. CP is a powdered crystalline admixture which is mostly used in hydrostatic conditions to improve water impermeability and self-healing properties of the concrete. CP is classified as a 'special purpose chemical admixture' as per Australian Standard AS 1478.1-2000.

### 3.1 Test methods

The watertightness of concrete was assessed by different test methods to establish its water penetration characteristics. The types of tests adopted in this study included evaluating the pore structure of concrete, permeability of concrete under hydrostatic conditions, and absorption rate of concrete under non-hydrostatic conditions. To assess pore structure, the apparent volume of permeable voids (AVPV) was measured in accordance with AS 1012.21:1999. In this test method, two standard cylinders (100 mm x 200 mm) were cured for 28 days in lime-saturated water and cut into 4 discs to perform the test in accordance with the standard test method requirements.

The permeability of the concrete subjected to water pressure (500 kPa) was tested in accordance with BS EN 12390-8:2009. Three cubes (150 mm x 150 mm x 150 mm) were cured for 28 days in lime-saturated water and subsequently pressurised for 72 hours. The water penetration depth was determined visually at the termination of the test by means of the application of methylene blue dye on the wet surface. Methylene blue was used to improve the accuracy of readings.

The absorption rate of the concrete in the absence of hydrostatic pressure was measured in accordance with ASTM C1585-11. Two standard cylinders (100 mm x 200 mm) were cured in lime-saturated water for 28 days and cut into 4 discs. In accordance with ASTM C1585-11, the test specimens were placed in an environmental chamber at a temperature of  $50 \pm 2^\circ\text{C}$  and relative humidity of  $80 \pm 3\%$  for 3 days. Then, each disc was placed in a sealable container and stored at  $23 \pm 2^\circ\text{C}$  for 15 days. The initial absorption rates were determined for each disc in accordance with ASTM C1585-11.

In addition to the aforementioned tests, compressive strength testing was carried out on cylinder samples at 28 days curing in lime-saturated water in accordance with AS 1012.9:1999.

### 3.2 Data analysis methodology

To analyse the data and rank the mix design factors influencing watertightness of the concrete, a series of full factorial analyses was performed. In these analyses, three factors, namely W/B, binder type and water-resisting admixture were considered as the variables. Table 2 shows the factorial experiment designs and the levels of variables. Main and interaction effects were considered to be significant when their corresponding confidence level was 95% or higher (17).

**Table 2. Factorial experiment design.**

Independent variable	Factorial experiment design for mixes with GP/FA		Factorial experiment design for mixes with GP/GGBFS	
	No. of levels	Nature of each level	No. of levels	Nature of each level
SCM	2	0% (control) 25%	2	0% (control) 40%
W/B	3	0.40 0.50 0.60	3	0.40 0.50 0.60
Water-resisting admixture	2	0% 1%	2	0% 1%

## 4. Results and discussion

### 4.1 Effect of factors on compressive strength

The plots shown in Figure 1 suggest that decreasing the W/B from 0.6 to 0.4 had the greatest effect on the outcome of compressive strength when compared to the effects of binder type and the addition of water-resisting admixtures (70% compared to 30% and 10%). Figure 1(b) shows that the addition of SCMs including FA and GGBFS decreased the compressive strength (30%). This decrease may be attributable to the slower hydration rate of SCMs given at 28 days curing (6). The addition of hydrophobic pore blockers had a minor effect on compressive strength whereas crystalline admixtures increased the strength (10%). This effect may be attributable to the formation of new C-S-H layers in the concrete matrix due to crystallisation of hydrophilic polymers (8).

**Figure 1. Effect (main) of factors on compressive strength.**

#### 4.2 Effect of factors on AVPV

Comparison of the slopes of the graphs in Figure 2 reveals that the addition of SCMs into concrete had the most significant effect on AVPV. The addition of FA and GGBFS increased the AVPV significantly (15%). As with the strength data, this may be attributable to the slower hydration rate of concretes incorporating SCMs and the presence of higher porosity in the concrete matrix at 28-days. This finding suggests that the performance of SCMs should be evaluated by long-term testing (up to 91 days). In addition, curing (quality and duration) is of more importance when SCMs are used compared to the concretes with 100% GP (7). Furthermore, the inclusion of admixtures together with GGBFS in the mixes resulted in lower AVPV (Figure 2(c)). This effect may be due to the differences in pore structure of the concretes with GGBFS compared to the concretes with FA and the capability of the admixtures in blocking particular pore sizes (12).

Figure 2. Effect (main) of factors on AVPV.

#### 4.3 Effect of factors on water penetration depth

Figure 3 shows the main effect of factors on permeability measured by the water penetration depth. Alteration of the W/B of the concrete had the most considerable effect on permeability. This effect was more pronounced for W/Bs ranging 0.50 to 0.60 than for W/Bs ranging from 0.40 to 0.50, which is similar to the results reported by Powers et al. (5); which indicated that the permeability increased at a much greater rate beyond a W/B of 0.50. Furthermore, the addition of FA increased the permeability (40%) whereas the addition of GGBFS decreased the same parameter significantly (65%). This finding may be attributable to the discontinuity of the capillary pores in concretes with GGBFS due to the finer particle size of GGBFS at 28 days as well as its higher CaO content, which gives cementitious properties to the binder (18). As with the AVPV data, water-resisting admixtures were more beneficial when used in concretes incorporating GGBFS. Similar performance was found for both hydrophobic pore blockers and crystalline admixture. This observation suggests that the hydrophobic pore blockers can also be used in hydrostatic conditions.

Figure 3. Effect (main) of factors on water penetration depth (permeability).

#### 4.4 Effect of factors on sorptivity

Sorptivity results shown in Figure 4 support the previous findings discussed in Sections 4.3. Comparison of the slopes shows that W/B and binder type had a more pronounced effect on reducing the absorption rate of the concrete (35% and 30% compared to 20% for water-resisting admixtures).

This finding demonstrates the significance of proper mix design in achieving a watertight system. The results also indicate that the behaviour of concrete in a non-hydrostatic condition is reasonably similar to its behaviour in a hydrostatic condition. However, the crystalline admixture was more effective than the hydrophobic pore blocker in reducing sorptivity (25% compared to 10%). This trend was apparent in mixes with FA as well as GGBFS.

Figure 4. Effect (main) of factors on sorptivity (absorption rate).

To depict more precisely the performance of water-resisting admixtures, the interactions between the W/B and admixture factors are plotted in Figure 5 and Figure 6. In factorial analysis, interactions are considered to be significant when the interaction plots are not parallel (17). Accordingly, the relationships presented in Figure 5(a) show that there is no interaction between the W/B and admixture factors when the compressive strength of concrete is considered. This means that the effects of the inclusion of HP or CP are similar in mixes incorporating a W/B of 0.40, 0.50 and 0.60. In contrast, Figure 5(b) shows that the influence of HP in reducing AVPV is more pronounced in the mixes with higher W/Bs (2% compared to 6%). Similar performances were observed when the water penetration depth and sorptivity results were analysed (Figures 5(c) and 5(d)). These findings suggest that the watertightness of concretes with lower W/B (i.e. less than 0.50) might not be influenced by the addition of water-resisting admixtures. This may be attributable to the lower porosity (i. e., effective and absolute porosity) and discontinuous pore structure in the matrices of concretes incorporating lower W/Bs (2). Thus, water-resisting admixtures may be most beneficial in lower quality concretes such as the concretes used in suspended slabs.

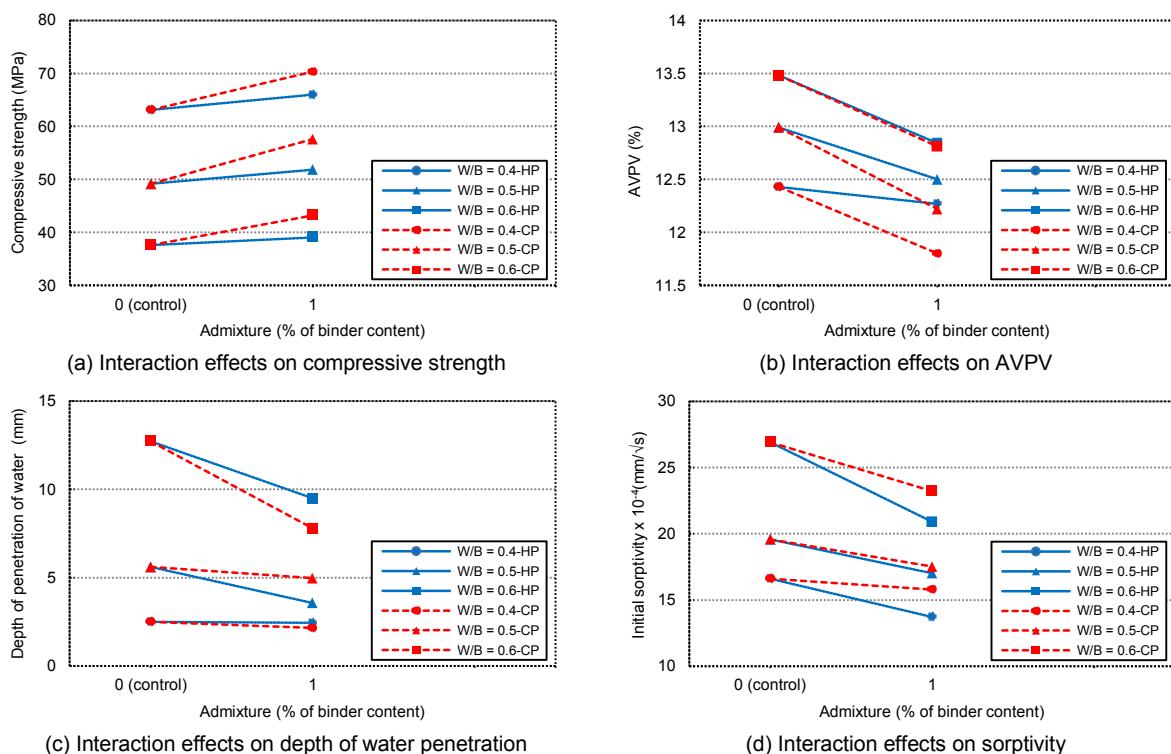

Figure 5. Effect (interaction) of W/B and admixtures.

#### 4.5 Effect of curing

Figure 6(a) shows that the AVPV of concretes with SCMs was highly influenced by the curing condition. The alteration of curing condition from a complete 28-days moist-curing to a combination of moist-curing (7 days) and air-curing (21-days) increased the AVPV of concretes incorporating FA and GGBFS by 13% and 10%, respectively. It may be attributable to the lower reactivity of SCMs in the relative humidities below 80% (6). However, this variation in curing had no considerable effect on the concretes with 100% GP cement.

Figure 6(b) illustrates the effect of curing condition on sorptivity. Generally, the change of curing condition from moist-curing to air-curing increased the absorption rate in all of the explored binder compositions. For instance, this variation in curing condition increased the sorptivity of concretes with 100% GP cement from  $8.5 \times 10^{-4}$  mm/ $\sqrt{s}$  to  $27.3 \times 10^{-4}$  mm/ $\sqrt{s}$  (300%). In addition, the sorptivity of concretes with FA increased from  $9.8 \times 10^{-4}$  mm/ $\sqrt{s}$  to  $39.1 \times 10^{-4}$  mm/ $\sqrt{s}$  (400%), whilst with concretes incorporating GGBFS, sorptivity increased from  $7.8 \times 10^{-4}$  mm/ $\sqrt{s}$  to  $23 \times 10^{-4}$  mm/ $\sqrt{s}$  (300%).

Figure 6. Effect of curing of concrete on water permeation properties.

#### 5. Conclusions

In this paper, the watertightness of concrete is evaluated, based on its pore structure and permeation properties, by means of different testing methods including AVPV, water penetration depth, and absorption rate (sorptivity). Accordingly, from the presented factorial analyses of the experimental data, the following conclusions are drawn:

- The watertightness of concrete is influenced by several factors such as W/B, binder type and water-resisting admixtures but at varying degrees. Therefore, advanced experimental mix designs are required to deal with these factors simultaneously.
- The W/B and SCM inclusions had a greater impact on watertightness when compared with water-resisting admixtures.
- At equivalent W/B, the inclusion of FA into the concrete mixes increased water permeation of concrete tested at 28 days and the addition of GGBFS improved its watertightness. Long-term testing and curing may be specified in practice when FA is to be added to concrete mixes. Caution must be exercised when the cement is replaced by FA in commercial mix designs.
- Hydrophobic and crystalline poreblockers are beneficial in both hydrostatic and non-hydrostatic conditions. However, their interaction with SCMs should be considered in any particular application.
- The addition of GGBFS to concrete mixes as a replacement for GP (40%) further aids water-resisting admixtures to achieve better performance in improving the watertightness of concrete.
- The effect of water-resisting admixtures on the watertightness of concrete is more pronounced in concretes with higher W/B (greater than 0.50). These admixtures are also effective in higher strength concretes (with lower W/B), but to a lesser extent.
- The sorptivities and AVPVs of air-cured concrete specimens were considerably higher than those for moist-cured concrete specimens. This observation was more pronounced in the

concretes incorporating FA and GGBFS when compared at equal W/B. Thus, proper curing of concrete is essential to achieve permeation reduction.

**Abstract:** In this paper, the effectiveness of wrapping by cloth impregnated with alkali hydroxide solution for concrete prism test (CPT) is discussed. First, RILEM AAR-4 and the CPT used in Japan are compared. Wrapping by cloth decreases leaching of alkali and drying during test period. Consequently, a new method in which concrete prisms are wrapped by cloth impregnated with sodium hydroxide solution and plastic film has been proposed. Except alkali wrapping with cloth and plastic film, the test procedure is the same as RILEM AAR-4. Following this method, the weight of prisms did not decrease, and stable expansion results were obtained. Furthermore, by this proposed method, ASR reactivity of two types of coarse aggregates was investigated in detail; one is andesite, another is chert. At 60°C, it results a clear relationship between expansion behavior and alkali content.

**Keywords:** ASR, CPT, wrapping, alkali hydroxide solution, expansion.

## 1. Introduction

Alkali silica reaction (ASR) is one of the possible deterioration mechanisms of concrete structures. ASR is due to a chemical reaction between reactive silica phases in aggregates and alkali hydroxides in the concrete pore solution, and it causes serious expansion and cracking in concrete. Although Stanton first recognized ASR in the late 1930's, it is still a significant problem regarding durability of concrete structures. Detecting methods of alkali-silica reactivity of aggregates and implementing ASR countermeasures have contributed to decreasing the risk of ASR. These methods, however, have imperfections and limitations.

It is necessary to improve the estimation procedure for highly reactive aggregate such as andesite containing opal or cristobalite/tridymite, or chert containing chalcedony (1). There are some difficulties for pessimum phenomena. First, the pessimum composition depends on the reactivity of aggregates (2). Second, at the pessimum composition, a higher content of pozzolanic materials is required than in the case that all aggregate is reactive (3).

Concrete prism test (CPT) is generally regarded as the best method to evaluate aggregate alkali-silica reactivity and to qualify preventive measures such as use of supplementary cementitious materials (SCMs). Some types of CPT have been already established. CSA A23.2 27A-09 and RILEM AAR-3 are famous methods. In order to accelerate ASR expansion, alkali content is increased to 5.25 or 5.5 kg/m<sup>3</sup> in concrete and temperature is set to 38°C, whereas RILEM AAR-4, which can accelerate reaction further of the temperature of 60°C, is now under preparation (4)(5). These methods use concrete specimens of 75\*75\*250 mm. Although they are easy to handle, alkali in concrete may leach out from concrete and alkali content may decrease significantly.

This paper investigates the effectiveness of alkali wrapping method in CPT to avoid alkali leaching. First, the result from two CPT methods are compared, and the necessity of water supply is discussed. The first one is based on the specification for the nuclear power related facilities in Japan, meanwhile, the other is RILEM AAR-4. In order to avoid alkali leaching and drying, wrapping by using an absorbent cloth including NaOH solution and a plastic film has been proposed. Then, the effectiveness of alkali wrapping in AAR-4 was examined. Moreover, this method was applied to the CPT varying the kind of aggregate type, alkali content in concrete and temperature.

## 2. Effectiveness of water supply in CPT

### 2.1 Experimental program

This section is based on the authors' previous paper (6). In order to provide the background to discussion in the following chapters, the results of previous experiments are necessary.

#### 2.1.1 Materials

Ordinary Portland Cement (OPC) ( $\text{Na}_2\text{O}_{\text{eq}} = 0.59\%$ ) specified in JIS A 5211, similar to CEM I 52.5 in EN197-1 was used. As SCMs, siliceous fly ash (FA) and ground granulated blast-furnace slag (BFS) were used. Physical characteristics are shown in Table 1.

**Table 1. Physical characteristics of cement and SCMs.**

Material	Density ( $\text{g}/\text{cm}^3$ )	Specific surface area ( $\text{cm}^2/\text{g}$ )
OPC	3.16	3110
FA	2.30	4190
BFS	2.89	4400

Coarse aggregate A1 and fine aggregate B1 are reactive aggregates, namely compose of andesite containing opal in vein. They have the same source, but the aggregate size is different. Moreover, andesite containing tridymite (aggregate C) and hornfels containing microcrystalline quartz (aggregate D) were used. As non-reactive aggregate, pure limestone (coarse aggregate G and fine aggregate H) was used. Aggregates G and H were from the same source. Physical properties of these aggregates are shown in Table 2.

**Table 2. Physical properties of aggregates.**

Aggregate	Dry density ( $\text{g}/\text{cm}^3$ )	Absorption (%)	Unit weight ( $\text{kg}/\text{L}$ )	Solid content (%)	Fineness modulus	Fines (%)
A1	2.46	2.33	1.41	57.2	6.60	4.2
B1	2.49	5.78	1.46	58.7	2.87	4.4
C	2.63	2.06	1.56	59.5	6.56	1.2
D	2.65	0.71	1.52	57.4	6.63	1.0
G	2.68	0.55	1.54	57.3	6.59	1.7
H	2.68	0.61	1.85	68.9	3.04	8.2

Table 3 shows the results of chemical method according to ASTM C 289. Aggregates A1 and B1 were judged as potentially deleterious. Aggregate C was judged as deleterious. Aggregate D seems to be innocuous because chemical method is not sensitive for late expansive aggregate containing micro/cryptocrystalline quartz. Andesite aggregate A1, B1 and C showed compositional pessimum effect at 30 mass% in the previous experiments.

**Table 3. ASR reactivity test results of aggregates checked by chemical method.**

Aggregate	Rc (mmol/L)	Sc (mmol/L)	Reactivity
A1, B1	207	672	Potentially deleterious
C	112	592	Deleterious
D	109	16	Innocuous
G, H	8	1	Innocuous

#### 2.1.2 Mixture proportions

Water content was kept constant as  $160 \text{ kg}/\text{m}^3$ . In some mixtures, OPC was replaced with 15, 25, or 35 mass % of FA, or 55 mass % of BFS. Slump was adjusted around 12 cm by

changing the dosage of air-entraining and water-reducing admixture. Air content was controlled to  $4.5 \pm 1.5$  % by changing the dosage of air-entraining admixture. Pellet type of sodium hydroxide (NaOH) was dissolved in mixing water to adjust alkali content of  $5.5 \text{ kg/m}^3$  in concrete.

### 2.1.3 CPT procedures

Table 4 shows the mixtures and test methods of CPT for each mixture. In this subsection, the results of two CPT methods are presented. The important differences between the two methods are the size of prism and whether prisms are wrapped by cloth or not.

**Table 4. Mixture proportions and CPT methods (O; Conducted).**

Mixture	Concrete materials			CPT	
	Aggregates		Binder	RILEM AAR-4	mJASS5N
	Coarse	Fine			
No.1	A1:G = 3:7	H	OPC100%	O	O
No.2	A1:G = 3:7	H	OPC75%+FA25%	O	O
No.7	G	B1:H = 3:7	OPC100%	O	O
No.8	G	B1:H = 3:7	OPC75%+FA25%	O	O
No.14	D	H	OPC100%	O	O

In the RILEM AAR-4 procedure, the specified size of the prisms is  $75 \times 75 \times 250$  mm. Specimens are stored in sealable stainless containers with water level of 35mm from the bottom, which are stored in a reactor generating  $60^\circ\text{C}$  and 100% relative humidity. After the test period, a sample of water at the bottom of container was taken, and the alkali concentration was measured so that alkali leaching was evaluated.

Another method exists in Japan, JASS 5N T-603. JASS 5N stands for Japanese Architectural Standard Specification "Reinforced Concrete Work at Nuclear Power Plants". In this method,  $100 \times 100 \times 400$  mm prisms are used, and they are wrapped with cloth impregnated by distilled water. The size of paper and weight of water are specified. In this study, two pieces of unwoven paper with  $355 \times 425$  mm were used, and 50 g of distilled water for each paper was added.

After having been wrapped with cloth, each specimen was covered by thin plastic film and was put into a thin plastic bag in order to prevent moisture movement between the specimen and surrounding environment. Then, three specimens for each mixture were placed vertically in a container, of which the temperature was controlled to be  $60^\circ\text{C}$  with a heater in water in the bottom of the thermally insulated container. JASS 5N T-603 specifies that the temperature shall be  $40^\circ\text{C}$ , however, in this experiment,  $60^\circ\text{C}$  was adopted (hereinafter, "mJASS5N" m; modified), as in RILEM AAR-4.

24 hours before length measurement, specimens were moved to a temperature controlled room at  $20^\circ\text{C}$ . Plastic bag, plastic film and cloth were removed. Then, the length and the weight of paper were measured. After measuring, distilled water was added to the same paper up to the weight of initial condition. After the whole test period, water content and alkali content in the paper were measured and alkali leaching were evaluated.

## 2.2 Results and discussion

The expansive behavior of specimens as measured according to mJASS5N and RILEM AAR-4 are shown in Figure 1. The relationships between the expansions between both methods are shown in Figure 2. In a wide range as shown in Figure 2(a), it seems to be a linear correlation for both methods. In the range of smaller expansion (Figure 2(b)), however, AAR-4 results in smaller expansion than mJASS5N.

It is possible that there was a difference in moisture supply. Figure 3 displays the relationship between mass change of specimens and expansions at 26 weeks. The mass gain in AAR-4 condition is always smaller than with mJASS5N procedure. However, the expansion according to AAR-4 was always slightly larger than with mJASS5N at the same mass gain and the moisture seems not to be the direct reason of discrepancy. Another possible reason is the difference in alkali leaching. Amounts of leached alkali were 2% or 3% of original 5.5 kg/m<sup>3</sup> for mJASS5N and 16% or 30% of that for AAR-4. The reason why limited amounts of alkali were leached in mJASS5N may be the use of the same paper, and the fact that just water was added in sealed condition. This means that all alkalis were kept in the paper and the plastic film, and no alkali go out from the system. More alkali leaching in AAR-4 may be caused by the water dropping when the container is cooled for the measurement even though the inclined inner roof is prepared, or moisture condensation in the container on the specimens when the container, especially the water in the bottom is heated after measurement during the specimens are cold. Therefore, because of the higher amount of alkali leaching, AAR-4 resulted in the less expansion. For rapid expansion, the effect of alkali leaching was limited because the most of expansion was happened before the first measurement. There is another possibility of the reason for limited alkali leaching of mJASS5N in its larger specimen size.

Figure 1. Expansion measured according to RILEM AAR-4 and mJASS5N.

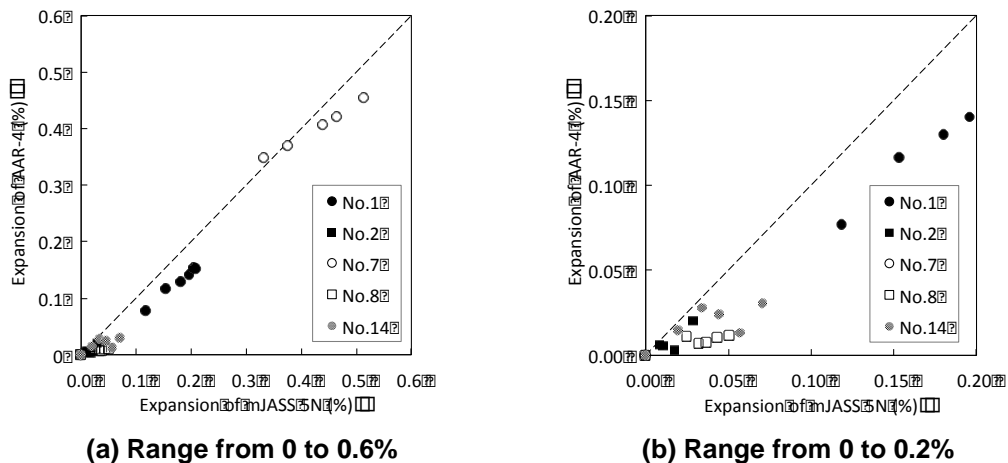

Figure 2. Relationship between expansion behaviors by AAR-4 and mJASS5N.

There is one more difficult point in AAR-4. Drying during cooling may happen because the stainless steel container gets cool faster than concrete prisms inside. Water in concrete prisms can move on the inside surface of container by condensation. When alkali amount is high, the equilibrium vapor pressure is low and vapor tends to be absorbed by concrete prisms. However, once the alkali content becomes less, the vapor absorbing tendency decreases and water may move from concrete prisms to the container. In real conditions of concrete structure, the most severe condition for ASR, except alkali supply from de-icing salt or sea salt, is continuous supply of water. Therefore, wrapping with cloth is considered as reasonably safe side.

The alkali leaching in the case of wrapping by cloth impregnated by distilled water is caused by the alkali movement from concrete specimens to cloth. Therefore, if appropriate amounts of alkalis are included in cloth in advance, the movement of alkalis is expected to be limited. CPT is an accelerated test in order to reproduce the worst case in field. Therefore, keeping alkalis and moisture is an essential point.

Figure 3. Relationship between expansion and mass change.

### 3. Proposal and examination of alkali wrapping method

#### 3.1 Experimental program

##### 3.1.1 Materials

Ordinary Portland Cement specified in JIS A 5211, similar to CEM I 52.5 in EN197-1 was used. In this subsection, reactive coarse aggregate A2 was used. Aggregate A2 was obtained from the same quarry as that of aggregate A1, but sampled season was different. Table 5 shows the result of reactivity analysis according to the chemical method. Limestone was chosen as the reference innocuous aggregate.

Table 5. ASR reactivity test results of aggregate A2 checked by chemical method.

Aggregate	Rc (mmol/L)	Sc (mmol/L)	Reactivity
A2	168	710	Potentially deleterious

##### 3.1.2 Mixture proportions

As shown in Table 6, there are 4 mixtures which have different alkali content. Alkali content was changed from 2.4 kg/m<sup>3</sup> to 5.5 kg/m<sup>3</sup>.

**Table 6. Alkali content, wrapping condition and mixture numbers (O; conducted).**

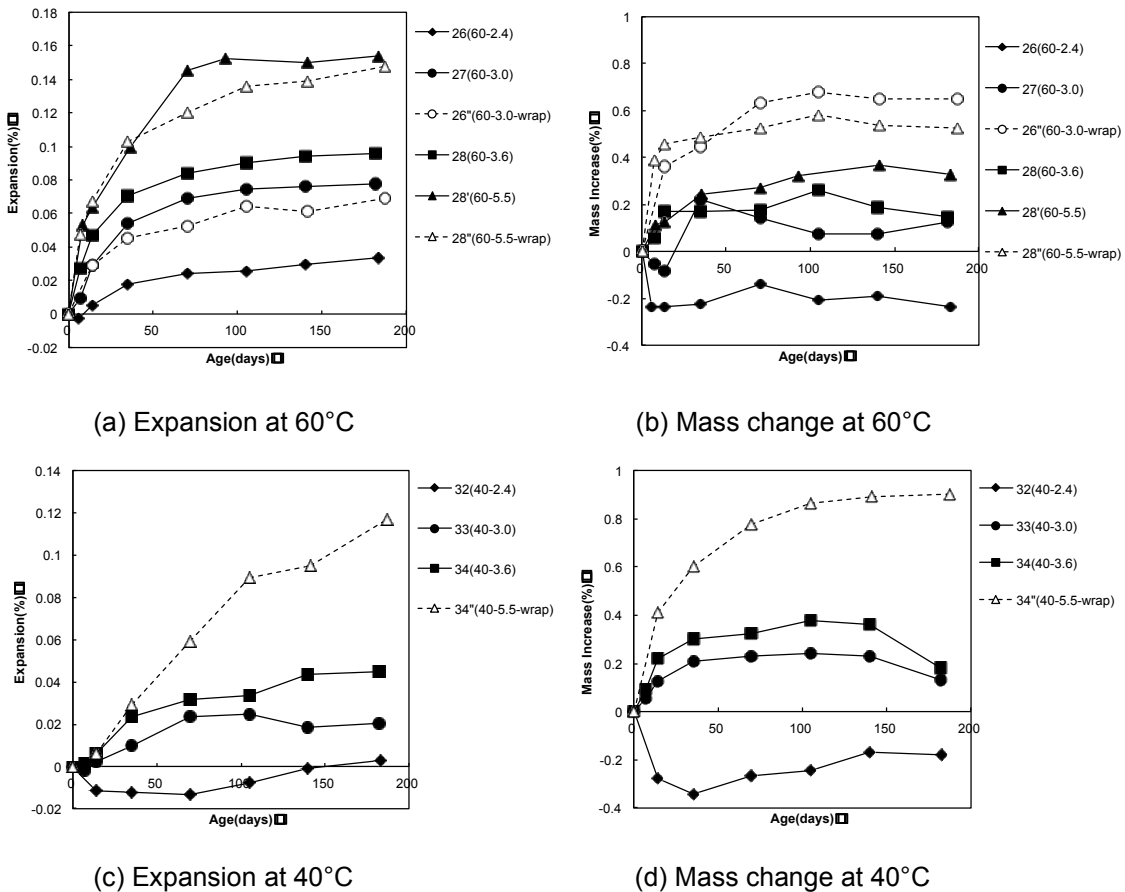

Alkali content (kg/m <sup>3</sup> )	60 °C		40 °C	
	AAR-4 (Without wrapping)	With alkali wrapping	AAR-4 (Without wrapping)	With alkali wrapping
2.4	O (No.26)		O (No.32)	
3.0	O (No.27)	O (No.26'')	O (No.33)	
3.6	O (No.28)		O (No.34)	
5.5	O (No.28')	O (No.28'')		O (No.34'')

**3.1.3 Test method**

Casting of concrete specimens and accelerated curing condition are almost same as according to AAR-4. The different point is whether the specimens were wrapped by the cloth including NaOH solution (alkali wrapping) or not. Concentration of NaOH solution was calculated by assuming chemical composition of C-S-H gel and alkali content in concrete (7).

**3.2 Results and discussion**

Figure 4 shows the expansion behavior and weight change at 60°C and 40°C. High temperature and high content of alkali correspond to the higher expansions. In the case of 2.4kg/m<sup>3</sup> of alkali, a weight reduction is observed. The test condition of AAR-4 is not enough to accelerate the ASR reaction. When the alkali content is low, specimens may dry. Meanwhile, when the alkali content is high, water absorption in pore solution will increase. In the concrete structure which has risk of ASR, actually, water will be supplied continuously. Therefore, the acceleration in AAR-4 method is not enough to examine the ASR reactivity.

**Figure 4. Relationship between expansion and mass change.**

From the results of this experiment, we propose new method detailed hereafter to evaluate ASR reactivity of concrete. This new method principally applies RILEM AAR-4 except for the wrapping procedure. Concrete prism shall be wrapped by cloth including NaOH solution and thin plastic film. The purpose of such wrapping is to avoid movement of water and alkali during test period. When the length and weight are measured, weight of paper also shall be measured. If the weight loss of paper is to be observed, water should be added to maintain the weight of paper. Concentrations of NaOH solution can be calculated by using alkali content of cement used and assuming chemical composition of C-S-H (7) .

#### 4. Verification of alkali wrapping method varying the temperature and alkali content

##### 4.1 Experimental program

In order to discuss the proposed CPT method, further experiments have been conducted. The effects of alkali content in concrete and temperature for acceleration of ASR reactivity were investigated. Picture 1 shows the wrapping procedure; (a) setting on a cloth (absorbable paper), (b) folding, (c) finish of folding, (d) fastening by rubber band, (e) wrapping by thin plastic film, (f) storage in stainless container.

Photo 1. Proposed alkali wrapping method.

##### 4.1.1 Materials

Ordinary Portland Cement specified in JIS A 5211, similar to CEM I 52.5 in EN197-1 was used. In this subsection, the same reactive coarse aggregate A2 as in Section 3 and the reactive coarse aggregate T were used. The rock type of aggregate A2 was chert including cryptocrystalline quartz and chalcedony. Limestone was the reference innocuous aggregate. The result of chemical method for aggregate T is  $S_c = 158 \text{ mol/l}$  and  $S_c = 2 \text{ mol/l}$ . Meanwhile, the result of RILEM AAR-5 for aggregate T is that expansion at 14 days reaches 0.173%.

##### 4.1.2 Mixture proportions

As shown in Table 7, there are 22 mixes which have different alkali content. Alkali content was changed from  $2.00 \text{ kg/m}^3$  to  $5.50 \text{ kg/m}^3$ . While aggregate A2 was combined with

limestone by 30% : 70% in volume, aggregate T was used by itself. Furthermore, for the mixture using aggregate A2, fly ash was added, and mitigation effect by fly ash also examined. Temperature was controlled to 20, 40 and 60°C.

**Table 7. Alkali content, wrapping condition and mixture numbers (O; conducted).**

Alkali content (kg/m <sup>3</sup> )	Aggregate A2			Aggregate T		
	60 °C	40 °C	20 °C	60 °C	40 °C	20 °C
5.50	O (No.28+) O (No.59)* O (No.60+)**	O (No.52)	O (No.55)	O (No.41)	O (No.45)	O (No.48)
4.75				O (No.42)	O (No.46)

## 4.2 Results and discussion

Figures 5 and 6 show the expansive behavior and the mass change of concretes using aggregate A2 and aggregate T, respectively. The color of the plots differs depending on the temperature condition.

### 4.2.1 Aggregate A2 (Andesite)

First, from Figure 5(a), in the case of 60°C, the higher the alkali content, the larger the expansion shows from early ages. After 10 weeks of test period, expansion speed decreased. Second, in the case of 40°C (Figure 5(b)), ranging the alkali content from 3.00 kg/m<sup>3</sup> to 5.50 kg/m<sup>3</sup>, expansion behaviors for 3 experiments seem to be almost the same. After 15 weeks, expansion of concrete with 3.00 kg/m<sup>3</sup> at 40°C exceeded the one with 3.00 kg/m<sup>3</sup> at 60°C. At 20°C, the beginning of expansion depends on the alkali content, and expansion with 3.00 kg/m<sup>3</sup> alkali reached to that of 4.25 and 5.50 kg/m<sup>3</sup>. Lastly, from the results of No.59 and No.60, 15% fly ash replacement was not enough for suppressing expansion, therefore, 30% replacement was required.

### 4.2.2 Aggregate T (Chert)

Both of 60°C and 40°C, the same trend of expansion behavior is observed. While expansion rate at 60°C until 5 weeks was very high, the expansion at 40°C also became remarkably large, and all mixtures of 40°C reached the same level as of 5.50 kg/m<sup>3</sup> at 60°C. There was no expansion for the specimen in 20°C.

### 4.2.3 Effect of temperature and alkali content

The relationship between alkali content and expansion at 26 weeks was clear as shown in Figure 7. In the case of 40°C and 20°C, however, the relationship was not clear. To clarify the mechanism of these behaviors, further analysis is required.

In addition, in the case of aggregate T which is chert including cryptocrystalline quartz and chalcedony, a test period of 15 weeks at 60 °C is able to detect ASR earlier than any other conditions. However, concretes with aggregate A2 including much crystalite continued expansion indefinitely. It would take much time to examine ASR reactivity.

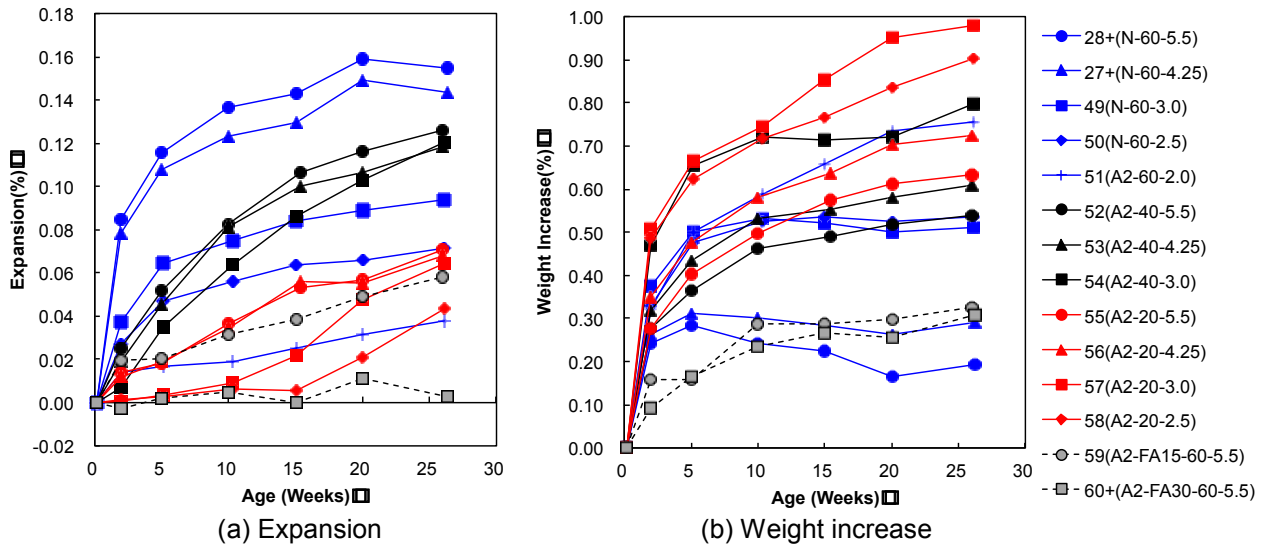

Figure 5. Relationship between expansion and mass change for aggregate A2.

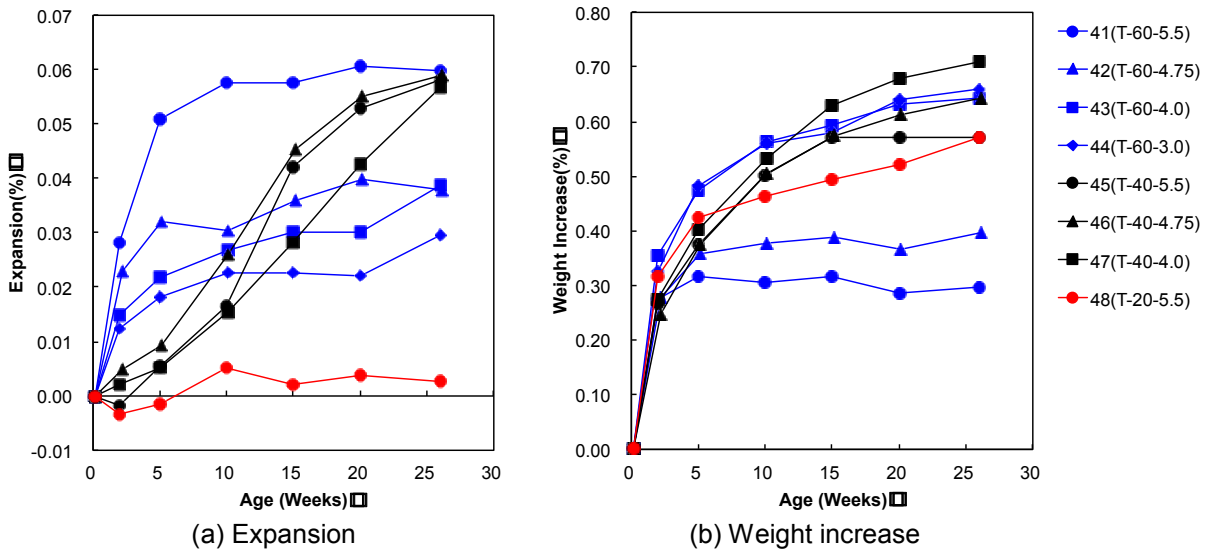

Figure 6. Relationship between expansion and mass change for aggregate T.

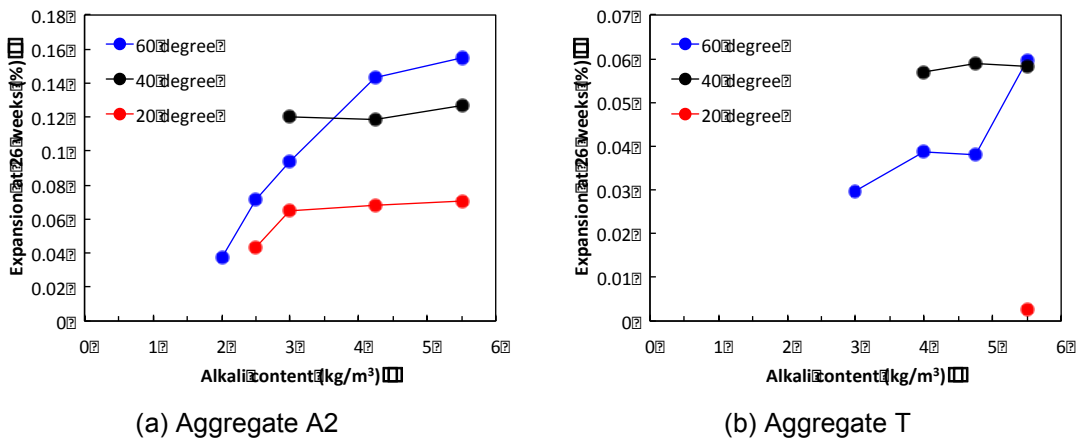

Figure 7. Relationship between Alkali content and expansion at 26 weeks.

Alkali wrapping method is able to decrease leaching of alkali and to avoid drying during test period. It is still yet difficult to evaluate the ultimate expansion from CPT test quantitatively.

## 5. Conclusions

In this paper, the significance of alkali wrapping for concrete prism test to evaluate ASR reactivity was presented. Several types of CPT were conducted. In Section 2, RILEM AAR-4 and CPT used in Japan were compared. In Japanese CPT, larger concrete prisms of 100\*100\*400 mm wrapped in cloth impregnated with distilled water and plastic film and plastic bag, were used. Wrapping by cloth decreased leaching of alkali and drying during test period. In Section 3, this new method where concrete prisms were wrapped by plastic film was qualified. This method did not decrease the weight of prisms, and it realized stable results of measurement. In Section 4, by this proposed method, ASR reactivity of two types of coarse aggregates were investigated; one is andesite, another is chert. As the results, in the case of 60°C, there was clear relationship between expansion behavior and alkali content, however, in the case of 40°C and 20°C, the trend was different from expected.

# Innovations in Admixtures for Piling Concrete

Bruno D'Souza<sup>1</sup> and Hairul Sarwono<sup>2</sup>

<sup>1</sup>Business Development Manager, Admixture Systems, BASF Australia Ltd

<sup>2</sup>Product Technologist, BASF Australia Ltd

**Abstract:** The use of Continuous Flight Auger (CFA) piles has gained considerable interest and popularity in recent years. With favourable geotechnical conditions CFA piling is the preferred method of deep foundation technology where installation speed and a large number of piles are required. In CFA pile construction it is considered good practice to commence drilling only after the concrete has arrived on the project site and delivery of the full volume needed for the completion of the pile without interruption is assured. The mix design, ambient conditions and characteristics of the soil at site play a significant role in the workability of concrete during reinforcement placing. In some soils, for example dry sandy soils may tend to dewater the concrete rapidly thereby reducing the workability of concrete. Loss of workability of concrete will in turn reduce the ability to successfully place the reinforcing cage. Conventional retarding admixtures can be used to achieve workability for an extended period of time but they also significantly retard the setting of concrete and hamper productivity. In long drilled shafts with higher than expected water contents it may be necessary to modify the concrete mix to prevent the washout of binder and fines for maintaining the integrity of the pile. Challenges like maintaining workability without excessive retardation and robustness during the installation of piles can be overcome through the use of innovative admixtures such as super slump retainers and colloidal materials capable of modifying the rheology of the mix.

**Keywords:** admixture, mineral additive, piling, slump retention.

## 1. Introduction

Deep foundation and ground engineering works include the construction of piles, diaphragm walls, displacement columns and retaining structures. A pile usually represents a slender structural member constructed in the ground. However, a pile is often used as a generic term to represent several types of deep foundations, such as CFA or driven pile, drilled shaft, caisson or an anchor.

Modern construction demands larger diameters and deeper shafts often with congested reinforced cages and steel elements. One of the challenges faced by engineers, contractors and concrete producers is to design an appropriate concrete mix for such specialized and often complex pours.

Large piles with diameters up to 2400mm and 45m in depth for high rise buildings in excess of 250m tall could use concrete with characteristic compressive strengths as high as 85 MPa. Moreover, cementitious binder contents in such high strength concrete mixes can exceed 600 kg/m<sup>3</sup> and therefore, present the concrete producer and contractor at the job site with issues related to workability & slump retention for the duration of the pour.

## 2. Properties of piling concrete

The integrity and high quality of the pile shaft is of paramount importance. With CFA piles, the pile is drilled to depth in one continuous operation using a continuous flight auger. The concrete then is pumped under pressure through a line from the top of the rig and delivered to the base of the auger via the hollow centre of the auger string. The concrete is continuously under pressure while the auger is smoothly lifted smoothly in one continuous operation. The reinforcement cage is then lowered into the fluid concrete to the required depth (1).

Some of the specific requirements for piling concrete used in continuous flight auger piles are high flowability or self-compacting yet non-segregating and cohesive properties without excessive bleeding over an extended period of time. The mix must also flow with ease between the reinforcing bars and into the interstices of the soil.

Therefore the other mix considerations are stability, filtration resistance with good workability life, passing ability and self-levelling properties that need to be maintained for the duration of the pour.

### **3. Admixtures for piling concrete**

Both low-range and high-range (superplasticizers) water reducing admixtures are routinely used in tremie, high flow and self-compacting concrete mixes for such applications. In addition, a retarder is commonly used in the same mix primarily to maintain slump for extended periods of time particularly for large pours, long hauls and in hot weather conditions. Conventional retarders maintain slump by retarding the set of concrete because they slow the rate of early hydration of cement. Retardation of concrete however, is accompanied by low early strength development. Extended set times and low early strengths are undesirable effects when speed and tight project construction schedules are of major consideration.

The authors would like to elaborate on the mechanism and potential applications of an innovative admixture and a mineral additive to meet some of the challenges posed by the construction industry described in the preceding section.

#### **3.1 Slump Retaining admixture**

Slump Retaining admixture (SR) is a relatively new class of admixture classified as Special Purpose, Normal Setting Admixtures or Type SN as per AS 1478.1-2000, Chemical Admixtures for Concrete, Mortar and Grout (2).

The chemical and physical behavior of polymers in concrete can be controlled through the efficient use of polymer chemistry and nanotechnology as depicted in the schematic modular diagram in Figure 1, Asmus, Kluegge et al (3).

SR is based on polycarboxylate ether polymers designed to a specific balance between electrical charges, side chains, length of the main backbone, new functional monomers and molecule geometry as shown in Table 1. For example a functional monomer (Block A) can be grafted to the polycarboxylate ether polymer to achieve control of workability without having the side effect of water reduction.

The functional monomer works by controlling the adsorption speed of the PCE to the surface of the cement particle thus providing workability retention after elapsed time without slowing the hydration process and retarding the set of concrete Asmus, Kluegge et al (3).

The attributes of such a functional monomer are beneficial for maintaining slump and workability for extended periods of time without impediment to the set times and early age strength developments of the mix. These benefits do not hinder the progress of work and aid in accelerating the project schedule.

These properties make it an admixture of choice in say CFA piling work where for example specifications call for a minimum of 15 MPa before pile construction can commence adjacent to a newly cast pile.

**Figure1. Schematic modular diagram of an engineered polycarboxylate ether polymer (3).**

**Table 1. PCE building blocks and their functionality in concrete (3).**

PCE Building block	Effect
Block A 	Slump retention
Block B 	Early strength
Block C 	Final strength
Block D 	Water reduction

A typical 50 MPa piling concrete mix used in the laboratory trials is shown in Table 2.

The performance of admixtures in these laboratory trials using identical mix designs is shown in Table 3.

Mix 1 containing a high range water reducer (superplasticizer) & retarder exhibits shorter slump & workability retention despite longer setting times compared with a SR incorporated in Mix 2 and 3.

**Table 2. 50 MPa piling concrete mix**

Ingredient	Quantity (kg/m <sup>3</sup> )
Cement	365
Fly ash	130
Water	198
20mm Coarse aggregate	720
10mm Coarse aggregate	180
Coarse sand	515
Fine sand	315

### **3.2 Mineral additive**

The mineral additive is a processed attapulgite, a hydrated magnesium aluminosilicate and principal member of the fuller's earth family of clay minerals. Attapulgite occurs as tightly packed bundles of submicron size particles whose lathe-like structure gives it unique colloidal and sorptive properties. The attapulgite needle-like particle shape is typically about 1 $\mu$  in length and approximately 0.10  $\mu$  across. Attapulgite can be characterized by its unique crystal structure. The 3-dimensional structure of attapulgite prohibits internal swelling action in the presence of water unlike some bentonites that swell owing the penetration of water between its layers Haden (4).

One of the reasons cast in situ piles fail is due to the discontinuity of concrete. Concrete stability is controlled by and related to the parameters of rheology and composition of the paste. Concrete placed at the base of a pile can be subjected to high hydraulic and hydrostatic head pressure and it needs to be designed to withstand this pressure. Working with less than ideal soils, soft, wet and in submerged conditions can also present difficulties with a propensity for washout of the binder from the concrete. Tremie concrete for example could be subject to free fall with a tendency to segregate and bleed especially with enlarged dimensions of the element.

The colloidal network created by the attapulgite particles forms a thixotropic gel as shown in Figure 2 that provides the concrete mix with anti-washout properties, improved cohesion, rheology, pumpability, stability and robustness required for concrete placed in environments and conditions described above. Due to the mode of action of attapulgite, the hypothesis is that the presence of such a mineral additive in concrete will not only enhance its ability to retain water under pressure but also improve the visibility stability index (VSI) making it suitable for the conditions and applications mentioned earlier. It is also envisaged that a concrete mix containing attapulgite will provide some support to the sidewalls of the drilled or bored shaft because of its thixotropic effect.

The additive complies with the requirements of a Special Purpose, Normal Setting Admixtures or Type SN as per AS 1478.1-2000, Chemical Admixtures for Concrete, Mortar and Grout (2). The testing and conformance of attapulgite to AS 1478 in a concrete mix confirms the compatibility for use in cement based applications including grouts and concrete for deep foundation works.

**Figure 2. Photomicrograph of particles in a colloidal network of attapulgite**

#### **4. Conclusions**

- Improved consistency and better control of slump, flowability, workability and stability can be achieved with the use of a Slump Retaining admixture
- A clay based mineral additive can impart stability, robustness and anti-washout properties to a mix by way of rheology modification
- New technology and traditional admixtures can be effectively used for piling concrete where quality, speed and economy are important

<sup>4</sup>Professor, Institute of Building Materials Research, RWTH Aachen University

<sup>5</sup>Professor, Institute of Structural Concrete, RWTH Aachen University

**Abstract:** This study presents a newly developed physically foamed lightweight concrete with an oven-dry density of 400 kg/m<sup>3</sup> produced with foaming agents under standard conditions. The foaming agents are described in detail and the influence of their interactions with other admixtures on foam stability is evaluated. Subsequently different production processes for foam and foamed concrete as well as potential problems are discussed. The foamed concrete is characterized by its oven-dry density, compressive strength, Young's modulus and its thermal conductivity. By comparing the foamed concrete with other heat insulating materials, the advantages and disadvantages of the new material are pointed out. Finally an example of the use of the lightweight concrete is presented. The foamed concrete substitutes polyurethane foams in sandwich elements. The new composite material is characterized by its heat insulating properties.

**Keywords:** lightweight concrete, heat insulation, foaming agents, protein, surfactants, sandwich element.

## 1. Introduction

At the present time the conception of sustainable and efficient building materials is one of the most important objectives. Therefore it is requested to lower the ecological footprint of existing and new materials. One section deals with heat insulating materials. Those materials are widely used in civil engineering to fulfil new energy conservation guidelines [1, 2]. The concrete industry has developed lightweight concrete masonry units and prefabricated elements with densities between 500 kg/m<sup>3</sup> up to 1200 kg/m<sup>3</sup>. There are different types of lightweight concretes:

- a) Particulate porous concrete
- b) Concrete with lightweight aggregates
- c) Chemically aerated and autoclaved concrete (AAC)
- d) Physical foamed concrete.

The density of lightweight concrete types a) and b) is limited by the used (lightweight) aggregates to a value down to 500 kg/m<sup>3</sup>. Due to the artificial air entraining process concrete types c) and d) can achieve lower densities and as a result those are used as ultra-lightweight concretes with densities lower than 500 kg/m<sup>3</sup>.

AAC is produced by using fine aluminium powder as air-entraining agent. Due to the chemical reaction of aluminium and hydroxide ions elemental hydrogen is formed and evaporates. This causes an expansion of the fresh concrete. The expanded concrete is then autoclaved to accelerate the hydration process and thereby to stabilize the porous binder matrix, resulting in high energy consumption during the production process.

For the production of foamed concrete surfactants or proteins are used to generate foams. Subsequently the foam is merged with fresh concrete to incorporate air voids into the binder matrix. Since there is no curing under special conditions afterwards, it's crucial that the foam stays stable until the hydration sufficiently advanced. The use of lightweight concrete depends on its density. While concretes with densities from 800 – 2000 kg/m<sup>3</sup> are well known and standardized [3, 4], concretes with a density lower than 800 kg/m<sup>3</sup> are subject of ongoing research. They show improved heat insulating properties, while the compressive strength and modulus of elasticity are decreasing (see Figure 1). Therefore the application range of ultra-lightweight concrete is limited to non-load-bearing construction elements.

**Figure 1: Correlation between Compressive strength, thermal conductivity and oven-dry density [5]**

As mentioned before, the foam properties play a major role in lightweight concrete production. Therefore it is necessary to understand the mechanism of foam formation.

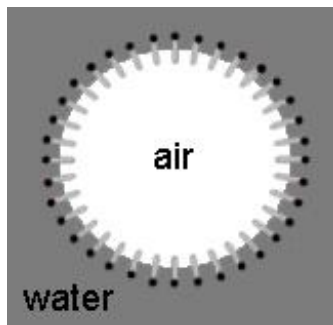

Speaking of foams, typically gas-liquid dispersions, in case of lightweight concrete air- water dispersions, are meant. To produce those dispersions, surface active substances are needed, which influence the surface tension of the continuous phase. One can differentiate between surfactants and proteins.

Surfactants are organic molecules, which consist of a hydrophobic and an ionic or rather non-ionic hydrophilic part, what makes them amphiphilic (see Figure 2a). By mixing them with water, surfactants start to assemble at the surface of the water, with their hydrophilic terminal groups orientated into the water. At low concentrations the interactions of the water molecules become weakened. Due to this effect, the surface tension is lowered. With increasing surfactant concentration, the whole surface is covered by the surfactant until a monomolecular surfactant layer has been formed as shown in Figure 2b. When this status is reached, the so called critical micelle concentration (cmc), the surface tension is minimized to a value defined by the used surfactant. If the concentration is further increasing, the surfactant will form micelles, due to their amphiphilic properties, as shown in Figure 2c.

**Figure 2: Pattern of: a) surfactant molecule; b) surfactant assembling at cmc; c) micelle formation above cmc [6]**

For foam production solutions with a surfactant concentration higher than the cmc are used. By introducing gas into the solution, e.g. via stirring, bubbles are formed and stabilized by the surfactant, due to their reorganization at the newly formed gas/liquid interfaces as seen in Figure 3 [7]. In this work four foaming agents based on surfactants were tested.

**Figure 3: Pattern of an air void stabilized by a surfactant**

Proteins are biological macromolecules, which are composed of amino acids. Due to the dominating functional groups – peptide bonds - within a protein, strong intermolecular interactions result and therefore proteins form complex tertiary structures as shown in Figure 4a.

If those complexes are unfolded, proteins become surface active as well. Due to different hydrophobic and hydrophilic side chains of the amino acids, the unfolded protein can assemble at an interface, where the hydrophobic side chains will emerge out of the aqueous phase (see Figure 4b).

**Figure 4: Unfolding Process of a protein: a) within the fluid; b) close to the interface; c) unfolded protein [8]**

By stirring a protein solution the unfolding process of the protein is accelerated and new air/liquid interfaces are formed (see Figure 4c). Thereby foam is generated. The intermolecular interactions of the protein chains should grant higher foam stability compared to surfactant based foam [9, 10].

## 2. Experimental details

### 2.1 Raw materials

#### 2.1.1 Cement

The choice of cement is an important factor in foamed concrete development. Due to the fragile foam structure it is necessary, that the cement reacts fast enough to stabilize the thin foam lamellas before they collapse. Therefore an ordinary Portland cement CEM I 52.5 R with a fineness of 4500 cm<sup>2</sup>/g and a d<sub>50</sub>-value of 15 µm was used for the investigations. The composition of the cement is shown in Table 1, the particle size distribution in Figure 5.

**Table 1: Mineral composition and particle size distribution**

Mineral phase	Quantity (wt-%)
C <sub>3</sub> S	72.1
C <sub>2</sub> S	7.2
C <sub>3</sub> A	12.1
C <sub>4</sub> AF	1.1
Free lime	0.1
Arcanite	0.6
Bassanite	1.9
Anhydrite	4.2
Portlandite	0.1
Calcite	0.3
Quartz	0.3

**Figure 5: particle size distribution CEM I 52.5 R**

### 2.1.2 Aggregate

Three different grain size fractions of a porous lightweight aggregate based on expanded glass were used. Material properties are listed in Table 2 and shown in Figure 6.

**Table 2: Manufacturer's data of the lightweight aggregate**

Grain size fraction (mm)	Bulk density (kg/m <sup>3</sup> )	Water adsorption (wt-%)	Mean grain strength (MPa)
0.1 - 0.3	950	35	2.8
1 - 2	400	19	1.6
2 - 4	320	14	1.4

**Figure 6: particle size distribution of the lightweight aggregates**

### 2.1.3 Admixtures

For the development of an ultra-lightweight concrete, an efficient foaming agent was needed. Therefore five commercially available substances were tested. Four of them based on surfactants (samples A-D), one was a protein based foaming agent (sample E, see Table 3).

Additionally a PCE based super-plasticizer was used to optimize the workability and flowability of the foamed concrete.

Referring to [9] a small amount of lithium carbonate was added for foam stabilization purposes.

**Table 3: Manufacturer's data of the foaming agents**

Sample	Ingredients
A	-Sulfohydroxypoly(oxy-1,2-ethandiyl- C10-C16-alkylether, sodiumsulfate (25-70%) -Sodiumolefin (C14/C16) sulfonate (10-20%) - Alkylaminoxid (3-5%)
B	-2-Butoxy-ethanol (25-50%) -Sulfonic acid, C14-16-alkanhydroxid- and C14-16-alkene, sodiumsulfate (2.5-3%) -Sodium laureth sulfate (1-2.5%) -Dodecan-1-ol (1-2.5%)
C	-Sulfonic acid, C14-16-alkanhydroxid- and C14-16-alkene, sodiumsulfate (5-10%) -Coconut oil, reaction product with diethanolamine
D	-Sulfonic acid, C13-18-alkanhydroxid- and C13- 18-alkene, sodiumsulfate (10-25%)
E	Unknown protein

## 2.2 Procedure

### 2.2.1 Foam optimization

In the first step the stability of the foam was optimized. Therefore 15 g of foaming agent solution were stirred with a hand mixer for 5 minutes. The produced foam then was poured in a measuring cylinder. The foam stability was quantified by the drained water over a defined period of time. The test was performed with different foaming agent concentrations (5 to 30 wt.-%).

### 2.2.2 Foamed concrete mixing process

Two mixing sequences were tested for their suitability. In the first methods, the fresh concrete and the foam are produced separately. Depending on the foam density and the targeted foamed concrete density, a defined amount of foam is subsequently added to the concrete slurry and homogenised. For the second method all raw materials are mixed simultaneously with high rotation speed (360 rpm). Due to the high shear forces the slurry foams up. The process is stopped, when the targeted volume is reached.

## 2.3 Characterization

The characterization of the foamed concrete was performed on an optimized mix (see paragraph 3). All samples were produced under standard conditions. Due to the low strength, they were retracted after two days with a following storage in a climate chamber (20 °C/ 65 % humidity).

### 2.3.1 Compressive strength and modulus of elasticity

The mechanical properties were tested after 7 and 28 days on cylinders with a height of  $h = 100$  mm and a diameter of  $d = 50$  mm and two installed displacement transducers. The load was increased by 500 N/min.

### 2.3.2 Thermal conductivity

Thermal conductivity was determined with the guarded hot plate method ( $\lambda$ -meter EP500, Lambda-Meßtechnik GmbH Dresden) referring to the EN 1946-2: 1999 [11] on coplanar samples with a base area of  $150 \times 150$  mm<sup>2</sup> and a height of 80 mm. The coefficient of thermal conductivity  $\lambda$  was measured at three different temperatures (10°C, 23°C and 40°C). For comparison a polyurethane foam sample with the same dimensions and a density of 36.1 kg/m<sup>3</sup> was tested.

### 2.3.3 Porosity and pore size distribution

The porosity was measured with mercury intrusion porosimetry (AutoPore IV, Micromeritics) within a pressure range of 0.0138 to 420.5802 MPa. Additionally image analysis via transmitted-light microscopy on thin sections was used to determine porosity and the pore size distribution of the voids entrained by the foaming agent. For that purpose the pictures were edited with the image analysis software SIS to differentiate the pores introduced by the lightweight aggregates and those produced by the foam.

### 2.3.4 Sandwich elements for heat insulating purpose

Sandwich elements were produced from the samples used for the thermal conductivity measurements. Both sides of the sample were enclosed by a 20 mm layer of a mortar (see Table 4), resulting in a sample with a base area of 150 x 150 mm<sup>2</sup> and a height of 120 mm (see Figure 7). The heat conductivity was measured at a temperature of 23°C.

**Table 4: Composition of the sandwich element shell mortar**

Component	Unit	Contents
CEM I 52,5 R	kg/m <sup>3</sup>	400
Aggregate		1600
Fly ash		100
Superplasticizer	% of cement	0,03
W/Z <sub>eq</sub>	-	0,463

**Figure 7: Produced sandwich element**

## 3. Results and discussion

Five foaming agents were tested for their stability in three different concentrations. The criterion for their stability was the drained water over 15 minutes. High foam stability results in a low amount of drained water. The results are shown in Figure 8.

**Figure 8: Results from the foam optimization experiments**

In general, foams made from foaming agents based on surfactants are less stable than protein foams, because of the intermolecular interactions between the unfolded and overlapping protein chains at the liquid-air interface. Accordingly the 10 % solution of protein foaming agent E produces the most stable foam. A 5 % solution of surfactant B shows competitive foam stability to the protein. For the following experiments surfactant B and E were used.

In a repetitive process the different raw materials and admixtures were tested in combination with the two described mixing methods until a stable foamed concrete with a density of 400 kg/m<sup>3</sup> was obtained. The final composition is shown in Table 5 and was produced with the simultaneous mixing method and foaming agent B.

**Table 5: Foamed concrete composition**

Component	Unit	Contents
CEM I 52,5 R	kg/m <sup>3</sup>	196
Lightweight aggregate		83,73
Superplasticizer	% of cement	0,25
Lithium carbonate		0,02
Foaming agent B 5%		0,25
Water/cement-ratio		-

The following remarks should be considered:

- The use of a superplasticizer is helpful to improve the dispersion of the concrete slurry in the foam.
- Because of the anti-foaming agent used in the superplasticizer, the dosage should not exceed 0.25 % of cement content.
- An optimized particle packing of the aggregates helps to stabilize the foamed concrete structure.

Despite of the protein foam stability it wasn't possible to produce a stable foamed concrete in our laboratory, which is contrary to the manufacturer who is capable to produce foamed concrete with densities down to 100 kg/m<sup>3</sup>.

The production volume of the in-situ mixed foamed concrete was limited to 4 liters due to the finite stirring possibility. For future investigations the pre-foaming method should be preferred.

The achieved density of the foamed concrete varied between 400 and 430 kg/m<sup>3</sup>. Due to the void entraining process it isn't possible to maintain a higher accuracy.

Table 6 shows the results of the measured mechanical properties after seven and 28 days. The achieved compressive strength is  $0.61 \pm 0.16$  MPa and the modulus of elasticity is  $0.531 \pm 0.023$  GPa. Referring to the summary in [12] the compressive strength of foamed concrete systems with densities from 360-1400 kg/m<sup>3</sup> usually is between 1-10 MPa, but the high water to cement ratio ( $w/c = 1.0$ ) should be considered.

**Table 6: Results of the mechanical properties**

Sample	Compressive strength (MPa)		Modulus of elasticity (GPa)	
	7 days	28 days	7 days	28 days
1	0,23	0,54	0,327	0,579
2	0,288	0,541	0,422	0,507
3	0,296	0,639	0,337	0,52
4	0,297	0,703	0,397	0,52
5	0,327	0,92	0,397	0,52
6	0,266	0,468	0,397	0,541
7	0,296	0,357	0,389	0,554
8	0,233	0,569	0,406	0,527
9	0,248	0,517	0,401	0,512
Average value	<b>0,28</b>	<b>0,61</b>	<b>0,386</b>	<b>0,531</b>
Standard deviation	0,033	0,160	0,032	0,023

The averaged results of the heat conductivity measurements are shown in Figure 9. Due to the low density of polyurethane (PU) foam, the achieved foamed concrete thermal conductivity is about six times higher. To improve the heat insulating properties the density needs to be reduced.

**Figure 9: Correlation between thermal conductivity and temperature (average values)**

Measurements via mercury intrusion porosimetry gave a mean porosity of 65.3%. To determine the pore size distribution of the air voids, thin sections were analyzed via transmitted-light microscopy. The image analysis software allowed the detection of the void content via gray value differentiation between the bulk phase (dark) and the voids (bright). Figure 10 (left) shows an example of an analyzed picture. A Porosity of 63.4 % arises from the image analysis and is in very good agreement with the mercury intrusion porosimetry measurements.

Additionally the pore sizes were quantified. The edge voids and lightweight particles were excluded from the detection, because they would falsify the analysis. As shown in Figure 10 (right) only the colored voids are included for the quantification. The resulting pore size distribution is shown in Figure 11.

**Figure 10: Transmitted-light image (left), detected pore sizes (gray, right)**

It has to be considered that the detection via microscopy includes a systematic error because the three dimensional void shape is neglected. For spherical voids the diameter is usually smaller than the real pore size, because voids are usually not cut in the center. Therefore Figure 11 gives just a hint of the real pore size distribution of the air voids. Due to the low magnification, which was chosen to analyze a larger sample area, pores smaller than 8 μm couldn't be detected.

**Figure 11: Detected pore size distribution via image analysis**

The sandwich elements were tested for their thermal conductivity. The results of the single components and combined elements are shown in Table 7.

**Table 7: Results for thermal conductivity**

Sample	$\lambda_{23^{\circ}\text{C}}$ (mW/m·K)	$R_{23^{\circ}\text{C}}$ (m <sup>2</sup> ·K/W)
Foamed concrete	126.5	0.63
Sandwich shell mortar	495.5	0.06
Sandwich with foamed concrete	188.33	0.64

Due to the comparatively high thermal conductivity of the mortar the sandwich shell has no significant influence on the thermal properties of sandwich elements.

#### 4. Conclusion and outlook

The presented work gives a perspective for foamed concrete as sustainable alternative to polymers as heat insulating material. For that purpose the main target is to develop low density products ( $<150 \text{ kg/m}^3$ ) to reduce the thermal conductivity in order to compete with polymer foams. Otherwise the use of foamed concrete is uneconomical due to the necessity of large dimension construction elements to achieve comparable thermal properties to polymer materials. On the other hand, sustainability, e.g. recycling and long-term stability as well as fire resistance, should be taken into account when comparing cementitious with polymeric foams.

For that purpose our ongoing investigations deal with a foamed concrete based on calcium aluminate cement targeting a density between  $130 - 150 \text{ kg/m}^3$ .

Furthermore the characterization of the sandwich elements is an ongoing process to adjust the different components to obtain a high load-bearing capacity.

**Abstract:** Mortars are traditionally made from a mixture of sand, a binder and water. However, modern factory-made mortars are currently, very complex materials. Indeed, to exhibit various properties from the fresh paste to the hardened material, mortar formulations are composed of many mineral and organic admixtures. Among organic admixtures, polysaccharides are widely used in mortar formulation to improve water retention capacity of the freshly-mixed materials. The water retention capacity is an essential property of mortars to enhance cement hydration and its adhesion to a substrate. Moreover, many polysaccharide admixtures, acting as viscosity-enhancing agents, prevent segregation and improve the homogeneity and workability of cement-based system. Indeed, the viscosity of the system strongly increases using polysaccharides. Nevertheless, polysaccharides, as sugars, act on cement hydration. The main drawback is the retarding effect in hydration mechanism and setting-time of the cement.

The aim of this study is to focus on the effect of guar gum derivatives on fresh state properties of Portland cement-based mortars, such as water retention, rheological behavior and the hydration delay. This work focuses on the guar gum derivatives since their manufacturing process is low pollutant and they provide very good properties to cement-based mortars. The results highlight that the chemical composition of guar gum derivatives (MS, DS, additional alkyl chain) are the key levers to improve water retention of mortars and to adapt the rheological behavior of the cementitious paste to a specific application.

**Keywords:** Cement; HydroxyPropyl Guar; Mortar; Rheology; Water retention.

## 1. Introduction

Modern factory-made mortars are complex materials, in which several kinds of admixtures are added in order to obtain specific properties, from the fresh state to the hardened material. Indeed, since many years, concretes, mortars or cement grouts with high fluidity have been developed, since their use implies many economical and technical advantages. However, the use of highly flowable mixtures may lead to segregation or excessive bleeding and subsequently, durability issues. In order to overcome this problem by enhancing the segregation resistance while maintaining high fluidity, viscosity-enhancing admixtures (VEA) are frequently introduced within the formulation (1,2,3,4). Among these admixtures, natural polysaccharides or their derivatives (such as welan gum, starch derivatives or cellulose ethers) are the most widely used. Moreover, the incorporation of these VEAs in shotcrete or render mortar is useful to ensure sagging resistance for thick application on vertical support, and to allow sufficient fluidity for normal pumpability by supplying shear thinning rheological behavior (5). Indeed, these admixtures provide, generally, high yield stress and apparent viscosity at low shear rate but low resistance to flow at high shear rate (6). However, their mode of action is not fully understood, since results are sometimes contradictory. Water retention (WR) is another essential property of monolayer render at fresh state. Indeed, high water retention improves the cement hydration and limits the absorption of the mixing water by a substrate and thus provides good mechanical and adhesive properties to the mortar (7). Among admixtures enhancing water retention capacity of the freshly-mixed mortars, cellulose ethers (CE) are the most widely used. Nevertheless, hydroxypropyl guar (HPG) are now also well-established in the construction industry as water retention agent for mortars (8,9,10,11). Since HPGs improve two main properties of mortar, they appear as suitable admixtures to be used in render formulation.

The aim of this study is to provide an understanding of the effect of chemical composition and structure of HPGs and its dosage on macroscopic properties of mortars. For this purpose, an original guar gum and five HPGs with specific chemical modifications, such as increase in MS<sub>HP</sub> or substitutions by hydrophobic

units, were selected. The impact of admixtures on the water retention capacity, on cement hydration and on the rheological behavior of mortars was investigated.

## 2. Materials and methods

### 2.1 Mineral products

Mineral products used in this study consist in blend Portland cement (Holcim), lime (Holcim), calcium carbonate (Calcitec V60, Mineraria Sacilese S.p.A.) and dolomite (Bombardieri and Leidi 0.1-0.4mm). The mineral compositions of the commercial Portland cement, CEM II/B-LL 32.5 R according to the European standard EN 197-1 (12), used are given in Table 1.

**Table 1. Mineral composition (% weight) of the investigated cement determined by XRF and XRD-Rietveld refinement.**

Chemical composition (% wt)				Phase composition (% wt)			
Oxides	XRF	Oxides	XRF	Phases	XRD (Rietveld)	Phases	XRD (Rietveld)
CaO	57.87	SO <sub>3</sub>	3.95	C <sub>3</sub> S	54.3	Calcite	28.9
SiO <sub>2</sub>	12.31	Na <sub>2</sub> O	0.99	C <sub>2</sub> S	3.5	Gypsum	3.0
Al <sub>2</sub> O <sub>3</sub>	5.25	K <sub>2</sub> O	1.66	C <sub>3</sub> A	4.7	Quartz	0.9
MgO	1.19	TiO <sub>2</sub>	0.16	C <sub>4</sub> AF	4.6	Free CaO	0.8
Fe <sub>2</sub> O <sub>3</sub>	4.05	LOI	13.7				

The phase composition was determined by Rietveld refinement method (Siroquant V2.5 software) after XRD analysis (D5000, Siemens) and the oxide composition was quantified by means of X-ray fluorescence spectroscopy. The median particle diameters by volume ( $d_{50\%}$ ) determined by means of laser diffractometry with dry powder disperser (Mastersizer 2000 and Scirocco dispersing unit, Malvern) was 5, 15, 20, 300 and 600 $\mu$ m for lime, cement, calcite and both dolomite fine aggregates, respectively.

### 2.2 Organic admixtures

Guar gum is a natural polysaccharide extracted from the seed endosperm of *Cyamopsis tetragonolobus*. This polymer consists in a  $\beta$ (1-4)-linked D-mannopyranose backbone with random branchpoints of galactose via an  $\alpha$ (1-6) linkage (Fig. 1(a)). Hydroxypropyl guar (HPGs) are obtained from the original guar gum via an irreversible nucleophilic substitution, using propylene oxide in the presence of an alkaline catalyst (Fig. 1(b)).

**Figure 1. Molecular structure of original guar gum (a) and HydroxyPropyl Guar (b)**

The manufacture of HPGs has the advantage of having a more reduced impact on the environment than cellulose derivatives. Indeed, guar gum is extracted by simple thermo-mechanical process, exhibits a higher chemical reactivity and is soluble in cold water thanks to its branched-chain structure with a lot of hydroxyl groups. Thus, the chemical modification of the original guar gum requires normal reaction conditions of temperature and pressure, does not generate large quantity of by-products, and requires minimal purification procedure (8). In this paper, five HPGs and an original guar gum provided by Lamberti S.p.A were studied. They exhibit roughly the same molecular weight, around  $2 \cdot 10^6$  g $\cdot$ mol<sup>-1</sup> since they are

all from the same original guar gum (noted HPG 6 in the paper) (13). Table 2 provides a qualitative description of the polymers used. The qualitative substitution degrees are provided by the manufacturers. The molar substitution ratio ( $MS_{HP}$ ) represents the number of hydroxypropyl units per anhydroglucose unit and is less than 3 for the investigated HPGs. The degree of substitution ( $DS_{AC}$ ) represents the amount of alkyl chain per anhydroglucose unit. The only difference between HPGs 1 and 3 is the molar substitution ratio, which increases, while HPG 4 exhibits an additional substitution (short alkyl chains).

**Table 2. Qualitative description of the HPG used.**

	$MS_{HP}$	$DS_{AC}$	Additional substitution
HPG 1	Low	-	
HPG 3	High	-	
HPG 4	High	Low	Short alkyl chain
HPG 6	-	-	-

### 2.3 Methodology

Mortars were prepared according to the following mixture proportions: 12% of cement, 3% of lime, 18% of calcium carbonate, 43% of dolomite Bombardieri and 24% of dolomite Leidi (by weight). The admixtures were in addition to the total dry mixture (i.e. cement, lime, calcium carbonate and dolomite) and are expressed in weight percent by weight of binder (% bwob). Dry mixture was blended in a shaker (Wab, Turbula, Germany) for 10 min. Deionised water was added in order to obtain a liquid-to-solid ratio  $L/S = 0.22$ . The mixing procedure was in accordance with EN 196-1 (14). All tests were carried out, at least, in triplicate and at a controlled temperature. A control test was also performed with a mortar without admixture.

### 2.4 Water retention measurements

The water retention capacity of freshly-mixed mortar was assessed using ASTM C1506-09 standard method (15). It had to be performed 15 min after mixing to measure the water loss of a mortar under partial vacuum. The standardized apparatus was submitted to a vacuum of 50 mm of mercury ( $6.6 \cdot 10^3$  Pa) for 15 min. Then, the water retention capacity, WR, was calculated using the following equation:

$$WR(\%) = \frac{W_0 - W_1}{W_0} \times 100 \quad (1)$$

where  $W_0$  represents the initial mass of mixing water;  $W_1$  is the loss of water mass after aspiration.

All the experiments were carried out at 23 °C. Three classes of water retention can be specified according to the DTU 26.1 (16). The first class (low WR category) contains mortars that exhibit WR lower than 86%. The second class (medium) corresponds to WR ranging from 86% to 94%. The last one (high) is defined by WR higher than 94%, corresponding to the required values in the field of rendering application.

### 2.5 Rheological behavior

The rheological measurements were performed with Rheometer MCR 302 (Anton-Paar), thermostated at 20 °C. The rheological properties of fresh mortars were investigated with vane-cylinder geometry (17,18). The mortar was introduced into the measurement system at the end of the mixing cycle. At 10 min, the mortar was pre-sheared for 30 s at  $100 \text{ s}^{-1}$  in order to re-homogenize the sample and to eliminate its shear history (19,20). After a period of rest of 5 min, the rheological measurements were started (total time = 15 min). The imposed shear rate was decreased by step from 300 to  $0.06 \text{ s}^{-1}$ . At each shear rate, the measuring time was adjusted in order to obtain a steady state whatever the formulation. The samples were systematically submitted to high shear rate ( $100 \text{ s}^{-1}$ ) for 30 s before each imposed shear rate in order to resuspend particles of mortar within the mortar mixtures. The results were expressed as shear stress  $\tau$  according to shear rate  $\dot{\gamma}$  and the Herschel-Bulkley (HB) model was applied to fit the experimental data and used to describe mortars rheological behavior (21):

$$\tau = \tau_0 + K\dot{\gamma}^n \quad (2)$$

where  $\tau_0$  correspond to the yield stress, K the consistency coefficient and n the fluidity index which characterizes shear-thinning behavior of mortar.

## 2.6 Adsorption curves of HPGs on binder

The adsorption isotherms were determined using the depletion method. The non-adsorbed polymer remaining within the pore solution was quantified by means of Total Organic Carbon (TOC) measurements. Prior to analysis, the pore solution was extracted from admixed or non-admixed mortar. The extraction was performed by means of two centrifuging steps. The first step consisted in the centrifugation of around 150 g of mortar at 5000 rpm for 5 min. The supernatant was, afterward, centrifuged again at 14500 rpm for 10 min in order to avoid the presence of mineral particles within the solution. The supernatant was diluted with hydrochloric acid solution at 0.1 mol.L<sup>-1</sup>. The total organic carbon was determined by combustion at 850 °C with a Vario-TOC Cube (Elementar). The adsorbed amount of polysaccharides was calculated from the difference of TOC content of the HPG reference solution and the TOC content of the supernatant.

## 2.7 Conductimetric measurement

Characterization of the delay induced by the studied admixtures on the cement hydration was performed by conductivity measurements. Conductivity measurements were carried out in lime suspension in order to obtain hydration kinetics close to that observed in cement pastes, in spite of a high liquid-to-solid weight ratio (L/S). Conductivity curves were interpreted according to explanations proposed by Comparet et al. (22). As soon as cement came in contact with liquid, the electrical conductivity increased as a consequence of the dissolution of the anhydrous phases. Then, nucleation of hydrates on the grain surface leads to a period where the conductivity evolves weakly. Conductivity then accelerated more quickly. The conductimetric slope is related to the growth rate of the hydration products. Meanwhile, cement dissolution still continued. The conductivity increases to the supersaturation with respect to portlandite and decreases rapidly due to its precipitation. Thus, an electrical conductivity drop is caused by the portlandite precipitation. The portlandite precipitation time was used as a benchmark to classify and to quantify the relative retardation ability of admixtures on cement hydration.

Experiments were performed in lime solution (20 mM), thermostated at 25 °C and continuously stirred. The liquid-to-solid weight ratio (L/S) used was equal to 10. Polymer-to-binder weight ratio (P/B) was fixed to 0.5%. Binder GUM 01 and admixture powders were blended in a shaker (Turbula, Wab) for 10 min before contact with the liquid phase. The control corresponds to the neat binder.

## 3. Experimental results

### 3.1 Impact of HPGs on the water retention property of fresh mortars

Fig. 2 represents the evolution of the water retention capacity of fresh admixed mortars, according to the polymer dosage. The non-admixed mortar exhibits a low water retention capacity of about 72% ± 0.3%. Then, as expected, the water retention increases with the use of HPGs and with increasing polymer dosage, until reaching a plateau with very high WR values (>97%). In the range of polymer dosage studied, the WR values reached for HPGs 3 and 4 are greater than 94% and therefore belong to the high WR class. The original guar gum and, to a lesser extent HPG 1, highlight a very limited impact, regardless of dosage until 0.2%. These results suggest that the substitution of hydroxyl units from original guar gum by hydroxypropyl units increases the WR of mortars. Furthermore, the increase in the MS<sub>HP</sub> (from HPG 1 to 3) improves the WR capacity of mortar, since HPG 3 provides the higher WR despite lower dosage.

The results highlight moreover the positive impact of additional alkyl chain on WR. Indeed, the highest WR are obtained with HPG 4 for the lowest polymer dosages. Moreover, concerning the shape of WR curves, an abrupt change in slope can be noticed for mortars admixed with HPGs 3 and 4, and with HPG1 but only above 0.15%. This occurs for a decreasing polymer dosage from HPG 3 to HPG 4.

Figure 2. Impact of polymer dosage on water retention capacity of fresh admixed mortars

### 3.2 Modification of cement hydration by HPGs

The conductimetric data highlights the impact of HPGs on the kinetics of hydration (Fig. 3(a)). By focusing on the portlandite precipitation time, it appears a wide range of delays induced by the admixtures. Among HPGs, HPG 4 exhibits the weaker delay (4.5 h) (Fig. 3(b)). The most important delay is observed for HPG 1 (17.8 h). The native guar gum induces the lowest delay in the portlandite precipitation. The increase in  $MS_{HP}$  (from HPG 1 to 3) leads to a decrease in the portlandite precipitation time. The comparison between HPG 3 and HPG 4 suggests the low impact of the alkyl chain on the delay of the portlandite precipitation.

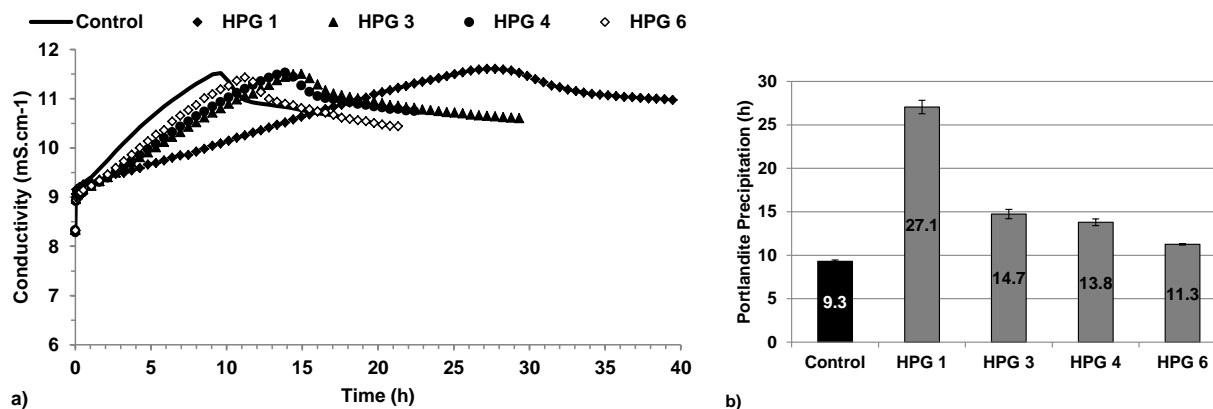

Figure 3. Influence of HPGs on conductimetric curves (a) and on portlandite precipitation time (b),  $[Ca(OH)_2]=20$  mM, L/S=10, P/B=0.5%

The conductimetric curves reveal a very low extension of the duration of the “period of low increase in conductivity” (Fig. 3(a)). This result highlights the weak influence of admixtures on the nucleation of the first cement hydrates. The same results were obtained by Poinot et al. (9). The delay of portlandite precipitation is mainly due to the slope decrease. The slope of the conductimetric curve, being linked to the growth rate of the hydrated cement phases, suggests that HPGs act preferentially on the growth of hydrates, rather than on their nucleation.

### 3.3 Adsorption curves of HPGs on binder

Fig. 4(a) shows the adsorption isotherms of the admixtures on Portland based-mortars. The results confirm the adsorption of original guar gum and HPGs on cementitious materials. It has been shown that the adsorption mechanism of galactomannose polysaccharides at solid–liquid interfaces involves strong hydrogen bonding (23). In the range of polymer dosage used in the study, no plateau was reached, and this, whatever the admixture. For the original guar gum (HPG 6), the adsorption is the highest of all the tested polymers and corresponds to a total adsorption higher than 98.5% of the introduced polymer. The presence of hydroxypropyl substitutions on the guar leads to a decrease in the affinity of the polymer with the binder since the adsorption of HPG 1 is lower by 35% than the original guar gum. Moreover, the

adsorption is further reduced by increasing values of  $MS_{HP}$  (64% for HPG 3 compared to HPG 6). This tendency is consistent with previous studies on HPGs and cellulose ethers (9, 24). Fig. 3(a) highlights also the effect of the additional alkyl chain on the adsorption. It appears that the hydrophobic side chains slightly intensify the adsorption of the hydrophobically modified HPG on surface of grains with respect to HPG 3.

From the TOC measurements, the real polymer concentration within the extracted pore solution was determined. Fig. 4(b) shows the evolution of this concentration versus the introduced polymer dosage. Excepted HPG 6, the amount of non-adsorbed polymer increases with increasing polymer dosage. According to the HPG, the concentration rises following this order: HPG 6 < HPG 1 < HPG 4 < HPG 3.

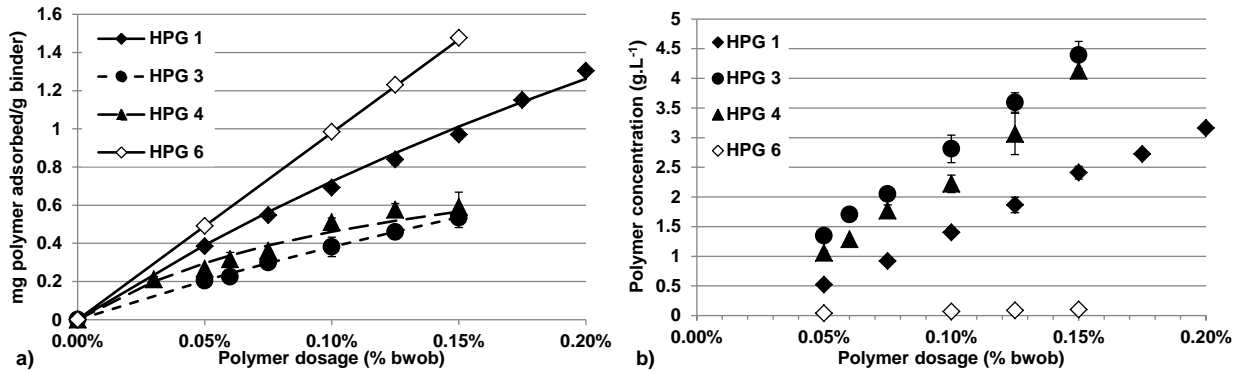

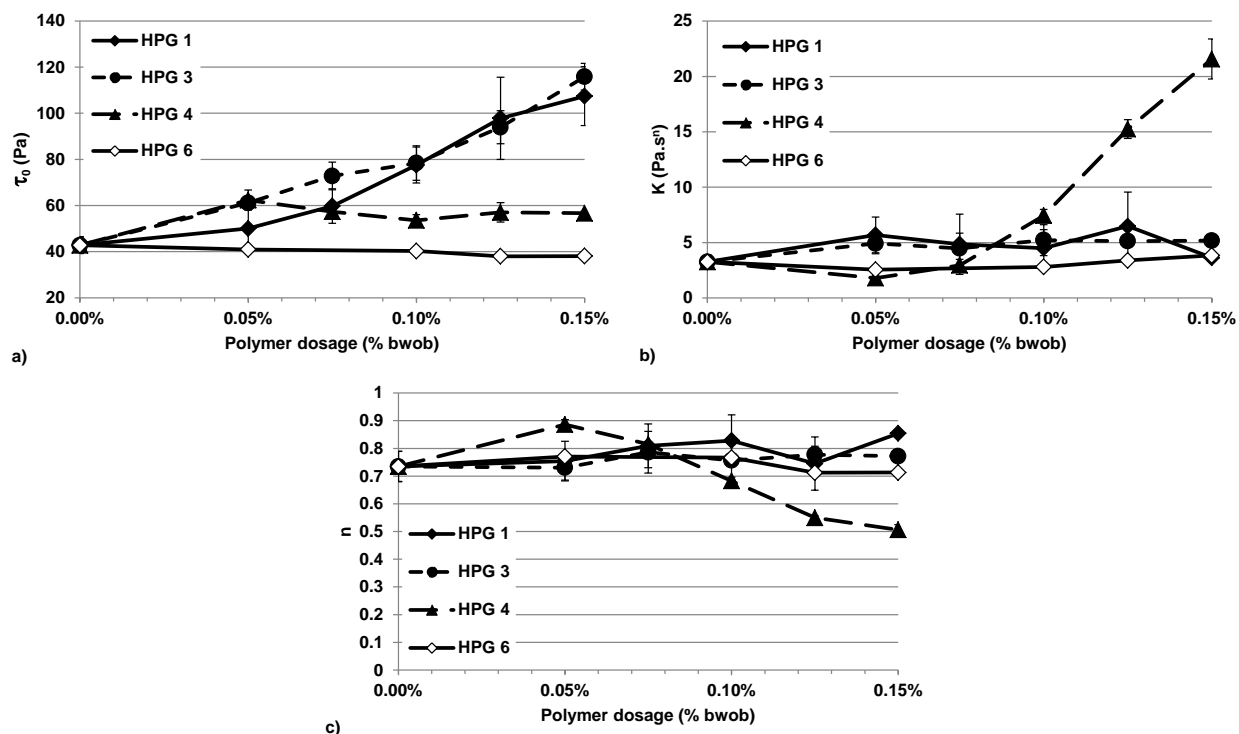

Figure 4. Adsorption isotherms of HPGs 1, 3, 4 and original guar gum (HPG 6) (a) and concentration of HPGs in extracted mortar pore solution (b)

### 3.4 Impact of HPGs on the rheological properties of fresh mortars

Fig. 5(a) shows the evolution of the yield stress, extracted from Herschel-Bulkley model, for all the studied mortars with and without admixture. The mortar without admixture exhibits a yield stress value of around 45 Pa. From the presented results, three different classes of HPG, inducing different evolution of the yield stress with the polymer dosage, can be highlighted for admixed mortars. The first category is only composed of the original guar gum (HPG 6), which induces a low and quasi linear decrease in the yield stress of mortar when HPG dosage increases. On the contrary, HPGs 1 and 3 lead to a continuous rise of the yield stress of mortars from 50-60 Pa to around 120 Pa with the increase in the HPG dosage from 0.05% to 0.15%. Finally, HPG 4 constitutes the third class of admixture. The use of this admixture leads an improvement of the yield stress compared to the non-admixed mortar, whatever the dosages tested in the study. However, the increase is not proportional to the admixture dosage. Indeed, our first dosage (0.05% bwob) leads to an increase in the yield stress. Beyond this dosage, increasing the dosage provides a slow and low decrease, before reaching a plateau. The value of the yield stress reached on the plateau is still higher than that of the mortar without admixture.

The evolution of the consistency coefficient ( $K$  from Herschel-Bulkley equation) during the increase of polymer dosage is presented Fig. 5(b). As in the case of the yield stress, the results can be divided into three classes of polymer. The first class is only composed of the original guar gum which provides a very low or negligible modification of the consistency coefficient with increasing polymer dosage compared to non-admixed mortar. HPGs 1 and 3, constituting the second group, induce first an increase followed by a plateau in the consistency coefficient. Finally, HPG 4 leads to a continuous increase in the consistency coefficient of admixed mortars.

Fig. 5(c) shows the evolution of the fluidity index ( $n$ ) versus the polymer dosage for all the studied mortars. It is worth to note that whatever the mortars, the values of the fluidity index are lower than 1, meaning that they are all shear thinning. Due to the high standard deviation, the value of the fluidity index of mortars admixed with HPGs 1 and 3 and 6 seem to be unchanged as the dosage of HPGs increase. However, HPG 4 leads to a low increase followed by a continuous decrease in the fluidity index until reaching values around 0.5. This means that the shear thinning behavior of mortars becomes more and more pronounced.

**Figure 5. Impact of polymer dosage on yield stress (a), consistency coefficient (b) and fluidity index (c) of fresh admixed mortars (HPGs 1, 3, 4 and original guar gum (HPG 6))**

## 4 Discussion

The effect of the original guar gum (HPG 6) is negligible from the WR point of view. Since the adsorption is higher than 98.5% of the initial amount of polymer, very few molecules are still in the pore solution. The composition of pore solution is thus close to that of the non-admixed mortar, leading to similar WR.

Concerning the hydroxypropyl guar, the results from WR experiments are consistent with those of previous studies performed with HPGs or CEs and with the proposed mechanism. Indeed, the WR of admixed mortars is mainly governed by the ability of polysaccharidic admixtures to form an associated polymer molecules network and to induce overlapping of polymer coils within the pore solution (10,25,26). When the polymer concentration in solution increases, the isolated polymer coils, existing at low concentration, begin to come into contact between them. This concentration is defined as the coil-overlap concentration (noted  $C^*$ ). Above this critical concentration, the polysaccharide aggregates stop the water flow by plugging the porous network of a thin polysaccharide-enriched filter cake at the interface mortar-substrate resulting in a sudden and sharp rise in WR curves (10). The abrupt change in slope is reached for a decreasing polymer dosage from HPG 1 to HPG 3. The only difference between these HPGs is the increasing substitution degree. According to literature, the increase in  $MS_{HP}$  does not lead to a change in  $C^*$  (27). However, the increasing substitution degree leads to a decrease in polymer adsorption on mortar components and hence an increase in polymer amount in pore solution (Fig. 4). Consequently, the coil overlapping occurs at lower dosage. The results highlight furthermore the positive impact of additional alkyl chain on WR. The presence of additional alkyl chains (HPG 4), despite slightly higher adsorption than HPG 3, leads to the formation of polymer associates at lower polymer dosage. Indeed, the interconnection between alkyl chains creates intramolecular and intermolecular interactions through specific hydrophobic interactions which cause a decrease in the coil-overlapping concentration (28,29). Consequently, the abrupt change in slope is reached for a lower polymer dosage of HPG 4 than HPG 3.

It is generally admitted that cement hydration delay induced by admixtures is due to adsorption of these molecules onto surfaces of the hydrating cement particles and/or surfaces of hydration products (30,31). Polysaccharides are molecules which contain a lot of polar functional groups (-OH). Therefore, strong interactions, through electrostatic forces and hydrogen-bonding, can occur between polysaccharides and the highly polar hydrated phases (31). This interpretation is consistent with our results, especially for

HPGs 1 and 3. Indeed, the increase in the  $MS_{HP}$  leads to a decrease in the amount of free hydroxyl groups on the backbone chain and in the polarity of the molecule. Therefore a drop in both adsorption onto the surfaces and delay of the portlandite precipitation, is observed. However, in the case of HPG 4, and more especially for HPG 6, the adsorption of the admixture is higher than that of HPG 3 but the delay in the portlandite precipitation is lower. Therefore, a competitive adsorption of admixture could occur between the constituents of the binder, promoting adsorption onto non-reactive phases (dolomites and/or calcite). To answer to this question, the conductimetric analysis should be carried out only with cement.

The rheological results (Fig. 5) highlight that HPGs 1 and 3, HPG 4 and HPG 6 behave quite differently. Indeed, HPGs 1 and 3 lead to a continuous increase in the yield stress, while HPG 4 modifies mainly the consistency coefficient and the fluidity index. HPGs 1 and 3 affect the rheological behavior of the admixed mortars in the same way, i.e. an increase in the yield stress, a low increase followed by a plateau in the consistency coefficient and a negligible modification of the fluidity index when the polymer dosage rises. Fig. 4(a) shows that HPGs adsorb onto particles constituting the mortar. Prima facie, this adsorption could be responsible for the increase in the yield stress because of bridging flocculation (24). However, despite a strong drop of the adsorption (50%) with the increase in the  $MS_{HP}$  (from HPG 1 to 3) the yield stress also increases. This suggests that the non-adsorbed polymer may be responsible for the yield stress increase. The potential loss of bridging can be compensated by an increase in the pore solution viscosity induced by the rise in the polymer concentration and/or by the depletion flocculation induced by the non-adsorbed coils (32). Moreover, the presence of HPG coils within the pore solution leads to an increase in the consistency coefficient ( $K$ ) compared to non-admixed mortars. However, the expected increase in  $K$  due to the rise of pore solution viscosity with the polymer dosage can be compensated by steric hindrance, leading to a plateau for  $K$ .

Since the adsorption of original guar gum is higher than 98.5%, one expects to detect a very strong increase in the yield stress compared to non-admixed mortar. However, the rheological behavior of the admixed mortar with HPG 6 is very close to that of the non-admixed mortar. This result suggests that the entire molecule of HPG 6 could be mainly adsorbed onto the surface of only one particle, limiting therefore the bridging flocculation. Moreover, the adsorption of the guar molecule onto a single particle leads to an increase in both steric hindrance and dispersion effects, leading to a low but continuous decrease in the yield stress. For dosages higher than 0.1% bwob, the concentration in polymer coils into the pore solution begins to slightly increase, leading to the beginning of the increase in  $K$  and of the decrease in  $n$ .

The additional alkyl chain also modifies the rheological properties of mortars. Contrary to HPG 3, HPG 4 leads to a strong and continuous increase in the consistency coefficient and a decrease in the fluidity index. These results highlight that mortars become more and more shear-thinning since the fluidity index decreases from 0.8 to 0.5. This rheological behavior gets more pronounced as the HPG dosage increases. These results are consistent with the fact that the hydrophobically modified HPG leads to the formation of coil overlapping at lower HPG dosage (0.05% in this study) since the presence of additional alkyl chains enhances the entanglement. Above this dosage, entanglement occurs between polymer coils, inducing a shear thinning behavior to the solution. At low shear rate, the entanglement of polymer coils leads to a higher pore solution viscosity and thus higher mortar viscosity. When the shear rate increases, the polysaccharide chains align in the direction of the flow resulting in less and less effect on mortar fluidity. The shear thinning behavior of the solution, and thus of the mortars, amplify with the increasing polymer dosage. The yield stress is also impacted by the additional alkyl chain. Indeed,  $\tau_0$ , of mortar admixed with HPG 4, increases for a dosage equal to 0.05% bwob then slowly decreases for dosages up to 0.075% bwob, before reaching a plateau for higher dosages. This result could be explained by a change in the HPG conformation due to the presence of additional alkyl chains. Indeed, as previously mentioned, alkyl chain creates intramolecular and intermolecular interactions through specific hydrophobic interactions. Intramolecular association of hydrophobic units tends to force the polymer chain into a more compact conformation (29,33). Moreover, the conformation of hydrophobically modified polymers in aqueous solution involves the presence of alkyl chains inside the coils in order to limit contacts between hydrophobic chains and water (29). Consequently, the hydrophilic groups, such as hydroxyl and hydroxypropyl, are preferentially on the outskirts of the coils, promoting the adsorption onto the surface of particles and therefore steric hindrance which implies a prevention of direct contacts between particles. Moreover, due to a more compact conformation and avoidance between water and hydrophobic units, the bridging ability of hydrophobically modified HPG should decrease. All these points should lead to a decrease in the yield stress.

## 5. Conclusions

In this paper, we studied the effect of several guar gum derivatives on water retention property and rheological behavior of mortars. Based upon the results, it was found that the original guar gum was totally adsorbed onto particle surface, leading to a negligible modification of WR and rheological behavior with respect to the non-admixed mortar. Depending of the chemical structure of HPGs, it is possible to promote the water retention according to two different ways. First, by increasing the MSHP of HPGs, the amount of adsorbed polymer drops, which leads to an increase in the HPG concentration within the pore solution and therefore to lower HPG dosage necessary to reach coil overlapping. Second, by enhancing overlapping, the hydrophobically modified HPGs improve the effectiveness of WR agent at low dosage. HPGs also modify the rheological behavior of the mortars. As in the case of WR, the hydrophobic characteristic of HPGs is the preponderant parameter. Indeed, it was shown that additional alkyl chain mainly leads to a more shear thinning behavior of the mortar and to a rise in the consistency coefficient, while classical HPGs strongly increases the yield stress.

# THE EFFECT OF SUPERPLASTICISERS AND VISCOSITY MODIFIERS ON THE RHEOLOGICAL PROPERTIES OF SUPER WORKABLE CONCRETE

Greg Langton<sup>1</sup> , Gary Boon<sup>2</sup>

<sup>1</sup>Product Technologist, Sika Australia

<sup>2</sup>Technology Manager, Sika Australia

## Abstract

In order to achieve super workable concrete the use of a super plasticiser is required. The selection criteria for choosing a set of admixtures for super workable concrete usually relies on slump, flow and T500 tests to determine the combination to give a suitable concrete rheology for the application. While these tests can be valuable they provide limited rheological information due to the low variation in shear rate applied through gravity.

To better understand the effect of super plasticisers and viscosity modifiers on concrete rheology a range of commercially available PCE (polycarboxylate-ether) super plasticisers and VMAs (viscosity modifying admixtures) were tested using a concrete rheometer. The testing will show the concrete rheology obtained across a broad shear range encompassing the typical forces applied to concrete from static segregation to pumping. Through this testing the yield stress, and thixotropy can be quantified, as well as understanding the phenomenon of sticky and un-pumpable concrete.

**Keywords:** Rheology, super plasticiser, viscosity modifying admixture,

## 1. Introduction

Super workable or self-compacting (SCC) concrete has been increasingly used in the marketplace due to its flow characteristics. It can flow around obstacles such as reinforcement and intricate formwork, gives a better surface finish, and has the benefit of reduced workforce requirement, and improved health and safety conditions due to reduced exposure to noise, vibration and manual handling. The use of a super plasticiser is essential to reduce yield stress to achieve flowable concrete [1]. The introduction of PCE technology gives rise to the ability for customization to optimize the performance of admixtures. PCE admixtures are comprised of long chain polymer backbones to which side chains are attached. The length of the side chains and backbone, and the degree of side chain grafting leads to vast performance differences. This leads to a large number of available products to choose from. As segregation resistance is also an important factor in super workable concrete viscosity modifying admixtures are commonly used in conjunction with superplasticisers. The VMA improves the homogeneity of the mix by reducing the risk of dynamic and static segregation. They achieve this through hydrogen bonding interactions within the aqueous phase causing an increase in yield stress which gives reduction of slump flow [2,3]

Traditional selection criteria for determining an appropriate admixture combination involves testing to determine workability. The slump test is the most commonly performed test for fresh concrete properties due to its simplicity. For flowing concrete the addition of the T500 test is common with the time for the concrete to reach a flow spread of 500mm recorded. These tests give a single point indication of a rheological property commonly associated with yield stress. Other descriptive terms commonly used including "sticky" can give more rheological information that may not be distinguishable through common testing but no quantitative information can be obtained [4].

This paper aims to show the importance of rheological testing in admixture selection for super workable concrete to optimize plastic properties, and quantitatively assess the workability of concrete over a broad shear range applicable to concrete pumping, placement and stability.

## 2. Testing Program

Plastic properties of concrete mixes were investigated while using four PCE superplasticisers sourced from three manufacturers and a starch based VMA. The water cement ratio was fixed and a target slump

flow of 670-700mm was used. The properties measured were slump flow using a standard Abrams cone in the upright position, T500, and rheology using a concrete rheometer. UCS specimens were also cast

## 2.1 Materials

A fixed mix design was used comprising of a 10mm aggregate, and two sands. The binders comprised of a type GP cement – AS3972-2010, GGBFS – AS3582.2-2001, Fly Ash – AS23582.1 - 1998 and densified silica fume - AS3582.3-2002.

## 2.2 Mix Proportions & Mixing Procedure

The binder proportioning and aggregate content is provided in Table 1. A fixed water content was used and adjusted for water contained in the admixtures. The materials were loaded in accordance with AS1012.2. All water and admixture was added within the first minute of mixing, and mixed for 10 minutes using a 70L Bennet pan mixer.

Material	kg/m <sup>3</sup>
Course Aggregate	900
Fine Aggregate	605
Type GP Cement	450
GGBFS	120
Fly Ash	90
Densified Silica Fume	40
Potable Water	180

Table 1: Mix proportions

## 2.3 Rheology Testing

Rheology tests were performed using Rheomix, a concrete rheometer built by the Material Physics department of Sika Technology AG, Zurich. The rheometer includes a steel cylinder with an anti-slippage cage, a rotating double helical spindle geometry [5], and is capable of testing over a broad shear and torque range. After a satisfactory workability is achieved as tested by slump flow, concrete is transferred to the rheometer cylinder and the geometry is attached. An initial manual test is conducted to determine the shear rate required to reach a torque of 20Nm. A test protocol is then assigned comprised of a pre shear increasing the shear rate in logarithmic steps to the predetermined maximum before a step wise reduction in shear rate to 0.01s<sup>-1</sup>. The typical protocol is shown below in graph 1.

Graph 1: rheology testing protocol

### 3. Results and Discussion

Admixture	Dose Rate ml/100kg binder	slump flow mm	T500 s	Viscosity Infinity Pa.s	Yield stress Pa	Amplitude Thixotropy Pa.s <sup>-n</sup>	1D UCS MPa
PCE-A	700	700	5	162	97	28	34.5
PCE-B	1060	690	4	45	23	9	25.5
PCE-C	700	670	5	147	248	98	34.5
PCE-D	820	690	3	66	36	9	33.0

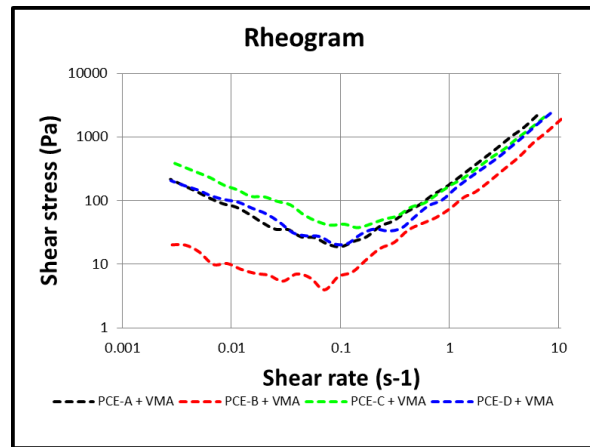

Table 2: PCE test results

Admixture	Dose Rate ml/100kg binder	VMA Dose Rate ml/100kg binder	slump flow Mm	T500 s	Viscosity Infinity Pa.s	Yield stress Pa	Amplitude Thixotropy Pa.s <sup>-n</sup>	1D UCS MPa
PCE-A	845	500	690	4	112	28	2	34.5
PCE-B	1261	500	690	4	49	6	0.3	21.5
PCE-C	810	500	680	5	105	51	8	33.0
PCE-D	930	500	690	5	87	31	4	31.5

Table 3: VMA test results

Graph 2: PCE rheograms

Graph 3: VMA rheograms

Table 2 shows the results obtained from four PCE samples. The admixture dose was fixed to achieve a target slump flow of 670-700mm. It can be seen that differing viscosity and yield stress are seen across the four tested PCE's. This suggests differing modes of dispersing action between admixtures. It can be seen from Graph 2 that PCE-C and PCE-D give lower yield stress than PCE-A and PCE-C. This would suggest improved flowability and an improve in placement. PCE-C and PCE-D also have a lower viscosity infinity. This gives an improvement in pumpability due to lower shear stresses being developed at higher shear rates. The lower viscosity achieved also gives the concrete a better feel (soft vs sticky). Difference is also seen in thixotropy, with PCE-C and PCE-D having a lower increase in shear stress that the added admixtures have improved dispersion effects at low shear rates. A lower 1 day compressive strength was seen with PCE-B. This is most likely due to retardation effects.

Table 3 and Graph 3 shows the results obtained when a dose of a starch based VMA is dosed with the four tested PCE's. As VMA's increase yield stress which leads to an increase in stability and loss of fluidity the dose of all PCE's had to be increased to maintain the target slump flow. From table 3 it can be seen that there is a reduction of the yield stress, and amplitude thixotropy when the tested PCE's are used with a VMA at a fixed slump flow. There is also a viscosity reduction for PCE-A and PCE-C, while an increase in viscosity is seen with PCE-B and PCE-D. A reduction in compressive strength at 1 day is seen with PCE-B to PCE-D when tested with the VMA. This is likely due to an increase in retardation due to increasing PCE dose to maintain the slump flow.

Graph 4: PCE-A vs PCE-A with VMA

Graph 5: PCE-C vs PCE-C with VMA

Graph 6: PCE-B vs PCE-B with VMA

Graph 7: PCE-D vs PCE-D with VMA

Graphs 4-7 compare the rheology between the tested PCE's and with the addition of a VMA. In graph 4 and 5 it can be seen that the addition of VMA with a fixed slump flow the yield stress is reduced leading to a more flowable concrete. The reduction in viscosity will also improve the pumpability of both mixes. Graph 6 shows a lowering of yield stress. Due to the low values achieved there is some noise in the results obtained under a shear stress of 10 due to the measurement resolution. In both graphs 6 and 7 an slight increase in viscosity is seen. From the above results it is clear that interactions between different PCE admixtures and the tested starch based VMA give differing rheological effects that cannot be measured by slump flow and T500 testing.

### 3. Conclusion

Through testing super workable concrete using a concrete rheometer over a broad range of sear stresses, detailed comparisons can be made between mixes to determine the most appropriate flow behavior for the application. The choice of superplasticiser has a large impact on the rheology of concrete with differences in yield stress, viscosity, and thixotropy being seen in the four tested admixtures. The inclusion of a VMA with an increased superplasticiser dose to maintain slump flow reduces yield stress and

thixotropy, and has variable impacts on viscosity. In determining a suitable admixture combination for super workable concrete the use of a concrete rheometer allows a fast and accurate characterization of concrete flow characteristics over a wide application range that cannot be determined by traditional single point testing such as slump flow and T500.

# Durability and Serviceability

# Concrete Durability Performance Testing – The Approach Adopted in a Concrete Institute of Australia Recommended Practice

W. Green<sup>1</sup> and F. Papworth<sup>2</sup>

<sup>1</sup> Corrosion Engineer, Vinsi Partners

<sup>2</sup> Managing Consultant, BCRC

**Abstract:** The Durability Series is a set of Concrete Institute of Australia recommended practices that provide deemed to satisfy requirements applicable to all concrete structure types based on standard input parameters for design life, reliability and exposure. The series includes details on project planning and implementation which if followed will increase the likelihood that the specification, design detailing and construction will be optimal to achieving the asset owner and community expectations regarding the long term performance of concrete structures. Also included are methods for modelling degradation over time and for crack control design. Thus the series provides what is described as a unified durability design process. This paper outlines the document in the series dealing with durability performance tests applied through design, construction and operational service life, i.e. Z7/07 Performance Tests to Assess Concrete Durability.

Z7/07 provides guidance on performance tests specific to the requirements of durability design, implementation and maintenance management. The document is intended to inform all parties involved in design, construction and maintenance about the benefits of durability performance testing and how as part of a durability planning and implementation process will lead to an increased likelihood of achievement of design life of concrete structures and buildings.

**Keywords:** durability, performance, testing, laboratory, field.

## 1 Introduction

In terms of durability performance testing, there has been a wide range of tests introduced to Australia over the years and this has caused considerable difficulty for:

- Asset Owners - appropriateness and the most cost effective testing regimes to achieve the outcomes and level of certainty sought.
- Designers –which tests are the most appropriate to specify and how much test data is required to ensure an appropriate level of statistical confidence from the test results underpinning the design is appropriate.
- Contractors – understanding and having confidence in the consistency, repeatability and validity of trial data and any quality control performance testing.
- Suppliers of Laboratory Testing Services – costs of registration for a wide range of tests despite some being rarely called for.
- General Users –gathering sufficient data to know the statistical confidence in the methods.

Durability performance testing can be required throughout the life of a project including the concept design stage (materials testing/trials, exposure assessment), design phase (concrete mix compliance), construction phase (concrete quality control testing) and the operation and maintenance phase (inspections, monitoring in situ service life performance). Z7/07 (1) provides an outline of durability performance testing under the following main headings:

- Mix Acceptance Tests

Testing during the design phase is conducted to support the design process, in particular to demonstrate that the combination of design details and practical concrete supply to the project will yield the desired performance.

The test methods are primarily required to provide measurements that are relevant to the potential durability of structural elements in specific exposures, and these values are used in predictive modelling processes to inform design decisions or to show a certain performance level has been achieved.

Prior to commencement of construction, trial mixes are generally required to produce samples for testing to demonstrate that the proposed mix design, using materials available to the project site, is suitable for the design life, exposure conditions and method of application.

- Tests For Quality Assurance

Quality assurance/control tests are primarily required to demonstrate consistency of supply in conformance with the works (project) specification and the properties established by acceptance trial mixes. Timeliness of results is therefore a highly important criterion, generally superseding the requirement to produce values for modelling purposes. Although strength tests of concrete are routine, durability tests are not and the type and frequency of tests must be specified in the project contract documents.

- Tests Where Placed Concrete is Suspect

The concrete performance in the field will differ to that in the trial mixes. To assess the extent of this, performance tests on the as-placed concrete might be required. This is often by non-destructive testing, or testing cores for strength or other properties. Such testing may be undertaken where there is doubt that the construction method or materials will have provided the required performance (e.g. routine testing has revealed an anomaly or trend of concern), or to verify the efficacy of the routine quality control testing program.

- Tests For Condition Monitoring

During the life of a structure it is necessary to check that the concrete is responding to the environment as expected. It is also often necessary to assess the residual life of the structure in order to determine what intervention is necessary (and when best performed) to reach the design life, or to assess the feasibility of extended operational service life. Some specifications now require that the maintenance manual for the structure be prepared at the time of design and that this include the type, frequency, extent and criteria for in-service testing.

For all test methods the limitations and advantages are given and where possible the variance of the test results stated. Variance is a major consideration in assessing the number of test results required and hence the practicality of applying the test.

## **2 Sampling and Sample Preparation**

Sampling and sample preparation requirements for fresh concrete and hardened concrete (including laboratory specimens and samples taken from in-situ concrete) and the frequency and extent of sampling are all necessary considerations prior to any durability testing whether it be concrete mix acceptance testing, quality assurance testing, testing where placed concrete is suspect or condition monitoring testing.

The accuracy of any test result is strongly influenced by the quality of the sample tested. Thus representative sampling, sample preparation, and the repeatability and reproducibility of the method are critical features. A sample may comprise one specimen or several replicate specimens. Several replicate specimens may be needed to comprise a representative sample of the concrete of interest.

The requirements for sampling fresh concrete are well developed in Australian Standards as it applies to compressive strength cylinders and these cylinders are generally used for other durability tests. However, Australian Standards only nominate requirements for compressive strength samples, the project concrete specification must nominate the number and type of samples required for durability related testing in addition to the frequency of sampling.

While the standard compaction procedures described in Australian Standards are satisfactorily consistent for measurement of macroscopic properties such as compressive strength, testing of durability related properties are inherently more sensitive to the microstructure and continuity of voids within the concrete. Published systematic repeatability studies of water permeability testing (2) have shown that consistency of concrete compaction of the sample is the primary factor that influences the often perceived poor repeatability/reproducibility of durability related tests. Compaction of test specimens using a vibrating table is preferred to other methods because it consolidates concrete with relatively little effort, therefore is the easiest way to consistently achieve good compaction in all samples. Where due care is taken in compacting the concrete, coefficients of variation for water permeability and absorption tests, for example, are comparable to those for compressive strength testing.

However, it is noted in Z7/07 that “durability” samples should not be given “special attention” to try and produce particularly high levels of compaction in order to secure favourable test results. For example, forensic investigation of past instances of failure to comply with specified water permeability criteria has found that over-zealous compaction can result in the formation of microstructural features such as segregation and bleed channels that adversely affect test results, even to the extent of compromising specification compliance (2).

The method of standard curing of concrete cylinders in temperate and tropical climates is well defined in Australian Standards. However, it is sometimes necessary to employ non-standard curing conditions in order to reflect the conditions under which the concrete will cure on-site. Examples of this include:

- Early age steam curing of precast elements.
- Temperature matched curing for maturity calculations.
- Unusually cold or hot conditions.
- Insulated conditions.
- Trial mixes that are performed in a different climatic zone to the project site.

Where non-standard curing conditions are required, these must be described in the project concrete specification.

Sampling from a concrete structure is often required to assess one or more properties. The sample type, size, locations and frequency of collection will depend on the properties to be determined, the reliability required for the results and the practicalities and cost of testing. Many test methods have specific requirements for the size and condition of samples. Unless sampling particular anomalies, a primary requirement is often to ensure that the extracted samples represent the bulk of the concrete in terms of properties such as aggregate distribution and voids.

The most common method for taking samples is by wet diamond coring. Where this is not convenient, drilled dust samples or dry grinding core cuts may be taken. A Section of the Z7/07 document (1) describes procedures for taking all three sample types.

Before taking the sample, the reinforcement position should be located and marked so that the sample can be taken over the reinforcement to inspect the physical condition of the reinforcement and measure the cover depth for verification of cover meter readings, or to avoid the reinforcement as required.

Furthermore, before taking the sample the concrete surface should be inspected and any defects recorded.

### **3 Concrete Mix Acceptance Tests**

If durability testing is required, the project specification should include:

- Test method according to some publicly available method.
- Sampling method (including curing), sample geometry and size (unless included in the method).
- Frequency of test and number of test specimens to be used to give one result (unless included in the method of test).
- Acceptance criteria (including tolerances) or details to be reported (if not clear in the method of test).

#### **3.1 Chloride Diffusion Tests**

While test methods have been developed that effectively measure chloride diffusion, there is still considerable debate about how these results should be applied. Tests that give the most precise estimate of chloride diffusion take a long time to complete. The original “steady state diffusion” (SSD) method of measuring chloride diffusion involved placing a sample in a cell with a chloride solution on one side and a solution with no chlorides on the other. The chloride concentration in the receiving cell was measured over time until a constant chloride ion concentration was achieved. The chloride diffusion coefficient was then calculated. However, the diffusion coefficient could take six months or more to measure, and require many chloride analyses. Because of the slow rate of increase in chlorides in the receiving side of the cell, it is easy to assume a steady state has been reached when it has not. This can lead to reporting of optimistic diffusion coefficients.

Rapid tests have been developed whereby the diffusion of chlorides is driven by a potential difference. The property measured under these conditions is often described as chloride migration rather than diffusion. The relationship between the results from rapid tests and the longer term tests is determined by the pore water chemistry of the individual concrete, which in turn is determined by the cement and supplementary cementitious materials (SCMs) chemistry, batch water supply, and admixtures. Therefore there is no universal relationship between results from each type of test, although calibration curves can be determined for individual concretes if required.

A range of test methods also exist for measuring or inferring the sample’s chloride ion diffusion coefficient. These include “non-steady state diffusion” (NSSD) and “non-steady state migration” (NSSM) methods. The resistance to chloride ingress is typically expressed as the chloride diffusion

coefficient. Because the test result is influenced by other ions present in the concrete, the result is often referred to as the apparent diffusion coefficient.

In Australia, the NordTest NT Build 443 (3) method is commonly used to test and pre-qualify concrete mixes for use in chloride-bearing environments. An alternative standard, ASTM C1556-11a (4), is based on NT Build 443. Although there are procedural differences between the methods, any effect on the test results has not been published at the time of writing such that the two methods are expected to produce similar results for practical purposes.

The diffusion coefficient will change with time as the concrete matures, therefore the age at which the test is carried out will determine the results. Thus apparent diffusion coefficients determined at early ages do not represent ultimate diffusion rates, particularly for concretes containing fly ash or slag.

Curing is followed by exposure to a chloride solution for at least 35 days. For a reliable result, the exposure period must be long enough for a measurable chloride ion concentration profile to develop. For high performance concretes, particularly those containing SCMs, exposure for 56 days or more is necessary to give time for sufficient chloride ions to penetrate.

NT Build 443 (3) or ASTM C1556-11a (4), modified in terms of a specific sample curing regime and to be consistent with standard Australian laboratory practice, are the recommended test methods for establishment of a concrete's chloride diffusion coefficient.

The 'modified NT Build 443 or ASTM C1556 method' is as follows:

- Production of concrete cylinders of dimensions used for standard compression test to AS 1012.8.1 (5).
- Curing of concrete cylinders to AS 1012.8.1 (5) to 28 days. This curing applies only to Portland and blended Portland cement concretes. The curing of other non-Portland cement binders is to be separately specified.
- At the age of 28 days, the specimens shall be exposed to water containing sodium chloride in accordance with NT Build 443 or ASTM C1556 at  $23 \pm 2^\circ\text{C}$ .
- The period of exposure to sodium chloride solution shall be 56 days typically.
- For core samples they shall be kept wet until delivery to the test laboratory. They must be representative of the concrete and/or structure in question and the concrete must be hardened to a minimum of 28 maturity-days.

There are no universal acceptance criteria for this test, as the required value is calculated based on modelling analysis. The following two-step process can be followed when specifying the chloride penetration resistance:

- 1) Establish a mean diffusion coefficient that gives the design life required by diffusion modelling and any allowances considered appropriate to provide a margin for error. It is essential that model values are reviewed by an experienced professional in terms of what can reasonably be expected to be achieved in practical concrete production prior to incorporation in a works (project) specification, otherwise there is a risk of specifying impractically low values that cannot be achieved in practice.
- 2) Specify the maximum diffusion coefficient to be achieved, or note the desired value and require that the actual value be reported. It is recommended that a specified value only be set where local suppliers have experience in meeting the proposed specified value. If local suppliers do not have the necessary previous experience in making this type of concrete then they will need to carry out trial batching to demonstrate they can produce this type of concrete with satisfactory consistency.

### **3.2 Carbonation Rate**

Under normal atmospheric conditions the deemed-to-comply concrete grade and cover requirements of Australian Standards will generally provide adequate protection. Because carbonation alone rarely causes significant corrosion, carbonation rate tests are not generally undertaken. However, carbonation rate testing is sometimes required, for example when:

- A mix does not perform well in general quality tests and the actual carbonation resistance of the mix is required.
- Non-standard materials are used and their performance has to be specifically assessed.
- The in-situ carbonation rates are high and/or the design life is 100 years or more, and a specific assessment of the concrete needs to be used to determine cover requirements.

Testing for carbonation rate is relatively simple. Concrete samples are cured for an appropriate time and are then placed in an airtight tank. The carbonation rate is accelerated by using a higher than

normal CO<sub>2</sub> content in the tank while temperature and humidity are held at a standard level. The CO<sub>2</sub> content must not be so high that it affects the chemical reactions that occur, or the morphology of the reaction products. When the results are used in modelling, allowance is made for the effects of actual exposure conditions compared to those in the tank.

The “Accelerated Carbonation Test” as detailed in FIB Bulletin 34 (6), modified to be consistent with standard Australian laboratory practice, is recommended in the Z7/07 recommended practice (‘modified FIB method’).

In the “FIB method”, the carbonation rate is accelerated by testing at a carbon dioxide concentration of 2% which is approximately 50 times the normal atmospheric CO<sub>2</sub> concentration but not so high as to change the reaction mechanisms or the morphology of the reaction products. After curing, concrete samples are exposed for 28 days. Thus, ignoring other factors the carbonation depth achieved during the test will be achieved in-situ in approximately four to five years (depending on wet/dry cycles in-situ).

### **3.3 Water Absorption and Sorptivity**

There has been a proliferation of this type of test in Australia. This may be due to the lack of clear standards being available before different methods were adopted by local authorities and variations of different tests were introduced into concrete product standards. A compounding factor is the different requirements of the test in different applications.

Absorption tests measure the total weight gained by concrete immersed in water. Absorption tests focus on filling the voids in concrete without reference to the rate at which this occurs, although in some tests water might only partially fill the voids. Results can be used as mix acceptance tests, but they cannot be used for modelling. Absorption test results are often referred to as the “volume of permeable voids (VPV)” or the “apparent volume of permeable voids (AVPV)”. Absorption values are expressed as percentage void space by volume of sample, or less commonly as the mass of absorbed water as a percentage of the dry mass of sample.

In contrast, Sorptivity tests measure the rate of water absorption. The results can be used in formulae for assessing the depth of penetration of water with time under capillary action. Sorptivity is measured by placing concrete in contact with water with no pressure head and measuring weight gain with time to obtain a sorptivity value. The corresponding visible height rise is often also measured, however this is a less accurate method for calculation of a sorptivity value. The result can be used for modelling of water ingress due to capillary rise, and can also be used as a quality assurance test. Sorptivity values are calculated as volume absorbed per unit surface area related to the square root of time, e.g. mm<sup>3</sup>/mm<sup>2</sup>/min<sup>½</sup> which is often reduced to mm/min<sup>½</sup>.

Both absorption tests and sorptivity tests are widely used in Australia for mix acceptance and quality assurance. Absorption tests are simple, therefore preferable where data for modelling is not required, while sorptivity tests are used where modelling of water ingress is required.

AS 1012.21 (7) is an Australian adaptation of the ASTM C642-06 (8) absorption test. In the AS1012.21 test method cylinders or cores are cut into four equal slices so that several results are obtained from one test specimen. The slices are dried to a constant weight then immersed and boiled in water in order to saturate the concrete’s permeable voids and thus give a measure of the total pore volume. Extensive work by VicRoads (9) has enabled them to assess the potential durability of concrete, as indicated by AVPV results, for concrete of different grades to ensure a high reliability that the mixes will be durable in the exposure for which they are intended.

The Taywood Sorptivity Test (10) was originally a brick test. Recognising the significance of the rate of water ingress due to capillary action, as opposed to tests which only measure the volume of pores, the original brick test was adapted for concrete in the late 1970’s. The test is mentioned in UK Concrete Society Technical Report TR31 (10) but was never standardised. The test has continued to be used by many people who had developed an understanding of concrete quality through the extensive use of this method and it is used in Australia for modelling purposes.

The ASTM C1585-11a (11) sorptivity test is relatively simple to undertake. Although it takes slightly longer than the Taywood Sorptivity Test and with shorter history of usage in Australia, it gives results that are more representative of in-situ concrete, and is an international standard. The fact that it is more representative of in-situ concrete is significant for modelling, which is a major advantage over alternative tests.

Recommendations in Z7/07 are:

- Where a general test of concrete quality is required for mix assessment or quality control it is recommended that the AS 1012.21 (7) AVPV test is used because it is already standardised and guidelines for interpretation of test results have been published, albeit for specific concrete mix designs.
- Where a sorptivity rate is required for use in modelling, the ASTM C1585 (11) test should be specified. This is because its method of specimen preconditioning means its results will more closely reflect the in-situ sorptivity.

The Z7/07 Recommended Practice also includes an analysis of assessment methods for water permeability, semi adiabatic tests to predict concrete adiabatic temperature rise, alkali aggregate reaction, delayed ettringite formation, sulphate resistance, abrasion resistance and concrete bleed.

## **4 Tests for Quality Assurance**

Testing for assurance that durability achieves expectations is undertaken throughout construction to verify durability is not compromised by unforeseen construction or material matters that may influence concrete performance.

### **4.1 Compressive Strength**

Z7/04 (12) notes that “One of the reasons that compressive strength is such a useful tool is that it is relatively simple to do, has a well-established methodology and hence low variance and established criteria for acceptance and sharing of risk. As such it is an essential part of the durability testing suite of tests”. However, it also notes that maintenance of the trial mix actual strength should be considered and provides a recommendation to that effect.

### **4.2 Cover**

After fixing the reinforcement and having largely completed formwork and screed rails in place the cover can be physically measured to ensure that it is within specification. This checking is particularly important as in some locations cover checking will not be practical after the concrete is placed. In these locations it also will not be possible to establish the cover distribution for residual life assessments later in the structure’s service life. Consequently Z7/07 provides a recommended procedure for pre-pour cover checks.

The placement of concrete can move the reinforcing within the formwork. It can either be weighed down or shift because of vibration, insufficient spacers etc. Confirming that the correct cover has been achieved is important to ensure that the construction process is properly managed. Where errors are made during construction of the first element, catching this early can prevent the problem persisting through every element. It is in the contractors’ interest to undertake post-pour checks on early pours to ensure the construction method will provide the cover specified, rather than checking cover at the end of a project and thus risk finding all pours have a cover deficiency due to a systematic error. Through the life of the structure the cover distribution will also be important for residual life assessments. Hence, Z7/07 includes a recommended procedure for post-pour cover checks.

### **4.3 Cracks**

If cracks form, investigation is required to determine whether they are acceptable or should be repaired. Whilst the design crack widths may be a guide, the actual cracks require specific evaluation of their likely significance over the design life. The cause and significance of cracks formed should be evaluated. Measuring crack width at the concrete surface to determine if the crack exceeds a given limit is not as straightforward as it seems because the width varies along the crack length. In addition, the crack width changes with concrete temperature (i.e. cracks close as the temperature increases) and moisture content (cracks close as concrete moisture content increases).

Z7/07 provides the following recommendations on crack measurement:

- a) The width values should be reported as maximum for each crack. A mean and distribution (with variance) can then be assessed for comparison with the design values.
- b) A measuring magnifier be used to give an accuracy of  $\pm 0.05$  mm. Crack width meters are suitable for first estimates of crack width (e.g. to assess which cracks need to be measured) but accuracy is only about  $\pm 0.1$ mm so they are not suited to more accurate assessments. With an appropriate crack width distribution the characteristic crack width can be assessed and used as the crack width.
- c) Crack widths should be measured during the coolest part of the day when they have a maximum width. This will make decision making conservative.

- d) Concrete core samples of 50 mm diameter can be taken through representative crack positions to the interior reinforcement depth to evaluate the crack depth and width beneath the concrete surface. When the core is removed from the structure, the loss of restraint from the surrounding concrete may result in widening of the crack, which requires evaluation for the specific crack and the measured crack width impact on durability, structural adequacy and contract requirements.

#### **4.4 Electrical Resistivity**

Electrical resistivity of saturated concrete is influenced by the nature of the cement (binder) system and in particular the use of SCMs, certain admixtures and water/cement (binder) ratio. Changes to binder composition and admixtures may not have a significant effect on strength, and hence resistivity is a useful quality assurance test on the concrete mix. There are two common types of resistivity test:

- Tests that are designed to measure resistivity, such as the 4 probe Wenner resistivity test.
- Tests that were designed to measure chloride ingress rate but in fact measure resistivity, e.g. Rapid Chloride Permeability Test, RCPT (i.e. AASHTO T277 (13) and ASTM C1202-12 (14)). RCPT tests are complex tests compared to resistivity and hence Z7/07 recommends that this test type not be included in specifications.

The four probe Wenner method of measuring concrete resistivity was developed for soils investigation and is used extensively to assess the resistivity of different soil layers. In this method four probes are spaced at equal distances apart. A current is passed between the outer probes and the voltage generated is measured between the inner two. In the adaptation of the test for concrete the probes are placed closer together than in soil tests. AASHTO TP95-11 (15) recommends a spacing of 1.5" or 38 mm. Different models of test equipment offer different probe spacings.

When used as a check on concrete variation, there are no established criteria for the test results. It is the variation in resistivity that is significant and the variation should only be used as an indication that there might be something untoward with the concrete that requires further investigation.

Temperature has a significant effect, therefore laboratory tests must be undertaken at a standard temperature (e.g.  $23\pm 2^{\circ}\text{C}$ ). Moisture content also has a significant effect, and hence samples should be tested for resistivity within 15 minutes of removal from the water bath. If core samples are to be tested, they should be preconditioned to a saturated state in accordance with AS 1012.14:1991 (16).

For structures in severe exposures it is recommended that:

- 1) 4 probe Wenner resistivity be measured in accordance with AASHTO TP95-11 (15) or equivalent to determine the mean resistivity for the concrete based on results from multiple batches with tests on three cylinders from each batch.
- 2) 4 probe Wenner resistivity be measured in accordance with AASHTO TP95-11 or equivalent on all 28 day age compressive strength tests undertaken. If resistivity trends up and results fall to 20% below the average result in the trial mix, then the designer and/or durability consultant should consider what actions should be undertaken to bring the mix back to the performance of the trial mix.

Z7/07 also includes an analysis of assessment methods for maturity, in-situ temperature and strain measurements and cross-hole sonic logging.

## **5 Tests Where Placed Concrete is Suspect**

The performance of a concrete in-situ will differ to its performance in trial mixes or laboratory tests on quality control samples taken during construction. Testing of as-placed concrete is not a common requirement, as in-situ concrete quality is generally accepted as being adequate if the mix supplied is in accordance with the specification and there is no reason to suspect that placing, finishing and curing were substandard. However, testing of the as-placed concrete during construction might be required for assurance of durability when the concrete mix, placing, or curing is suspect. This is analogous to non-destructive testing (NDT), or testing of cores for strength where the designer or contractor is not satisfied that the method of construction will provide the strength specified.

Z7/07 reviews tests for many aspects of concrete assessment and only the more common aspects are included here.

### **5.1 Cover**

Both the reinforcement location/spacing/position and the depth of cover over reinforcement are important, and may need to be determined when investigating the quality of a concrete placement.

The types of equipment available for non-destructively locating reinforcement and measuring its cover depth include magnetic reluctance and pulsed eddy current covermeters, ground penetrating radar (GPR) and ultrasonic pulse echo (UPE). The applications, limitations and recommended procedures for these are described in Z7/07. It is concluded that each instrument has its place. For example:

- Magnetic reluctance covermeters were first developed in 1955 and the method measures small changes in the electromagnetic field of the core, and it can be strongly affected by variations in the core e.g. temperature, external magnetic fields. Devices might have different heads with varying coil arrangements for specific purposes such as determining cover of congested reinforcement, measuring cover in different depth ranges, and for bar diameter estimation.
- In the pulsed eddy current method a pulse of current creates a magnetic field through the coils in the instrument, which induces an eddy current in the reinforcement. Devices have different heads with varying coil arrangements for specific purposes such as determining cover around core holes, measuring cover in different depth ranges, and for bar diameter estimation. Alternatively, various coil types might be housed in one measuring head and are tuned for sensitivity to bar spacing or cover depth. These coils can then be interpreted conjunctionally to give greater functionality.
- Widespread cover surveys are possible with small hand held GPR units and as it is not influenced by steel mass prior knowledge of the reinforcement layout is not required and complex and heavily reinforced sections can be measured. However calibration is vital.
- Higher performance GPR equipment is available that can detect reinforcement at greater depths, but its use is rarely warranted for development of cover distributions as the units are more cumbersome and more expensive. These units can be useful to measure reinforcement locations on both faces.
- Where cover is critical and reinforcement bars are masked by steel fibres, UPE is a consideration for post-pour quality assurance checks of standard rebar (e.g. edges of precast segments).

## **5.2 Compressive Strengths**

Tests for concrete strength fall into two main categories, destructive tests and non-destructive tests. Destructive tests give a definitive value directly measured from the structure, but as they damage the concrete they are generally restricted and only provide information about the small area tested. Non-destructive tests can be carried out over wide areas on the structure. However, they do not definitively measure strength, and accurate interpretation of results requires calibration against results from tests on laboratory specimens or destructive in-situ tests.

Measuring compressive strength of concrete in an existing structure will generally involve a combination of non-destructive tests (i.e. no concrete removal) and destructive tests (e.g. core samples extracted). The amount of concrete removed must not reduce the structural capacity or other performance parameters of the element.

CIA Z11 [17] gives general guidance on evaluating concrete strength from the results of testing cores taken from the structure. It describes the reasons for strength evaluation by the use of cores, and how to obtain cores from concrete structures so that they will be suitable for testing and the test results will be "significant" in the true statistical sense. Steps in the determination and evaluation of concrete strength from the results include providing for corrections to the indicated compressive strength of the core for length to diameter ratio of the core; presence of reinforcement in the core; position of the core axis in relation to the standard cylinder axis; age of the concrete; quality of compaction of the concrete; and, the curing regime experienced. A feature of the correction for quality of compaction of the cores is a series of photographs of concrete of known void contents. This visual means of correcting for excessive voids in the cores is presented with an alternative procedure using actual density measurements of the cores [18].

Z7/07 recommends that the practices in CIA Z11 be followed, with extra interpretation as in BS EN 13791 [19] and associated documents.

Z7/07 also reviews various non-destructive test methods for strength assessment of concrete. Although useful tools for an indication of strength they are more generally useful to indicate strength variations with core results used to gauge the strength of zones defined by NDT measurements.

## **5.3 Detecting Defects in Concrete**

Defects may be detected to a limited extent by visual inspection of the surface and/or core samples. A range of non-destructive test methods is available for determining whether defects are present over wider areas. Z7/07 indicates that many tests have a role to play in detecting defects and use of two or more tests in conjunction with each other generally provides a superior assessment. Tests

summarised in Z7/07 include ultrasonic pulse velocity (UPV), ultrasonic pulse echo (UPE), impact echo, impulse response and ground penetrating radar (GPR).

#### **5.4 Assessment of Concrete Surface Quality**

The quality of the concrete surface greatly influences the durability of the concrete. In turn, the surface quality is determined largely by curing method and duration. Inadequate curing may reduce compressive strength, but the effect on durability is likely to be greater. When the quality of curing is suspect, measurement of the surface's resistance to ingress of water or air by methods such as those described in Z7/07 (initial surface water absorption and torrent air permeability) is possible but is not frequently done.

The biggest issue with these types of tests is that the test result is affected by the concrete moisture content. Consequently, care is required when interpreting the results. They are also influenced by the surface finish/texture, which may affect the correct functioning of the test equipment. The most common methods of assessing the quality of as-cast concrete is to take samples and measure the performance using laboratory tests such as water sorptivity or volume of permeable voids (VPV) although a test related directly to the mechanism of deterioration may be considered.

### **6 Condition Monitoring**

Condition monitoring is an asset management function undertaken to assess whether a structure is still able to fulfil its levels of service and how it is performing with respect to its design life. This informs the asset owner on future maintenance expenditure and when either major renewals and/or replacement of the asset should be planned.

Monitoring is not solely collecting and storing data. It requires the data to be interpreted, and decisions made about when intervention is necessary to maintain serviceability or structural performance. Criteria for interpreting data and signalling a need to consider changing the monitoring methods or frequency intervention must be established at the same time as the methods for collecting and storing data.

Condition monitoring can be undertaken in various ways. The asset owner needs to be clear on the advantages and disadvantages of the approaches including:

- **Intermittent Visual Inspection:** Visual inspection will only detect visible damage. Unless conducted regularly, by the time damage occurs, deterioration might be advanced and options for preventative maintenance might be reduced or lost. Visual inspection can be undertaken relatively cheaply over the whole structure at frequent time intervals.
- **Intermittent Site Testing:** Site testing can be undertaken to monitor the rate of deterioration, and predict residual life based on the observed deterioration rate. Calculating residual life often requires various assumptions to be made as it is impractical to measure all parameters in the models. This can lead to large errors in predictions.
- **Permanent Surface Mounted and Embedded Monitoring:** These are installed preferably at the time of construction but can also be retrofitted. Some monitoring methods facilitate the assessment of residual life and because they establish a base line at construction for items like strain they give more extensive information not obtained from intermittent site testing that starts once the deterioration is imminent. This type of monitoring has a significant capital outlay and ongoing maintenance and operating costs, therefore it should only be installed where the asset's owner will commit to undertaking the monitoring throughout its service life. Where monitoring of this type is undertaken it must be considered throughout the design phase and into the construction phase.

Z7/07 provides useful background on visual inspection and various tests that are used within the monitoring frame work. These include intermittent site tests (e.g. electrode potentials, carbonation depth, chloride profiles, concrete resistivity, polarisation resistance, petrographic examination, microbial analysis) and permanent monitoring systems (e.g. corrosion initiation, corrosion rate, strain, vibration and deflection).

### **7 Conclusions**

Performance testing as part of a durability planning and implementation process will lead to an increased likelihood of achievement of design life of concrete structures and buildings.

Performance test methods used to inform durability design often do not accurately reflect processes that occur in the field. Whether the results are used to compare different materials or to predict their performance, it's important to account for the limitations of the method.

Therefore, it is strongly recommended that the selection of test methods, design of test programs, and interpretation of the results be performed by experienced professionals who have appropriate knowledge of both the testing processes and the deterioration processes that occur in structures exposed to various environments. This will ensure that test results, and the outcomes of predictive modelling based on the results, are interpreted appropriately.

# A Discussion on the Autogenous Shrinkage Interpretation from the Experimental Shrinkage Measurement Based on the Australian Testing Procedure AS1012.13

William A. Thomas<sup>1</sup>, James Mohammadi<sup>2</sup> and Dr Warren South<sup>3</sup>

<sup>1</sup>Chief Engineer, Concrete – Boral Construction Materials, Brisbane, Queensland, Australia

<sup>2,3</sup>Research and technical services – Cement Concrete and Aggregates Australia, Sydney, New South Wales, Australia

**Abstract:** This paper discusses a suggested experimental procedure for performing an accurate assessment of the concrete shrinkage. The suggested experimental procedure is based on the Australian shrinkage assessment terms and concept, addressed in the current version of Australian Standard AS3600. Following the introduction of the current version of Australian Standard AS3600, it has been noted that there are difficulties in relating test data from concrete drying shrinkage tests carried out in accordance with the Australian Standard AS1012.13 to the design shrinkage strain calculated in AS3600. This issue arises as a result of AS3600 approach for conducting shrinkage calculation by separating the forms of shrinkage into autogenous and drying shrinkage components. This paper discusses these types of shrinkage and their relationship to shrinkage measured according to AS1012.13. It goes on to propose possible procedure of using such test results to assist prediction of the design shrinkage strain by the methods proposed in AS3600. In addition, the proposed test method for measuring the autogenous shrinkage provides a consistent experimental method, which reveals the portion of autogenous shrinkage out of the total shrinkage. Besides, the proposed test method is used for assessing the effectiveness of mitigation methods applied specifically for the reduction of autogenous shrinkage.

**Keywords:** Drying Shrinkage of Concrete, Autogenous Shrinkage, Design Shrinkage Strain

## 1. Introduction

The current version of AS3600 [1] Clause 3.1.7.1 deals with the concrete shrinkage by introducing a parameter termed design shrinkage strain ( $\epsilon_{cs}$ ) of concrete. The design shrinkage strain ( $\epsilon_{cs}$ ) of concrete is determined from measurements on local concrete. In a situation which the design shrinkage is predicted, it can be estimated by calculations provided by AS3600 Clause 3.1.7.2. This calculation addresses in AS3600 Clause 3.1.7.2 separates the sources of concrete shrinkage between autogenous shrinkage ( $\epsilon_{cse}$ ) and drying shrinkage ( $\epsilon_{csd}$ ) as demonstrated in Equation (1).

$$\epsilon_{cs} = \epsilon_{cse} + \epsilon_{csd} \quad (1)$$

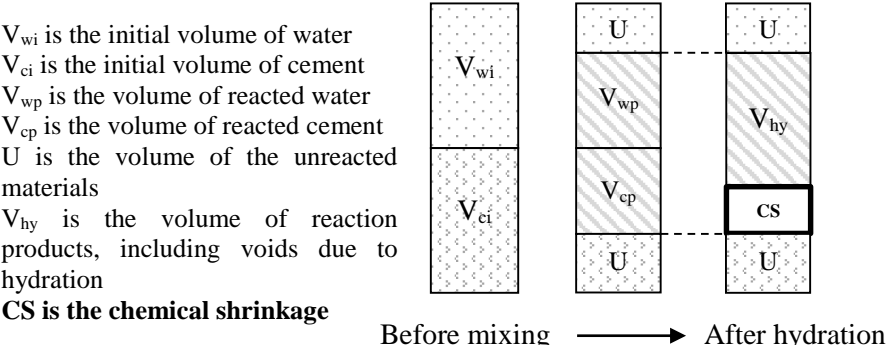

where,  $\epsilon_{cs}$  is the design shrinkage strain of concrete,  $\epsilon_{cse}$  is the autogenous shrinkage strain, and  $\epsilon_{csd}$  is the drying shrinkage strain

This change reflects the current European Codes EN1992-1-1 [2]. However, the two types of shrinkage noted in AS3600 Clause 3.1.7.2 now no longer have specific Australian Standard test methods from which the effect of intrinsic mix properties, such as concrete mix design values for these properties can be determined. The AS3600 code user is given the options of determining drying shrinkage “by tests after eight weeks of drying modified for long-term value, in accordance with the existing test method AS1012.13 [3], but the user is not advised as to how this data can be interpreted. In the previous version of AS 3600 [4] the value of basic shrinkage strain of concrete  $\epsilon_{cs,b}$  was either a default value of 850 micro-strains or directly assessed using the standard shrinkage test AS1012.13 value for drying shrinkage at 56 days as the value.

This problem arises from the fact that the Australian standard AS 1012.13 actually measures the entire shrinkage under the drying condition, which is different to just the drying shrinkage. The entire shrinkage under the drying condition includes both the drying shrinkage and autogenous shrinkage.

Autogenous shrinkage is considered to be a type of “drying” shrinkage that occurs when there is no loss of water from the concrete, but moisture is removed from the concrete pore structure through

internal hydration of the binder rather than drying from the exposed surfaces of a concrete structure. The hydration reaction starts after water is mixed with cement. This reaction is time-dependent and involves only a portion of the mixed cement and water. It is observed that the resultant products of this reaction have less volume compared to the summation of the volume of reacted water and cement. Figure1 illustrates the difference between the volume of concrete resources and products resulted from cement reaction, when the ambient temperature is kept constant (the thermal expansion negligible). This form of chemical shrinkage has two major stages. The first one is named the plastic deformation, which includes concrete deformation in the plastic state and before the concrete initial setting time. The second stage is after initial concrete setting, when the hydrating cement has formed some structure that is capable of resisting stress and further chemical reaction in concrete results in the autogenous shrinkage. Accordingly, when a sufficient structure is formed to restrain chemical shrinkage following initial setting, the volume of the movement becomes “self-desiccation” shrinkage or “autogenous shrinkage” [5].

**Figure1: Volume of Cement, Water and Hydration Products [6]**

The autogenous shrinkage magnitude is largely an intrinsic characteristic and is independent of member size, and concrete ambient condition. In contrast, the drying shrinkage where the size and shape of member as well as the surrounding environment are significant factors in the rate of drying from exposed surfaces and so the rate of “drying shrinkage”. In contrast to the autogenous shrinkage, which is caused by chemical reaction, the drying shrinkage is the shrinkage resulting from the effects of the loss of moisture from the concrete surface and is partly reversible when the concrete is re-saturated.

As mentioned above, factors affecting the autogenous shrinkage are different from the factors influencing the drying shrinkage. Although the current version of AS3600 proposes a model for estimating  $\epsilon_{cse}$  and  $\epsilon_{csd}$  separately, unfortunately the Australian Standards provide no means of separately measuring these values in sampled concrete. For a concrete test specimen, the given standard test method for drying shrinkage will contain both of these components of shrinkage. These components are varying in proportion, and it is difficult to now interpret and relate standard test data to AS3600 design values without further guidance being given. In the following sections the authors will review literature relating to interpretation of the two forms of shrinkage, review selected test data and recommend a method for interpretation of test data that can be applied by users of AS3600.

**2. Autogenous and Drying Shrinkage**

A review of the literature on this property of concrete yields a significant number of papers detailing the proposed mechanisms and magnitude of this form of shrinkage [7–9]. The complexity of trying to relate this data to that of the standard concrete shrinkage test AS1012.13, is that the test data incorporates a number of different forms of volume change as a result of the various elements of the curing process that a specimen is subjected to and how this may, or may not, be related to concrete formed into a structure. Some of the forms of volume change that need to be considered are:

- (a) Early Chemical Shrinkage

- (b) Thermal expansion or shrinkage
- (c) Autogenous Shrinkage
- (d) Swelling on saturation
- (e) Drying Shrinkage
- (f) Carbonation Shrinkage

In Table 1 below the authors suggest the likely volume changes (as above) that will influence the unrestrained shrinkage of a standard test specimen used for a drying shrinkage test carried out in accordance with AS1012.13.

**Table 1: Typical Characteristics of Free Volume Change of Shrinkage Samples**

Curing Period	Method of Curing	Likely Influences on Volume Change (from forms of volume change listed)
0 hours to 24 hours	Field or Laboratory specimen "sealed" in form.	(a), (b), (c) and possibly (e) to some extent
24 hours to 7 days	Specimen placed in lime saturated water at 23°C.	Possibly (c) to some extent and (d)
7 days to 63+ days	Specimen surface dried and maintained at 23°C and 50% Relative Humidity	(c), (e) and possibly (f)

Other test methods such as ASTM 1698 [10] provide a method for assessing autogenous shrinkage and is only suitable for cement pastes and possibly mortars. Neither of these methods are suitable for assessing the autogenous shrinkage component of a standard shrinkage test but do have value in gaining a better understanding of the nature of and time dependency of autogenous shrinkage at early ages. It can be seen that autogenous shrinkage is likely to have an influence on the final cumulative shrinkage on most parts of the test specimen's combined curing periods with the probable exception of the period of wet curing where, depending on the concrete permeability, there will be a ready supply of water to replace chemically reacted water with the net impact being expansion or swelling.

In the case of a concrete structural element cast in a dry environment (i.e. not in water or subject to wet curing) the main influences on volume change will be (a), (b), (c) and to a lesser extent (e) until initial in form or other form of curing is complete and then (b), (c), (e) and (f) after curing is complete. In this case it can be seen that autogenous shrinkage will have a continuing influence on the members volume change from the time of hardening after placement.

A literature review discovered a number of methods for assessing a concrete mix autogenous shrinkage. Holt (2005) proposes three methods ranging from assessing plastic concrete chemical shrinkage using water displacement to casting a test slab in forms and assessing dimensional change after casting [9]. Further, using a mechanical measuring gauge [6], or laser sensors [11] were also suggested in the literature. Although there are different methods available to be applied for measuring autogenous shrinkage, the selected method should be consistent with the current method AS 1012.13 used for measuring shrinkage under the drying condition. The proposed model in AS3600 for estimating the autogenous shrinkage is provided in equation (2) below.

$$\varepsilon_{cse} = \varepsilon_{cse}^* \times (1 - e^{-0.1xt}) = (0.06f'_c - 1) \times (1 - e^{-0.1xt}) \times 50 \times 10^{-6} \quad (2)$$

where,  $t$  is time in days after initial setting of the concrete,  $\varepsilon_{cse}^*$  is final autogenous shrinkage and  $f'_c$  is the 28-day characteristic compressive strength of concrete in MPa.

Literature revealed that the autogenous shrinkage is dependent on the chemical composition of cement and concrete materials, and also the mix proportioning [6]. In order to assess the effectiveness of any selected mix design, and selected mitigation methods applied for producing concrete with lower autogenous shrinkage, it is required to have a method specifically measure the autogenous shrinkage. There are different methods addressed by literature for mitigating the autogenous shrinkage such as using low heat (LH) cement, introducing expansive additives, using shrinkage reducing agents (SRA's), adjusting water reducer dose, adjusting gypsum level in cement, replacing a portion of cement with fly ash and increasing the water to cement (W/C) ratio. All these

methods can have effect in managing autogenous shrinkage and their level of effectiveness needs to be assessed by testing for any specific mix design.

In its defined form (from AS3600 [1] and EN 1992 [2]) drying shrinkage would be a combination of all shrinkage after taking account of autogenous shrinkage and any thermal shrinkage. To that extent it will contain some impact from carbonation shrinkage unless the measurement technique used seeks to avoid any availability of CO<sub>2</sub> or carbonation shrinkage is assessed separately removing the impact of carbonation removed from the over-all shrinkage measurement.

In its purest form “drying shrinkage” should be reversible. In other words, a concrete that has been dried for a period of time and the drying shrinkage component measured, with impacts of carbonation and autogenous shrinkage removed from the total shrinkage, may be re-saturated and the specimen should expand to the full amount of this drying shrinkage component. In reality the drying shrinkage is not fully reversible and literature suggests that the degree to which it is reversible will vary between 30% and 60% as a result of the introduction of additional links within the hydrating cement gel during the initial drying period [12].

Drying shrinkage occurs under drying conditions, which are not associated with chemical or autogenous self-desiccation of a concrete test specimen or a concrete structure, and takes place through the exposed surfaces of the concrete. The rate of drying is dependent on factors such as the concrete members’ size and shape as well as the exposed surface ambient conditions (temperature, air speed and relative humidity) and the permeability of the concrete. AS3600 and EN 1992 provide formulae for estimating the drying shrinkage component of a structure over time as impacted by environment (relative humidity) and member dimensions.

As shown in Equations (3), (4) and (5) from AS3600, at any time “*t*” after the commencement of drying, the drying shrinkage strain shall be taken as:

$$\varepsilon_{csd} = k_1 \times k_4 \times (1 - 0.008 \times f'_c) \times \varepsilon_{csd,b}^* \quad (3)$$

where, *k<sub>1</sub>* is the time after the commencement of drying in days, the value of the factors *k<sub>4</sub>* for the test prism is approximately 0.65 (drying room in AS1012.13 test environment is equivalent to an “interior environment” in AS3600), *f'<sub>c</sub>* is the 28-day characteristic compressive strength of concrete in MPa, and  $\varepsilon_{csd,b}^*$  is the final basic drying shrinkage strain, which is taken as  $800 \times 10^{-6}$  for Sydney and Brisbane,  $900 \times 10^{-6}$  for Melbourne and  $1000 \times 10^{-6}$  elsewhere.

$$k_1 = \frac{(0.8 + 1.2e^{-0.005t_h}) \times t^{0.8}}{t^{0.8} + 0.15t_h} \quad (4)$$

where, *t* is the time after the commencement of drying in days, *t<sub>h</sub>* is hypothetical thickness of a member in mm calculated using Equation (5)

$$t_h = \frac{2A_g}{u_e} \quad (5)$$

where, *A<sub>g</sub>* is gross cross-sectional area of a member in mm<sup>2</sup> and *U<sub>e</sub>* is exposed perimeter of a member cross-section plus half the perimeter of any closed voids contained therein in mm.

Finally, consideration should be given to the fact that the design shrinkage strains ( $\varepsilon_{cs}$ ) provided by Clause 3.1.7.2 of AS3600 has a range of  $\pm 30\%$  error. The test method for assessing concrete shrinkage, AS1012.13, uses a concrete prism of approximate dimensions 75mm×75mm×280mm. Accordingly, the calculation for the above AS3600 parameters based on the AS1012.13 sample size are tabulated in Table 2.

**Table 2: The calculated Drying Shrinkage parameters for Test Specimen based on AS 3600 Model**

$f'_c$ [MPa]	$t_h$	$k_d \cdot (1 - 0.008 \cdot f'_c)$					$k_d$	$\epsilon^*_{csd,b}$
		0-Day	7-Day	14-Day	56-Day	1000-Day		
20	37.5	0.000	0.690	0.897	1.231	1.475	0.65	800
50	37.5	0.000	0.493	0.641	0.879	1.053	0.65	800
100	37.5	0.000	0.164	0.214	0.293	0.351	0.65	800

<sup>1</sup> days after placing under drying condition (7 days from casting)

The above parameters (using  $\epsilon^*_{csd,b} = 800$  micro-strain) are further converted to estimated drying shrinkage values in Table 3 below.

**Table 3: The calculated Drying Shrinkage for Test Specimen based on AS 3600 Model**

$f'_c$ [MPa]	Drying Shrinkage (Microstrain)				
	0-Day	7-Day	14-Day	56-Day	1000-Day
20	0	359	466	640	767
50	0	256	333	457	548
100	0	85	111	152	183

<sup>1</sup> days after placing under drying condition (7 days from casting)

### 3. Estimate Concrete Shrinkage Using Numerical Models

The drying shrinkage test method used in Australia is AS1012.13. The test method assesses the total drying shrinkage of a concrete prism of approximate dimensions 75mm×75mm×280mm that has been cured for 7 days, 1 day at ambient temperature in moulds and 6 days in lime saturated water set at 23°C. Following this initial curing the specimen is placed in a drying environment kept at a temperature of 23°C and relative humidity of 50% for a further period (usually a further 56 days) with regular measurements of total shrinkage taken up to the end of the testing period.

As noted in Section 2 the “total shrinkage” measured by the test method AS 1012.13 is the total shrinkage under drying conditions, which contains components of “drying shrinkage”, autogenous shrinkage and possibly carbonation shrinkage. Based on information provided by Neville [12] the authors have estimated that it is probable that carbonation shrinkage of a concrete test specimen over 56 days drying is relatively low. The carbonation shrinkage is estimated by the authors as being in the likely range of 2 to 15 microstrains at most [12]. On this basis, the authors believe that it is reasonable to include any carbonation shrinkage as part of the overall drying shrinkage and not assessed separately [5].

Based on this, the shrinkage of concrete test specimens will be composed of a combination of residual autogenous shrinkage combined with drying shrinkage. On the assumption that the amount of remaining autogenous shrinkage between 7 days from casting to 63 days from casting (56 days of drying) can be estimated from a member with dimensions of the test specimen noted above and will have an estimated value taken from AS3600. Estimates from AS3600 in Table 4 below can provide an approximate comparison in the relative proportions of drying and autogenous shrinkage in three different concrete grades. Field test results to AS1012.13 on S50 grade concrete typically present values of shrinkage of approximately 650 microstrains at 56 days drying for sample S50, which is slightly higher than the total shrinkage of S50 grade concrete, calculate using AS3600 and EN 1992-1-1 models (refer to Table 4 & 5).

The autogenous shrinkage for different ages is calculated and presented in Tables 4 & 5. It should be taken into account that the presented autogenous shrinkage values are adjusted by subtracting the value of autogenous shrinkage at the start of drying condition (after 7 days of curing). This subtraction provides a similar reference point for measuring both autogenous and drying shrinkage.

Table 4 & 5 data ignore any potential differences in the impact of water saturation curing used from day 2 to day 7 in the test method on the value of the remaining autogenous shrinkage from 7 days to

63 days. This arises from the assumption that autogenous shrinkage is related to binder hydration and pore size. The autogenous shrinkage mechanism is more significant for higher strength, low W/C ratio concrete with a dense matrix with low porosity. Accordingly, concrete held at a constant temperature for the 6 days of saturation curing may have a relatively minor impact on these factors compared to a specimen which has no drying from the surface but no added water from curing and held at the same temperature for 6 days (stated for autogenous shrinkage only).

**Table 4: The Estimated Drying and Autogenous Shrinkage by AS 3600 Model**

Shrinkage Type	Applied Model	Concrete Grade [MPa]	Estimated Shrinkage by Type [Microstrain]				
			0-Day <sup>1</sup>	7-Day	14-Day	56-Day	1000-Day
Autogenous	AS3600	20	0	2	4	5	5
Drying			0	359	466	640	767
<b>Total</b>			<b>0</b>	<b>361</b>	<b>470</b>	<b>645</b>	<b>772</b>
Autogenous	AS3600	50	0	25	37	49	50
Drying			0	256	333	457	548
<b>Total</b>			<b>0</b>	<b>281</b>	<b>371</b>	<b>507</b>	<b>597</b>
Autogenous	AS3600	100	0	62	94	124	124
Drying			0	85	111	152	183
<b>Total</b>			<b>0</b>	<b>148</b>	<b>205</b>	<b>276</b>	<b>307</b>

<sup>1</sup> days after placing under drying condition (7 days from casting)

Table 4 above is can be repeated for the test specimen using the formulae provided in European Standard EN1992-1-1 as set out in Table 5 below.

**Table 5: The Estimated Drying and Autogenous Shrinkage by EN1992-1-1 Model**

Shrinkage Type	Applied Model	Concrete Grade [MPa]	Estimated Shrinkage by Type [Microstrain]				
			0-Day <sup>1</sup>	7-Day	14-Day	56-Day	1000-Day
Autogenous	EN1992-1-1	20	0	3	5	10	15
Drying			0	255	355	506	583
<b>Total</b>			<b>0</b>	<b>258</b>	<b>360</b>	<b>516</b>	<b>598</b>
Autogenous	EN1992-1-1	50	0	12	19	38	59
Drying			0	178	249	354	409
<b>Total</b>			<b>0</b>	<b>190</b>	<b>268</b>	<b>392</b>	<b>468</b>
Autogenous	EN1992-1-1	100	0	26	43	87	132
Drying			0	95	133	189	218
<b>Total</b>			<b>0</b>	<b>121</b>	<b>176</b>	<b>276</b>	<b>350</b>

<sup>1</sup> days after placing under drying condition (7 days from casting)

As can be seen from the data presented in Table 4 & 5 the two standards have slightly differing estimates on the amount of autogenous shrinkage that occurs between 7 days from casting and 63 days from casting and drying shrinkage over the period from start of drying to 56 days drying. For example grade S50 concrete will have an autogenous shrinkage portion from 7 days to 63 days (56 days drying) estimated as 49 micro-strains while it is estimated as 38 micro-strains using EN1992-1-1 model. The differences in total shrinkage estimated for shrinkage test specimens between the two standards are generally within the  $\pm 30\%$  suggested by both standards. It is evident that the estimate of total shrinkage for test specimens is significantly lower than is seen in these grades of concrete in practice (and as reflected in the 2001 and previous versions of AS3600 where typical 56-day drying shrinkage test data was used to estimate total shrinkage).

Considering reported data from literature, autogenous shrinkage can vary significantly for a concrete of the same characteristic strength based on constituents such as binder composition and admixtures (Holt [5]). In view of this the authors recommend that a test method for assessing the autogenous shrinkage component of the standard concrete shrinkage test is developed so that the “basic drying shrinkage” as defined in AS3600 may be better estimated from testing.

#### 4. Applying AS3600 Model for Concrete Shrinkage Estimation

The process of estimating the design shrinkage strain given in AS3600 is outlined by Gilbert (2002) [8] in his earlier proposal to Australian Standards. In essence the standard provides three ways to estimate this value. The first (default) method is to estimate the total shrinkage based on the Standard's formulae and a basic drying shrinkage strain value given for different regions. The second requires knowledge of typical drying shrinkage test values for given mixes available in a particular project location. The third method requires a test of the specific concrete mix in accordance with Australian Standard AS1012.13 to determine the shrinkage (typically after 63 days from casting or 56 days drying after the initial 7 days curing). In Standard AS3600 the total member shrinkage is given as being a combination of drying shrinkage ( $\epsilon_{csd}$ ) plus the autogenous shrinkage ( $\epsilon_{cse}$ ) at any given time ( $t$ ). Unfortunately the AS1012.13 test, as noted in previous sections, provides data that contains both drying shrinkage and autogenous shrinkage and these need to be separated out so that the test value can be useful in estimating the value of drying shrinkage component in either of the second or third methods noted above.

The problem here is one of timing and its impact on the test method used. Autogenous shrinkage effectively starts from when the concrete reached initial setting (normally within 4 to 12 hours of mixing the concrete) whereas drying shrinkage only starts after ceasing moist curing (in the case of the test method after 7 days). It would seem that in order to interpret the standard test results then the component of autogenous shrinkage in the test drying period needs to be estimated and removed from the result so as to report a final drying shrinkage value for the test prism of the standard dimensions. One way to achieve this is to use the AS3600 equation for the autogenous shrinkage from 7 days to 63 days (test specimen drying period) to determine the correction value to the 56 days drying test value so as to estimate the actual drying shrinkage component. This autogenous shrinkage component is dependent on characteristic compressive strength in the standard and the authors have calculated the relevant values in Table 4 above based on the AS3600 equations. The influence of time and curing on shrinkage based on AS1012.13 can be considered by the estimation of the autogenous shrinkage using equation (2) derived from AS3600 above. For example for the S50 concrete, the autogenous shrinkage is calculated from this formula to be 50 microstrain at the initial time of starting drying of the shrinkage test specimen (7 days). This value can then be subtracted from the estimated autogenous shrinkage from this equation at later ages and the net differential autogenous shrinkage deducted from AS1012.13 test results at these ages to estimate the drying shrinkage component.

The above method is an approximation and may be sufficient for estimation but the problem with the above analysis is that the actual value of the autogenous shrinkage test has been shown to vary significantly for the same concrete strength and needs to be assessed by testing of the same concrete rather than estimated in this way.

The authors propose a means of being able to carry out this testing is to cast duplicate specimens the same concrete used to cast test specimens for assessment of "drying shrinkage" to AS1012.13. These duplicate specimens need to be "sealed" after the initial 7-day curing cycle of the AS1012.13 method to prevent water ingress or surface drying and their shrinkage measured in the same curing temperature to that of AS1012.13 with the resultant shrinkage of these duplicate specimens measured being attributed to the autogenous shrinkage component of the same concrete over this curing period.

#### 5. Proposed Methods of Relating Shrinkage Test Data

As autogenous shrinkage is defined as the shrinkage that occurs through self-desiccation after setting of plastic concrete then the author's believe that it is feasible to assess the impact of this on a standard shrinkage test carried out in accordance with AS1012.13 by using duplicate samples of the same concrete as cast for the standard "drying shrinkage" testing that are subject to the same curing up to 7 days from casting as the standard "drying shrinkage" specimens as noted above.

The author's note that following the curing procedure for the proposed method is going to omit the significant proportion of autogenous shrinkage during the first 7 days after setting. Selection of the autogenous reference point for the samples cured 7 days results in neglecting almost 50% of the total autogenous shrinkage if using formula (2) above as a guide. This method is purely recommended for "correcting" the AS1012.13 method for the component of autogenous shrinkage over the period of the test and not as an estimate of the concrete total autogenous shrinkage including the period from setting to 7 days. The authors recommend that a separate test method for autogenous shrinkage from setting to 7 day's is developed along similar lines to those proposed by Holt [6].

Accordingly, after the standard curing regimes noted in AS1012.13 up to 7 days from casting the test specimens the "autogenous shrinkage" specimens are removed from moist curing and measured, in the same way as detailed in AS1012.13 for the specimens used for the current "drying shrinkage" test. The additional process of "towellling" the specimens is applied to dry to a saturated surface dry condition except that the authors recommend that each specimen mass is then measured to  $\pm 0.1$  gram accuracy (including the standard "drying shrinkage" specimens). After finishing each measurement, the autogenous shrinkage specimens are quickly returned to a storage that prevents loss of moisture through evaporation from the concrete surface. This storage will be maintained at  $23^{\circ}\text{C} \pm 2^{\circ}\text{C}$  and may be storage in a sealed container suspended over water on a rack or by sealing the surface of the concrete specimens to prevent moisture loss. These specimens are measured for shrinkage or expansion at the same storage ages (maturity) as the 'drying shrinkage' test specimens and each specimen mass recorded at the time of measurement as noted earlier. The "autogenous shrinkage" test specimen measurements will be accepted provided mass loss or gain does not exceed 0.2 gram over the measurement period. The results of autogenous shrinkage from 7 days to the time of measurement ( $\epsilon_{cset}$ ) can then be used to assess the drying shrinkage of the concrete by deducting  $\epsilon_{cset}$  from the standard total shrinkage value assessed by the method of AS1012.13.

It is the authors' opinion that this test method needs significant assessment to validate. The test method outlined here should be trialled to assess the drying shrinkage on a number of concrete mixtures ranging in grade strength from 20MPa to 100MPa as common grades used in construction. The method for storing the test specimens to prevent absorption or loss of water is varied to obtain "sealed specimen" behaviour with no loss or gain of moisture. The aim of the proposed test program will be to provide recommendations on suitable methods to prevent loss of moisture from the autogenous shrinkage specimens so that this may be adopted as a standard method in Australia and assist with aligning the resulting net drying shrinkage test data with the relevant provisions of AS3600.

## 6. Conclusions

This paper discusses the design and application of a test method, which may provide more accurate estimates of the actual drying shrinkage of concrete, specifically. A new method based on the Australian shrinkage test method AS1012.13 is proposed subject to a review of methods to be used in curing autogenous shrinkage test specimens. The suggested method follows mirrors the required procedure which is described in the current AS1012.13. The proposed method provides a means to interpret the characteristics of concrete based on experimental results and not just on the AS3600 model and assumed values, which only considers strength grade of concrete and has 30% error margin in prediction.

**Abstract:** This paper describes the development of a common Nordic test method for the evaluation of hydrophobic impregnations for concrete, for protection against chloride ingress. The first stage of the experimental campaign served to evaluate the influence of the precondition environment before surface treatment, curing time and type of surface on the performance of the impregnation agent. In the second stage, a round robin test involving 3 Nordic laboratories was conducted; the results showed very little variation and were compared to results obtained according to previous standards in order to define performance requirements. Finally, data from field exposed specimens for more than 5 years was used to validate the suitability for use.

**Keywords:** Concrete, hydrophobic impregnation, chloride ingress, performance test, diffusion of chlorides.

## 1. Introduction

In the northern European countries de-icing salts are frequently used on road bridges during the winter season, causing a very harsh environment, especially for concrete edge beams. A large part of the maintenance costs of road bridges are due to repair or replacement of edge beams due to corroding reinforcement. With the aim to extend the service life of the edge beams, hydrophobic impregnation have been used in order to prevent or slow down the ingress of chloride ions into the concrete. Thus, the influence of the hydrophobic impregnations on the chloride penetration is a very important property for hydrophobic impregnation agents used for this purpose. However, according to the harmonized European standard EN 1504-2 [1], the property "diffusion of chloride ions" is for hydrophobic impregnations "subject to national standards and national regulations".

Therefore, the transport and road administrations of Sweden, Finland and Norway use separate national methods to evaluate this property of the hydrophobic impregnating agents for concrete. The existing methods differ in many ways and the results are not directly comparable. Therefore, the transport and road administrations of Sweden, Finland and Norway initiated a project with the aim to establish a common Nordic method to evaluate the protection against chloride ingress of this kind of products. The three administrations started the project by reviewing and comparing the three existing Nordic methods and other relevant methods, their advantages and draw-backs in order to create a basic setup for a new method.

It should be pointed out that the purpose of both the existing methods and the new method is to classify hydrophobic impregnating agents with regard to their capability to protect concrete from chloride ingress and not to monitor the performance of these agents under realistic conditions. However, the method should be able to distinguish between products which give a satisfying protection against chloride under field conditions and those who don't. Therefore, the method needs to be validated against data obtained from field experience. It is also an advantage if the results with the new method correlate to results obtained with the existing methods.

In all three methods the efficiency of the agents is obtained by comparing the amount of chlorides in impregnated concrete samples with the amount of chlorides in samples without impregnation after a certain period of exposure to chlorides. In the existing Norwegian method the chloride exposure consists of cycles of 4 hours spraying with 3% NaCl-solution and 4 hours drying in a chamber kept at 50% RH for a period of 42 days. In both the Swedish and the Finnish methods the exposure to chlorides is obtained by submerging the specimens in a solution with 15% NaCl-solution for 56 days.

The Norwegian method uses sawed surfaces (half cubes), the Swedish method uses sawed 20 mm thick concrete slices and whilst the Finnish method uses form surfaces of cubes. There are also many other diverging details of the testing procedure in the existing three methods, such as:

- type of concrete in the specimens used as substrates;
- the age of the concrete specimens;
- treatment and conditioning of the specimens before application of the impregnating agent;
- the way the impregnating agent is applied and the amount controlled;
- length of the period of curing after the impregnation is applied and before exposure to chlorides, as well as the climatic conditions during this period;
- the part of the specimens used for the chloride analysis (e.g. in the Swedish the outermost 2.5 mm are taken away before analysis);
- the way to express the efficiency of the impregnating product;
- the way to express the requirement: single limit value for acceptance or different levels.

The Norwegian exposure method is more close to the kind of environment a concrete surface may be exposed to in reality than the kind of exposure used in the other two methods. It has a more realistic chloride concentration of the exposure solution and more realistic climatic conditions. However, this method suffers from problems with reproducibility due to the difficulty to control the climate in the testing chambers. For this reason and also for the sake of simplicity submersion in a NaCl-solution was a preferred procedure.

In [2] four different exposure methods were compared; permanently submerged in 16.5% NaCl-solution; periodically submerged in 16.5% NaCl-solution (in principle 1 day submerged and 1 day in 50% RH); permanently submerged in 3% NaCl-solution and in a salt-spray chamber with 3% NaCl-solution (4 hours spraying and 4 hours drying). All exposures were continued for 56 days. Although the measured chloride levels varied substantially between the different exposure methods, there was not a big difference in the calculated efficiency of the impregnating agents obtained. This indicates that the impregnated samples and the reference samples are influenced in a similar and proportional way, regardless of the exposure method. A higher NaCl-concentration in the solution was preferred since it diminishes the effect of the detection limit of the chloride testing equipment on the result.

One inconvenience with the Swedish method is that the type of concrete to use reference is only made to EN 1766 [3] without specifying exactly which of several possible compositions (w/c ratio) should be used. There are cases where the product has first been tested on a concrete with w/c=0.45 and failed the test; the test was then repeated on a concrete with w/c=0.70 and the product passed.

One feature of the Norwegian method that was seen as something that should be kept in the new method was that the exposed sample was ground, in distinct levels, from the surface down to 15-25 mm to obtain a chloride profile. Another feature was the way to express the efficiency of the product, i.e. the filter effect defined as:

$$FE = 1 - \frac{Cl_I}{Cl_R} \quad (1)$$

where  $Cl_I$  is the amount of chloride ions in the impregnated sample and  $Cl_R$  is the amount of chloride ions in the reference samples: Both should be determined or estimated (if  $\sim 0$ ) down to the same depth.  $Cl_I$  and  $Cl_R$  can also be seen as the area under the chloride content profile of the impregnated and reference samples respectively.

Based on this review and the possibility to use supporting EN-standards a basic setup of the method was decided:

- Reference shall be made to MC (0.45) with  $D_{max}=10$  mm, according to EN 1766 [3] for substrates;
- The procedures shall have a well-defined starting point (specimens water cured for 28 days);
- Chloride exposure submersion of specimens in 15% NaCl-solution for 56 days shall be used;
- The chloride profile shall be determined;
- The efficiency of the product shall be expressed as a filter effect;
- It shall be possible to satisfactorily control the amount of impregnation agent applied;

It was also decided that before formulating the method and carry out a round robin test, a pre-study to clarify the influence of some unsettled parameters, primarily concerning the conditioning of the concrete samples before application of the impregnation and the treatment and curing of the specimens between the application of the impregnation and the submersion in the chloride solution.

Based on the basic setup and the results from the pre-study a method description should then be formulated and a round robin exercise with at least one laboratory from each country involved should be carried out, in order to ensure that the method gives reproducible results.

## 2. Pre-study: The influence of conditioning before and after application of the impregnation

### 2.1 Aim

The pre-study was set up to clarify the following questions:

Does the determined protective effect of the impregnations vary

- with type of application surface; sawed surface or form surface?
- if a sawed surface is let to dry directly or if it is treated with lime water?
- with the length of the drying period before application of the product?
- with the length of the period from application of the impregnation to the start of the exposure to the chloride solution?

### 2.2 Experimental

#### 2.2.1 Specimen preparation

The concrete used in this study was of the type MC (0.45) according to EN 1766 [2]; the mixture proportions are given in Table 1. Concrete cubes, with the dimensions of 100 mm x 100 mm x 100 mm, were cast in plastic moulds, demoulded after one day and stored in water for 27 days. At the age of 28 days, the cubes were cut in halves and all the surfaces, except the test surface (either cut or form) were coated with epoxy resin and allowed to dry for one day before preconditioning.

**Table 1. Concrete mixture proportions.**

CEM I 52.5 R (kg/m <sup>3</sup> )	Aggregates 0-10 (kg/m <sup>3</sup> )	Water (kg/m <sup>3</sup> )	Superplasticizer (wt.% CEM)	Air (%)	Slump (mm)
395	1800	178	0.5	1.5	180

#### 2.2.2 Specimen preconditioning

The influence of 3 different preconditioning environments, before application of the impregnation, on the protective effect of the impregnations was evaluated. Tests were conducted on cut surfaces.

- 7 days at (20±2) °C and (60±10) % RH, further on referred to as S;
- 3 days in saturated Ca(OH)<sub>2</sub> followed by 3 days at (20±2) °C and (60±10) % RH, further on referred to as H;
- 3 days in saturated Ca(OH)<sub>2</sub> followed by 7 days at (20±2) °C and (60±10) % RH, further on referred to as C;

Specimens aimed at studying the influence of the type of application surface were preconditioned during 7 days at (20±2) °C and (60±10) % RH (S).

### **2.2.3 Application and curing of the impregnation agent**

In this study two silane-based impregnation agents were used; a liquid, referred to as P1 and a gel, referred to as P2. Reference specimens are referred to as R. The hydrophobic agents, P1 and P2, were applied following the recommendations given by the producers, in the concentrations of 300 g/m<sup>2</sup> and 500 g/m<sup>2</sup>, respectively. After application of the impregnation the specimens were cured during 7, 14 and 28 days at (20±2) °C and (60±10) % RH and are further on simply referred to as 7, 14 and 28.

### **2.2.4 Exposure and chloride analysis**

After curing, both reference and treated specimens were immersed in 15% NaCl-solution, in separate containers, during 56 days. At the end of the exposure period, the samples were removed from the solution, surface dried with absorbent paper, sealed in plastic bags and stored at (20±2) °C before dry grinding on a lathe with a diamond tool. The following layers were ground: 0-2; 2-4; 4-6; 6-10; 10-15 and 15-20 mm (with an accuracy of 0.5 mm). After grinding, the powder samples were dried at 105 °C and stored in a desiccator prior to chloride analysis. The acid soluble chloride content in each layer was determined by potentiometric titration according to AASHTO-T260 [6] and expressed in wt.% of sample (oven dry concrete).

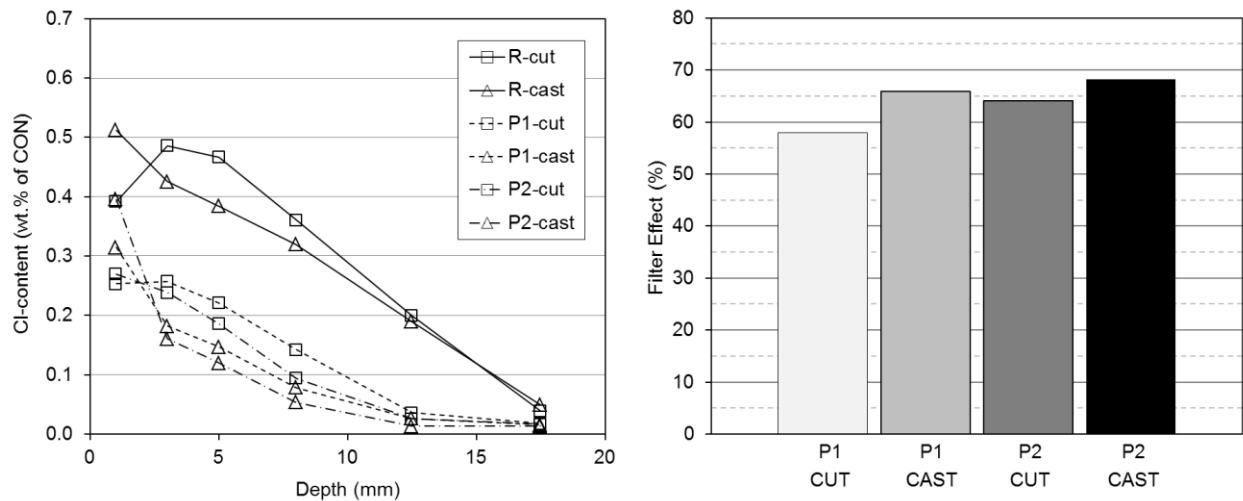

## **2.3 Results and discussion**

### **2.3.1 Influence of the type of application surface**

Figure 1 shows the chloride profiles obtained for the two types of treated surfaces (cut and form) as well as the respective filter effect for the 2 products tested. During casting, due to the presence of the formwork, concrete elements develop an outer layer richer in cement paste. When compared to the bulk concrete, such layer has a higher cement paste content, which gives a higher chloride binding capacity and a finer microstructure which can decrease the penetration depth of the impregnation agent.

The results in Figure 1 (left) show that except for the first layer, the chloride content is lower for the specimens in which the form surface was treated. Additionally, a higher filter effect for form surfaces was obtained (Figure 1 right), suggesting a somewhat beneficial effect when compared to cut surfaces. It is however unclear which effect is dominant: if the higher binding capacity of the first layer richer in paste (form surface) or the influence of the surface on the penetration depth of the treatment.

Therefore, if form surfaces are to be adopted for future reference, the chloride content should be expressed in weight % of binder. On the other hand, if cut surfaces are to be used, the results may be satisfactory expressed in weight % of concrete, as long as the curing period after application of the impregnation is short enough to avoid significant carbonation and the exposure period is short enough to avoid significant calcium leaching of the first few millimetres of the exposed surface.

**Figure 1. Results for cut and form surfaces cured during 28 days after application of the hydrophobic agent: (left) chloride profiles; (right) filter effect. Each data point is the average of 3 specimens.**

### 2.3.2 Influence of the preconditioning and curing time

Figures 2 and 3 show the chloride profiles taken as the average of three parallel specimens as well as the filter effect obtained with products P1 and P2. The results are shown for the different precondition environments and grouped as a function of the curing time.

The results show that the precondition environment before surface treatment does not significantly influence the resistance against chloride ingress.

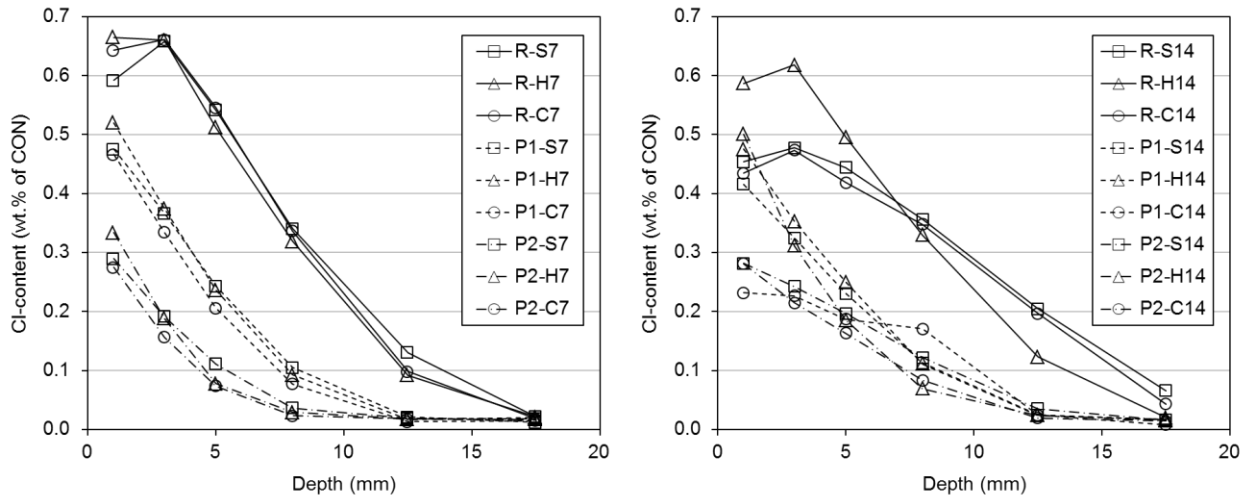

Essentially, for the specimens cured for 7 days after treatment, typical diffusion profiles were obtained; this is due to the relatively short drying period, implying that the degree of capillary saturation of the concrete pores is still very high. At this curing age, the main difference is observed at the surface layer of the reference specimens of the type S, which show a lower chloride level; such difference may be explained by the longer drying time when compared to type H and by the filling of the pores with calcium hydroxide when compared to type C.

Specimens cured for 14 days, do not present a clear behaviour in terms of the chloride transport mechanism and evaluation is not so straight forward, because the chloride profiles show characteristics typical of both diffusion and capillary suction. Apparently, for this curing length, the type of preconditioning environment has some influence, especially on the reference specimens; while specimens of the type S and C cured for a total of 21 days (7 days before treatment and 14 days after treatment) show profiles of the convection type, specimens of the type H cured for a total of 17 days (3 days before treatment and 14 days after treatment) show typical diffusion profiles.

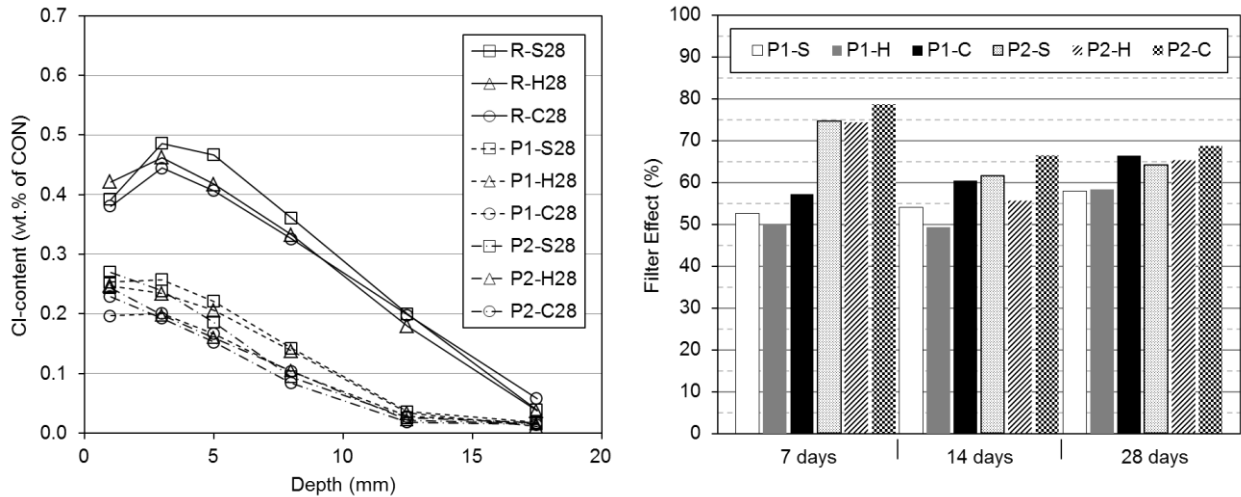

Finally, for the specimens cured during 28 days after treatment, typical convection profiles were obtained; due to the longer drying period, the degree of capillary saturation of the outermost layers is lower. Here chlorides are mainly transported by capillary suction and the chloride content up to a depth of 5 mm does not vary so much.

The results of the filter effect in Figure 3 indicate that, as long as the drying period before treatment is the same (7 days, specimens' type S and C), treatment with calcium hydroxide is beneficial; for all the curing ages (7, 14 and 28 days), higher filter effect was obtained. Whether chemical (binding) or physical (pore filling), the exact reason for this result is not clear.

Except for the specimens treated with P2 and cured for 7 days after treatment, the chloride protection slightly increases with the curing time. However, it is not clear which factor is most dominant: the polymerization of the impregnation agent or the cement hydration. Nevertheless, enough curing time is necessary for the treatment to be efficient, which may not be achieved at the end of 14 days.

**Figure 2. Chloride profiles measured for series cured during 7 (left) and 14 (right) days after application of the hydrophobic agent. Each data point is the average of 3 specimens.**

**Figure 3. Chloride profiles measured for series cured during 28 days after application of the hydrophobic agent (left) and filter effect (right). Each data point is the average of 3 specimens.**

### 2.3.3 Comments on the performance of the hydrophobic agent

The results in Figures 2 and 3 show that both products behave in a similar way with regard to the protection against chloride ingress; this is not surprising, since both are agents of the silane-type. However, while P2 is more effective for shorter curing periods, P1 requires longer curing time; the better short-term performance of P2 may be explained by the presence of bentonite clay which can efficiently block the capillary pores from the outermost concrete layers. With time, the difference between the effectiveness of the two products decreases. Regardless of the conditions tested, both products reduce the total chloride ingress to more than 50% when compared to non-treated samples.

### **2.3.4 Remarks on the development of the test method**

Concerning the development of a test method, none of the precondition environments clearly compromised to the robustness of the test results. Although not reported in this paper, the repeatability of the method was similar for all the tested conditions.

Although, precondition of the type C leads to better results expressed in terms of the filter effect, the results are consistent for all the curing periods after treatment of the samples; thus the absolute value becomes of no interest since it does not influence the filter effect and the fail/pass criteria for the test method. Moreover, under a practical point of view, precondition type C increases the number of experimental steps, without significantly better results, when compared to precondition type S; thus the latter is preferable. Finally, it should be pointed that such preconditioning (immersion in calcium hydroxide) is not representative for conditions in the field.

The preconditioning period after sample treatment should be 28 days: first, enough time should be given to the hydrophobic treatment to polymerize; secondly, the chloride profiles from the specimens cured for 14 days are difficult to evaluate and finally, the results of the filter effect are not consistent for the products tested.

## **3. Round robin exercise**

### **3.1 The tested method**

For the Round Robin test (RRT) three laboratories were involved; CBI in Sweden, SINTEF in Norway and VTT in Finland. A detailed experimental procedure (according to section 2.2) was distributed to the participating laboratories. Each laboratory was responsible for purchasing all the materials for their tests. The main features of the method were:

- MC (0.45) according to the mix design in Table 1;
- CEM I 52.5;
- Specimen precondition: 7 days at  $(20\pm 2)$  °C and  $(60\pm 10)$  % RH (type S);
- Curing of the hydrophobic agent: 28 days.
- Grinding steps for chloride analysis: 0-2; 2-4; 4-6; 6-10; 10-15; 15-20 and 20-25 mm.

For the test, three silane-based impregnation agents were used; a gel (P2), a liquid (P3) and a crème (P4). These were applied following the recommendations given by the producers, in the concentrations of 500 g/m<sup>2</sup>, 200 g/m<sup>2</sup> and 200 g/m<sup>2</sup>, respectively.

### **3.2 Comments on the execution of the round robin test**

Despite the attempt to make the method description as un-ambiguous as possible, some deviations between how the tests were performed at the three laboratories revealed that it was not precise enough.

According to the method description the specimens should be preconditioned and conditioned after application of the impregnating agent in a climate chamber at  $(20\pm 2)$  °C and  $(60\pm 10)$  % RH. At CBI and VTT climate rooms controlled at  $(20\pm 2)$  °C and  $(65\pm 5)$  % RH were used for both these periods. At SINTEF a room regulated  $(60\pm 5)$  % RH was used for preconditioning and one regulated at  $(50\pm 5)$  % RH was used after the application.

As regards the cement type, both CBI and VTT used a CEM I 52.5 R (from different manufacturers) with a high specific surface (500-600 m<sup>2</sup>/kg). SINTEF used a CEM I 52.5 N intended for use in infrastructures, with a much lower specific surface (360 m<sup>2</sup>/kg) and with a low alkali content (0.6%).

For the chloride analysis reference was made to AASHTO T 260, (or another method with the same or better precision), and the result should be given as percent of the dry sample mass. However, it was not stated if this meant oven dry or surface dry mass. According to AASHTO T 260 both options are possible. CBI and SINTEF have analyzed oven dry samples and VTT has analyzed surface dry samples.

### 3.3 Results and discussion

The results from the RRT are shown in Figures 4 and 5. Analysis of the chloride profiles (Figure 4) shows that highly reproducible results were obtained. Yet, some main differences are noticeable. The outermost layers (0-6 mm) of the reference specimens show the largest spread in the results. CBI shows a typical diffusion profile but in which chloride content in the first 4 mm is nearly maximum for this type of concrete, i.e. there is a saturation of free and bound chlorides. SINTEF shows a less steep chloride profile indicating a higher degree of capillary suction associated to more harsh drying conditions (50% RH). VTT shows a typical diffusion profile where the higher surface chloride content is associated to the higher paste content for the concrete tested (composition not given in this paper). When comparing the results from the treated samples, the main difference is the higher surface chloride content of the VTT specimens which is also due to the higher paste content. Finally, P4 shows higher spread in the results at a depth between 4 and 12 mm, the exact reason is unclear.

The fact that the major differences are associated to the chloride content at the surface layers indicates that handling of the specimens, especially after exposure, is crucial. Although the results, expressed in terms of the filter effect are very similar for all the laboratories (except for the specimens treated with P4), better instructions must be provided during the formulation of the test method.

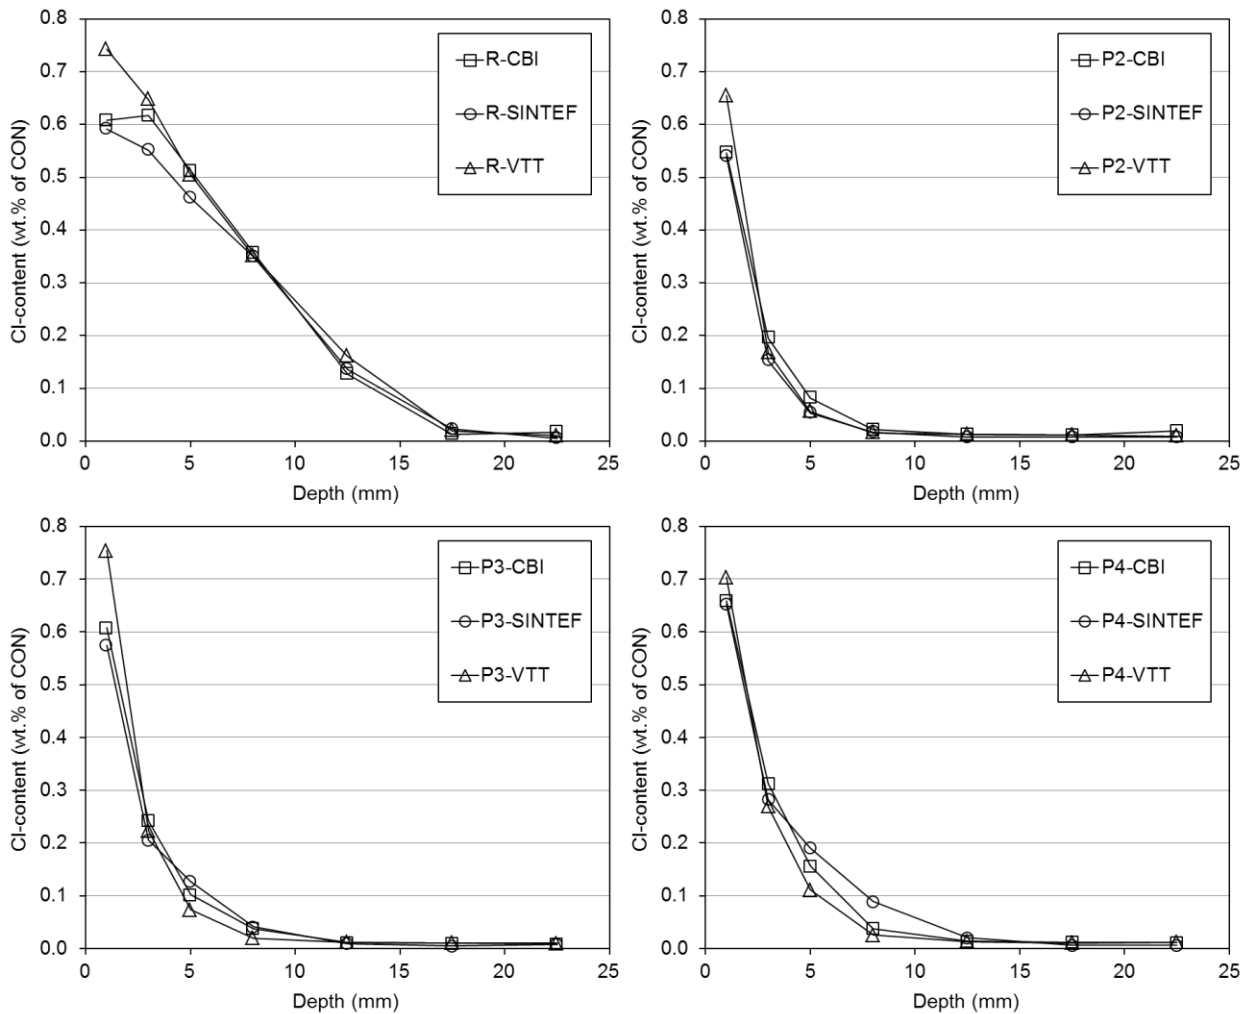

Figure 4. Chloride profiles measured at each laboratory. Each data point is the average of 5 specimens.

Figure 5. Filter effect obtained at each laboratory.

#### 4. Comparison with the existing methods and field results

It is not difficult to correlate the results with the new method ( $FE_{0-25}$ ) to results obtained with the existing Swedish method, when a concrete with W/C-ratio 0.45 has been used. Taking into account that 2.5 mm of the outermost surface is taken away and the 20 mm sample has been exposed to chlorides at both surfaces this will be equal to the relative chloride content of the sample between 2.5 and 17.5 mm depth. The difference between this content and the one obtained between 2 and 20 mm ( $FE_{2-20}$ ) will only be marginal, since beyond 17.5 mm the chloride content in both the impregnated specimens and the references is very close to 0. The requirement of the existing Swedish method corresponds to that  $FE_{2-20} \geq 0.85$ . Using all the results from the round robin exercise, it can be shown that a  $FE_{2-20}$  equal to 0.85 corresponds to a  $FE_{0-25}$  around 0.65. It is also rather easy to relate the results obtained with Finnish method to the filter effect of the new method. However, the Finnish method was recently modified and we have had difficulties to find any results acquired with it.

The requirements level when the Norwegian method is used is  $FE=0.75$ . It is not as easy to relate the results from the Norwegian method to the new method as for the Swedish or Finnish method, since the differences in the procedures are much greater. According to [3] somewhat higher filter effects are obtained when salt-spraying is used for the chloride exposure compared to permanent submersion. The Norwegian method uses much shorter periods for pre-conditioning and exposes the sawed surface to lime-water after sawing. Lengthening the preconditioning period and omitting the exposure to lime-water of the sawed surface both diminishes the value of the filter effect. Moreover, the Norwegian method uses shorter periods for the conditioning after application. As can be seen from the pre-study the influence of prolonging the conditioning periods also influences the filter effect, however not in the same way for all products. On the whole the  $FE_{0-25}$  obtained for a certain product will be lower than the filter effect obtained with the Norwegian method.

Based on the comparison and considerations above, a preliminary assumption of a requirement level for the protection against chloride ingress of hydrophobic impregnation agents can be around  $FE_{0-25}=0.65$  for the new method.

The influence of hydrophobic impregnations on the chloride ingress has also been the subject of several field studies, both in a road environment and a marine environment. However, finding results which can be compared is not without problems. There are many hydrophobic agents on the market, sometimes exactly the same product is sold under several different trade names. In many cases, products that were used in earlier studies do no longer exist or has been substantially modified. Thus, results for exactly the same product obtained with the different methods and from field studies are not easy to find. Another parameter that varies in the different studies is the amount of product applied and the conditions under which they were applied. Test results with the products P1, P2, P3 and P4 obtained with the different methods and the outcome of a couple of field evaluations are summarized in Table 2.

**Table 2. Classification and performance of different products.**

Product	Swedish Method	Norwegian Method	Pre-Study FE <sub>0-20</sub>	Round Robin FE <sub>0-25</sub>			Marine Environment after 10 years <sup>3)</sup>	Road Environment after 5 years <sup>4)</sup>
				CBI	SINTEF	VTT		
P1	Approved		55					Clear effect
P2	1)	Approved	63	66	69	68	Clear effect	Clear effect
P3	Approved			61	61	62		
P4	2)			54	49	60		
1) Did not pass at w/c=0.45; very good performance at w/c=0.70 2) Not tested with w/c=0.45; approved when tested with w/c=0.70 3) Data from [4] 4) Data from [5]								

## 5. Conclusions

The proposed method to classify hydrophobic impregnations with regard to protection against chloride ingress gives sufficiently reproducible results. Even though, the form of the obtained chloride profiles vary somewhat when determined at different laboratories, this does not influence the parameter chosen to describe the efficiency of the products, the filter effect, more than marginally. Since the filter effect is based on the amount of chloride in impregnated samples in relation to the amount of chlorides in un-impregnated samples, the variations in procedures causing differences in chloride profiles, influences the references and impregnated samples to the same degree. However, the reproducibility of the method may be enhanced if some parts of the procedures are made more precise.

Even though the method uses experimental conditions, such as submersion in a solution with unnaturally high concentration of NaCl and application of impregnations to sawed surfaces, the results seem to be relevant when compared to results with other test methods with more realistic conditions and field experiments.

<sup>1</sup>ACCIONA Infraestructura

<sup>2</sup>CBI Swedish Cement and Concrete Research Institute

**Abstract:** ACCIONA Infraestructura, a Spanish contractor, uses the caisson method for the construction of breakwater structures. One of its floating docks, Kugira, is one of the largest of its kind in the world and it can produce concrete caissons measuring 70 m long by 36 m wide and 35 m high. Concrete caissons made in floating docks are gradually immersed in sea water as they are built; thus, the set concrete is exposed to sea water at a very early stage, within 18 to 48 hours after casting in sliding formwork. In order to study the durability of slag concrete using this construction method, the properties of concrete exposed to sea water at a very young age have been tested. Specimens were exposed to artificial sea water by the ponding method at different ages (16h, 1, 2, 3, 7 and 28 days) for a period of 6, 18 and 36 (analysis pending) months. The following properties were measured and compared with unexposed specimens: compressive strength, water and oxygen permeability, pore size distribution, migration coefficient DNT492 and chloride profiles. After 6 and 18 months ponding, lower chloride contents were measured for the specimens exposed to sea water after 28 days curing compared to those exposed at early ages. However, this difference significantly decreases within a small depth from the exposed surface. Also the migration coefficient DNT492 decreases significantly with the increase of the age of the concrete. With regards to water and oxygen permeability, no significant differences were found. In this paper, a summary of all these works is presented.

Apart from this laboratory analysis, real scale tests were performed at site with the aim to increase durability by the addition of nanosilica particles. The characterization of these real scale tests are also described and discussed in this paper.

**Keywords:** concrete, caissons, durability, chlorides, nanosilica.

## 1. The construction method

In the floating dock construction method, concrete is cured (mainly) under sea water; the caisson is progressively submerged as the caisson walls are casted and slide through the formwork. A typical caisson made with the Kugira floating dock (owned by ACCIONA Infraestructura) is 66.85 m in length, 34.60 m in width and up to 34 m in height. It is divided in 8 sections, in a total of 32 inner cells, weighing more than 12000 metric tons. More than 5000 m<sup>3</sup> of concrete and 500 tons of steel are used for the construction of each caisson. The construction method can be described in the following main steps:

- With the pontoon fully out of the water, the deck is cleaned and the caisson structure is stacked.
- The caisson base moulds are assembled, the reinforcement of the base slab and wall fixings are placed and the bottom slab is casted.
- The sliding mould and the steel truss are lowered.
- As the sliding of the caisson shaft starts, the base slab mould is removed and concreting of the caisson shaft starts. The concrete is poured in successive 30 cm thick layers at an average rate of 2 m every 12 hours.
- The floating dock is stage ballasted by flooding the ballast tanks to ensure that both the caisson and the dock are sunk in a balanced and proportionated way.
- When sliding has reached 8 m, several 300 mm tubes are put in place to communicate between the different shaft cells; this way the caisson is divided in 8 sectors so that when ballast is introduced the caisson will remain horizontal.
- At 12 m, 8 more tubes are placed in the exterior screens (1 per sector) to be able to locate the valves needed for anchoring the caisson.
- At 17 m, the towing hooks are placed to allow the caisson to be towed out to sea.
- Once the sliding is finished, the mould is removed and the caisson is ballasted with sea water.
- The floating dock is ballasted until the caisson rises of the deck and floats.
- Finally, the caisson is towed to the quay wall and the valves are open to fill the cells with sea water until the hole block is settle in the sea bed.

**Figure 1. Caissons construction method. Right) Kugira floating dock, and left) detail of the bottom part of the sliding formwork.**

## 2. Approach

### 2.1 Objectives

The objectives of this study were:

- To investigate the influence of early exposure to artificial sea water on the concrete's mechanical and transport properties.
- To determine the chloride transport properties in concrete by accelerated methods
- To analyze the influence of the use of nanosilica in the improvement of the strength and durability of concrete at real scale.

### 2.2 Test programme

All materials and the mix design are representative of those usually used in the construction process. Tables 1 and 2 show the composition and the sample matrix, respectively; the concrete follows the standard EN 206-1 (2000), fulfilling the minimum requirements for the exposure class XS3.

**Table 1: Concrete mix proportions.**

W/C	CEM III/A 42.5 N/SR (kg/m <sup>3</sup> )	Sand 0-4 (kg/m <sup>3</sup> )	Aggregate 4-16 (kg/m <sup>3</sup> )	Glenium C303 SCC (% of CEM)	Pozzoloth 488N (% of CEM)	Slump (mm)
0.45	350	918	1048	2.0	0.4	200

Specimens were tested at the ages of 16 h, 1, 2, 3, 7 and 28 d; these ages have been decided according to the details of the construction methods. The following curing conditions were employed:

- 16 h and 1 d: cured in the form;
- 2, 3 and 7 d: cured in the form for 1d and from then on under water;
- 28 d: cured in the form for 1 d, then 6 d under water and from then on stored at 20 °C and 65 % RH.

At the age of exposure (16 h, 1, 2, 3, 7 and 28 d), the specimens were immersed in artificial sea water, the composition of which is given in Table 3.

**Table 2: Sample matrix.**

Number/Type of samples	Cube 100 mm	Cube 150 mm	Cyl. Ø100 mm	Cyl. Ø150 mm							Total
					16 h	1 d	2 d	3 d	7 d	28 d	
Compressive strength (before exposure)	X				3	3	3	3	3	3	20 <sup>a</sup>
Compressive strength (after 6 months immersion)	X				3	3	3	3	3	3	18

Rapid chloride migration			X		2	2	2	2	2	2	12 <sup>b</sup>

<sup>a</sup> 2 extra specimens were tested at the age of 180 days

<sup>b</sup> 2 extra cylinders (4 specimens) were tested at the age of 180 days

**Table 3: Composition of artificial sea water.**

Composition		Artificial seawater	
	(in ‰)		(in g/l) for 100 l (g)
Total salinity	35	NaCl	24.6 2460
Chloride	19.345	KCl	0.67 67
Sodium	10.752	CaCl <sub>2</sub> ·2H <sub>2</sub> O	1.36 136
Sulfate	2.701	MgSO <sub>4</sub> ·7H <sub>2</sub> O	6.29 629
Magnesium	1.295	MgCl <sub>2</sub> ·6H <sub>2</sub> O	4.66 466
Calcium	0.416	NaHCO <sub>3</sub>	0.18 18
Potassium	0.390	pH	8.2

### 2.2.1 Ponding tests and artificial sea water exposure

In these tests, the following properties were examined:

- Compressive strength before exposure to artificial sea water, at the ages of 16 h, 1, 2, 3, 7, 28 and 180d, according to EN 12390-3 (2009);
- Compressive strength after exposure for 6 months in artificial sea water, for specimens exposed at the ages of 16 h, 1, 2, 3, 7 and 28 d, according to EN 12390-3 (2009);
- Pore size distribution on paste samples, at the ages of 16 h, 1, 2, 3, 7 and 28 d by mercury intrusion porosimetry between 0.004 and 100 µm. This pore size range is important for all transport phenomena including capillary water transport and chloride diffusion. At the selected ages, the samples were immersed in 2-propanol (alcohol exchange) for 3 days in order to stop the hydration, vacuum dried and stored in a desiccator containing nitrogen to avoid carbonation.
- Microstructural analysis on polished cross sections of concrete, at the ages of 16 h, 1, 2, 3, 7 and 28 d by scanning electron microscopy (SEM). At the selected ages, hydration was stopped by means of alcohol exchange. After dried, the samples were impregnated with epoxy resin and finely polished using petroleum as grinding liquid.
- Chloride profiles on concrete samples, tested according to ASTM C1543-10a (2010) (ponding method). At the ages of 16 h, 1, 2, 3, 7 and 28 d the samples were exposed to chloride solution (3% NaCl) during 6, 18 and 36 (analysis pending) months. At the end of the exposure period, the samples were ground on a lathe in the following steps: 0-2, 2-4, 4-6, 6-9, 9-12 and 12-15 mm for the specimens exposed during 6 months; 0-2, 2-5, 5-8, 8-12, 12-16, 16-20 and 20-25 mm for the specimens exposed during 18 and 36 (analysis pending) months. The acid soluble chloride content (total chloride content) was determined according to AASHTO T-260 (1997). Additionally, for the age of 28 d, the influence of the exposed surface was studied by comparing the chloride profiles for both cast and cut surfaces.
- XRD on powder samples of concrete, after 18 months ponding: for the samples exposed at the ages of 1 and 28 d, grinding steps 0-2, 2-5, 5-8, 8-12, 12-16, 16-20 mm; for the samples exposed at the ages of 2, 3 and 7 d, grinding step 0-2 mm.

### 2.2.2 Rapid chloride penetration test

The chloride migration coefficient, based on non-steady-state experiments was measured according to NT Build 492 (1999). In this test, an external electrical field (10-60 V DC) is applied axially across a test specimen ( $\varnothing$  100 x 50 mm) to accelerate the process of chloride migration. At the end of the test period (typically 24 hours), the specimen is axially split into two half and the chloride penetration depth is measured using a colorimetric technique (silver nitrate spray). The chloride migration coefficient is then calculated from the chloride penetration depth.

## 3. Results

### 3.1 Ponding tests and artificial sea water exposure

#### 3.1.1 Compressive strength

Figure 2 shows the results from compressive strength measured before (left) and after (right) exposure to artificial sea water. Slow hydration continues throughout 6 months and the relative strength gain from 28 to 180 days is about 6 %. Figure 2 (right) shows that the age of the concrete at the time of exposure does not affect the strength development. The compressive strength after 6 months exposure is 5 to 10 % lower when compared to non-exposed specimens, which is within the variation of strength testing. From the results there seems to be no visible influence of the exposure to seawater on compressive strength.

Figure 2. Compressive strength (left) before and (right) after 6 month exposure to sea water

#### 3.1.2 Pore size distribution

In practical terms, it is the capillary pores that are of major importance for the chloride ingress since the gel pores are too small to allow significant transport of species by diffusion or capillary forces. Although macro pores have no capillary action, these can also be of importance under submerged conditions.

The pore size distribution of cement paste samples at the ages of 16 h, 1, 2, 3, 7 and 28 d was characterized by mercury intrusion porosimetry (MIP).

The objective was to compare the pore size distribution of the cement paste at different ages of hydration. The results are shown in Figures 3. It can be seen that, as the hydration proceeds, there is a refinement of the pore structure together with a significant decrease (about 50 % from 16 h to 28 d) in the total pore volume. Most significant, is the increase in the gel pores (< 10 nm) and the decrease in both smaller (10-100 nm) and larger capillary pores (0.1-1  $\mu$ m).

Regardless of the exposure environment, concrete exposed at an early age will have a higher chloride diffusion coefficient since both the moisture content and the volume of capillary pores is higher; however capillary suction is relatively small. As the hydration proceeds, the volume of capillary pores decreases and with it also the diffusion coefficient.

Figure 3. Absolute and total pore volume distributed according to the pore size at each age

### 3.1.3 Microstructural analysis

The microstructure of the concrete samples at the ages of 16 h, 1, 2, 3, 7 and 28 d was characterized by scanning electron microscopy. SEM images in Figure 4 show an overview of the cementitious matrix for samples 16 h, 1, 7 and 28 d. Detail pictures are shown in Figures 7 to 10.

Figure 4. SEM photo micrographs of the cement paste at different ages (backscatter mode)

The micro structure of the slag cement containing concrete is, as expected, porous at young age  $\leq 1$  d, which is visible in the SEM backscatter images in form of black to dark grey areas (Fig. 4). Up to an age of 7 days the porosity is continuously decreasing (Fig. 4) and not so much different from the 28 day sample. This confirms the results from the development of the pore size distribution as shown in Fig. 3. The reaction of the slag is not visible at 16 h, where mostly the clinker phases are dominating the hydration. Some of the capillary porosity can be attributed to the clinker reaction: C3S and C2S are dissolving faster in the pore solution as hydration products are formed, which results in open space around the grains.

After 1 d, however, the slag started to react. In this stage only the partial dissolution of slag grains were visible. Hydration products in form of hydrotalcite like phases were not observable by SEM at this stage. After 7 d reaction of slag was clearly evident. In some of the grains the formation of a new Mg containing phase was observed. This phase is generally referred to as hydrotalcite  $Mg_6Al_2(CO_3)(OH)_{16} \cdot 4(H_2O)$ , which

is a main hydration product of slag with higher magnesium content and which composition and crystal structure may vary within certain limits.

After 28 d the micro structure of the concrete is denser and the hydration of slag and the formation of hydrotalcite around the slag grains are more pronounced. The hydration process of slag will not stop under water saturated conditions but will go on for several months or even years.

### 3.1.4 Chloride profiles

The chloride profiles after 6 and 18 months exposure (ponding method) are summarised in Figure 5. After 6 months exposure, no significant difference was found between the ages of 1 and 7 days except for the surface chloride content (CS). At early ages (1 day), the higher concrete permeability leads to distinctively higher chloride ingress, which is indicated by higher Cl concentrations in the first 5 millimetres. However, after a certain time with the refinement of the pore structure (Fig. 3) and because chloride diffusion is, in general, a slow transport process, the diffusion coefficients decrease with time and therefore almost the same chloride concentrations were analysed at depths larger than 5 mm.

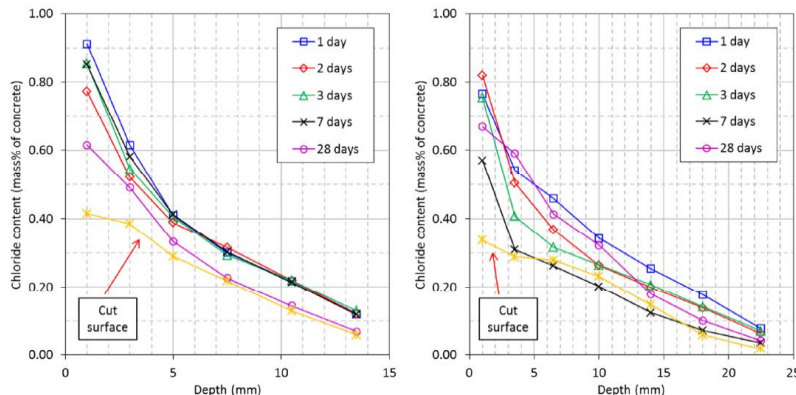

In general, the chloride ingress is more severe in specimens exposed at early age (1-7 days) when compared to those exposed at the age of 28 days. The main reason is associated with the strong decrease in porosity as shown in Figure 3, leading to lower permeability. While the curing age has, in general, a positive influence in reducing the total chloride content, it can be seen that this effect is more pronounced at the outermost layer. In fact, due to the combined transport mechanisms of capillary suction and diffusion, the relative difference in the chloride content between 28 days (circle) and 1-7 days (other curves) decreases with the penetration depth, since in the case of specimens exposed at 1-7 days the only relevant transport mechanism is diffusion.

The influence of the casting surface on the chloride ingress is also shown in Figure 5 for the case of specimens exposed at the age of 28 days. It can be seen that, up to a depth of 6 mm, the chloride content is higher for cast surfaces due to the higher cement content and therefore, chloride binding capacity; however, this does not seem to influence the chloride ingress.

Based on the mixture proportions the binder content can be calculated as 14 % by mass of concrete. In addition, based on the experience from Tang et al. (2013), a difference of 4 % binder per mass of concrete can be assumed between the outermost layer (paste rich) and the bulk concrete. Therefore, when expressed in terms of binder, the chloride contents shown in Figure 5 varied between 2.3-5 % at a depth of 0-2 mm and between 0.4-0.9 % at a depth of 10-15 mm.

After 18 months, however, there is a distinction between the chloride profiles of specimens exposed at different ages. Clearly, the influence of the exposure age becomes less pronounced. With exception of the surface chloride content, specimens exposed between 2 and 7 days show lower chloride contents when compared to those of specimens exposed at the age of 28 days.

Therefore, there is no reason to assume that the early age exposure has a negative influence on the chloride penetration. An interesting feature though is shown for the specimens exposed at the age of 7 days. The total chloride content is in general the lowest, showing also the lowest surface chloride content.

**Figure 5. Profiles of chloride ingress in concrete exposed at different ages: (left) after 6 months exposure; (right) after 18 months exposure (36 months analysis pending)**

### 3.2 Rapid chloride penetration test

Figure 6 shows the non-steady-state migration coefficients obtained at different ages. At the age of 1 day, the chloride migration coefficient is relatively high. However, only one day later (2 days old), this value drops drastically to about 50% and further on by about 90% at the age of 28 days. At the age of 28 days, the  $D_{NT492}$  obtained is within the range of those reported in ECO-Serve (2005), i.e. between 5 to 10  $\times 10^{-12}$   $m^2/s$ . A direct comparison between the two results,  $D_{NT492}$  and  $D_{F2}$ , is not possible since these are obtained under different experimental conditions (i.e. migration and diffusion). In the field, chloride penetration through concrete exposed in marine environments occurs mainly by combined capillary suction/diffusion in atmospheric and tidal zones and by diffusion only in submerged zone.

Since the concrete is exposed at very early ages, capillary suction is rather limited and the diffusion coefficients are much lower than the migration coefficients measured by accelerated methods. Nevertheless, accelerated methods give a good indication as to the resistance of concrete against chloride ingress.

Figure 6. Evolution of the chloride migration coefficient  $D_{NT492}$  as a function of the specimen age

## 4. Real scale tests. Use of nanosilica to improve the concrete performance

Apart from the laboratory tests devoted to give durability guarantees for the floating dock construction method, real scale tests at work site are presented in this manuscript. A conventional concrete made following the standard EN 206-1 fulfilling the minimum requirements for the exposure class XS3 has proven to be durable; nevertheless, advanced concrete containing nanosilica has optimized to improve even more the performance of concrete and to give additional guaranties to the client.

The benefits of employing nanosilica in concrete have been widely studied in literature (Singh, 2013) and it is not the aim of this study to give additional light to this fundamental understanding. In this section the use of nanosilica in the construction of the Açu port complex located at São João da Barra, Rio de Janeiro (Brazil) is presented.

The Table 4 shows the mix design of the conventional concrete used at site and also the advanced concrete that was proposed and used in the second part of the works. The conventional concrete fulfilled all the requirements successfully, which was not easy at all taking into account the available raw materials and suppliers at site. Nevertheless, it was decided to improve even more the mix design, and then, an advanced mix design was proposed, developed, tested and used during the rest of the works. The requirements were a slump of  $22 \pm 2$  cm and a compressive strength class of C40/50.

Table 4: Approximate concrete mix proportions.

Mix	W/C	CP III RS 40 (Brazilian standard)	Sand 0-2	Sand 0-4	Aggregate 4/12	Aggregate 12/19	Admixture		Slump
							1	2	
							Kg/m <sup>3</sup>		% of CEM
							WRA	Super plasticiser	mm
Conventional concrete	0.40	420	350	500	475	600	1	0.6	23
							0.4	0.6	
Advanced concrete	0.40	410	350	500	475	600	0.4	0.6	23
							0.4	0.6	

A total amount of 22 caissons of 6000 m<sup>3</sup> each was made using a nanosilica-based suplespastisicer at 0.55 % with respect to the cement content. Taking into account the solid residue of this admixture, more than 70 tons of nanosilica was used.

The observed improvement by adding nanosilica was quite significant in terms of workability and setting time robustness and compressive strength results. Also the bleeding was reduced. The main reason is that the concrete porosity decreases significantly with the addition of nanosilica. Then, the strength and durability (decreased water permeability up to a 30%) were highly improved. In fact, the production and quality control managers decided to decrease the cement content up to 10 kg/m<sup>3</sup> because the higher compressive strength obtained. Those results are statistically treated and shown in Figure 7.

**Figure 7. Statistical results of compressive strength of concrete made with conventional admixtures (boxes 12-18) and with nanosilica-based admixtures (boxes 20-26)**

**Figure 8. Work site pictures. Provisional Kugira protective dock, Kugira and 22 cm slump**

## 5. Conclusions

In this study, the influence of the early age exposure to sea water on the durability properties of slag concrete, generally used by ACCIONA Infrastructure for the construction of caissons by the floating dock method, was investigated.

For the tested concrete composition, the **compressive strength** was approximately 70 MPa at the age of 28 days. Early age exposure to chloride environment did not influence the compressive strength when compared to concrete cured for the same period under normal conditions (20 °C and 65 % RH).

**Mercury intrusion porosimetry** measurements have shown a significant decrease (about 50 %) of the total pore volume between 16 hours and 28 days mature samples. More importantly an increase in the gel pores and a decrease in the larger capillary pores was measured. Although the porosity (both total and capillary) is higher at early ages, its influence on the durability of the concrete, namely the resistance against chloride ingress, is limited. The main reason is that, at early ages, the degree of capillary saturation is expected to be higher than at the age of 28 days and thus diffusion is the only relevant mechanism for chloride transport.

**Microstructural studies** using scanning electron microscope (SEM) confirmed the results obtained by mercury intrusion porosimetry. SEM images showed that at very early ages ( $\leq 1$ d), the porosity of the cement paste is high and mainly the clinker phases react. The porosity then significantly decreases until the age of 7 days. The reaction of the slag is visible already from 1 day but more pronounced after the age of 7 days where the formation of hydrotalcite around the grains is clearly visible.

With regards to **chloride ingress**, after 6 months ponding no difference was found between specimens exposed at the ages of 1 to 7 days; lower chloride contents were measured for the specimens exposed after 28 days curing. However, the relative difference significantly decreases within a small depth, from 0.25% at the surface to 0.10% at a depth of 3 mm. The chloride diffusion coefficient appears to remain constant already after the age of 3 days. After 18 months exposure, only specimens exposed at the age 1 day show higher chloride contents. when compared to the remaining exposure ages. Again, no clear negative influence of the exposure age on chloride penetration was found: lower chloride values were measured for specimens exposed at the ages of 2 to 7 days when compared to those measured for specimens exposed at the age of 28 days. Except for the specimens exposed at the age of 1 day, after 18 months exposure, the chloride diffusion coefficients are much lower than those measured after 6 months exposure. It is recommended to compare the effect of the exposure age on the resistance against chloride ingress for concretes made with slag cement and ordinary Portland cement; although slag concrete is known to have a high resistance against chloride ingress due to its refined pore structure and binding capacity, sometime is required for the secondary pozzolanic reactions to take place, which may not be achieved in such short exposure times.

The **rapid chloride migration test** provides a good indication as to the resistance of the concrete against chloride ingress. The migration coefficient decreases significantly with the age of the concrete at the time of the test. However, at the age of 28 days,  $D_{NT492}$  was found to be in the range of values reported in the literature. In practice however, chloride transport through concrete exposed under submerged conditions occurs by means of diffusion mechanism meaning that the difference in chloride penetration between specimens exposed at the age of 1 day and 28 days is expected to be rather small (as indicated by the results from 6 months ponding experiments).

In **summary** the results indicate an only weak influence of early age exposure on the investigated concrete properties. Chloride ingress was higher in the surface zone of specimens exposed to artificial seawater at early stage but after ca. 5 mm depth the chloride levels tend towards the ones which were exposed after 28 d. Higher chloride content in surface zones in slag containing concretes with subsequent strong reduction in concentration is well known from other studies (e.g. Hong and Hooton, 1999) independent of the curing age and time of exposure. And these earlier studies showed also the lower chloride concentration and higher chloride binding capacities of slag containing concretes.

Regarding the **tests done at site in Brazil**, by means of the addition of nanosilica, the durability was improved and the concrete cost was reduced showing that it is possible to increase the lifetime of a civil structure without increasing the final cost.

**Abstract:** Durability specifications for reinforced concrete structures can be divided into the traditional prescriptive approach, in which limiting values are set for strength classes, cement contents and water/binder ratios, and performance-based approaches which should fundamentally be based on measurements of concrete properties that can be used as input parameters in service life prediction models. The research discussed in this paper compares the prescriptive approach presented in the Eurocode (EN 1992-1-1: 2004 [1]) to the performance-based approaches for concrete durability used in South Africa. A total of 12 different concrete mixes with 4 different binder combinations were designed according to the specifications given in the British National Annex (NA to BS EN 1992:1) [2] to the Eurocode, focusing on environmental classes related to chloride-induced reinforcement corrosion. The concretes were assessed with the South African Durability Index test methods. The results indicate that the prescriptive specifications of the Eurocode for concrete containing plain CEM I may not be adequate for the marine environment, resulting in lower durability than expected. In contrast, the prescriptive design specifications for the marine environment for concretes containing cement extenders such as fly ash, silica fume and slag, may be conservative, especially for environmental class XS1. As a consequence, it is proposed that engineers consider performance-based design approaches as a useful alternative for projects where traditional prescriptive approaches appear inadequate.

**Keywords:** Concrete durability, performance design, chloride ingress

## 1. Introduction

Durability design and specifications for reinforced concrete structures have become increasingly important in recent years, largely as a result of deteriorating concrete infrastructure and the financial burden associated therewith. The prescriptive design approach for durability, which is common to most national standards and specifications, sets limits on material selection and mix design parameters in relation to the prevailing environmental condition and assumes that the structure is inherently durable if these limits have been met. In contrast, performance-based design commonly includes the measurement of material properties that can be used to predict the performance of the structure and can therefore account for the important project-specific aspects of material selection and construction methods.

The prevailing mechanism causing premature deterioration of and damage to reinforced concrete structures is reinforcement corrosion resulting from carbonation, or the ingress of chlorides from the marine environment or the use of de-icing salts, often in connection with insufficient cover depth. The end of the service life of reinforced concrete structures is usually defined as the time when the corrosion initiation period ends and corrosion propagation starts. This is linked to the chloride concentration at the reinforcement exceeding a certain threshold value, or the carbonation front reaching the reinforcement. Performance-based design of reinforced concrete structures is therefore commonly based on the modeling of chloride ingress and carbonation. To this aim, the concrete's resistance against the ingress of harmful substances can be assessed with appropriate test methods. The South African performance method for durability design, which is already applied in practice on a large scale, makes use of transport properties such as oxygen permeability and chloride conductivity to model the service life of RC structures [3, 4].

The South African National Standards for the design of concrete structures are primarily based on (outdated) British Standards. Following the implementation of the new Eurocode in the UK [1, 2], it is anticipated that the Eurocode will in the near future also be adopted in South Africa. A South African National Annex will then need to be drafted as well. In this research, the potential durability of concrete mixes that meet the prescriptive design specifications of the Eurocode was evaluated using performance-based service life prediction models and test methods that are accepted in South Africa. Like this it could be evaluated if the durability specifications of the Eurocode offer a rational design concept for the South African industry.

## **2. Prescriptive design for durability according to Eurocode 2 and the British National Annex**

Eurocode 2, the European standard for the design of concrete structures consists of the common European document [1], which is the same for all member countries of the European Union, and the National Annexes (NA) which contain country-specific design parameters based on local conditions, experience and traditions. For durability design of concrete structures, Eurocode 2 prescribes indicative concrete strength classes in relation to different environmental exposure classes and presents requirements for minimum cover depths. For reinforcement corrosion a total of 10 environmental classes are presented, divided into corrosion due to carbonation (Exposure Class XC), general chloride exposure (XD) and chlorides from sea-water (XS). The design value for concrete cover depends on the so-called Structural Class, which relates to the required service life, concrete strength class, member geometry, and construction quality.

More detailed requirements for the composition of the concrete are presented in EN 206 (BS EN 206-1: 2000 [6]), which covers specification, performance, production and conformity of concrete and which needs to be considered in addition to the recommendations given in Eurocode 2. EN 206 allows the designer to use performance-related design methods for reinforced concrete structures, based on satisfactory experience with local practices in local environments or data from established performance test methods. EN 206 further includes prescriptive specifications for concrete durability and, in addition to the strength requirements of Eurocode 2, presents limiting values for maximum water/binder ratios and minimum cement contents in relation to the prevailing environmental exposure class. EN 206 therefore allows both performance-based and prescriptive design approaches but due to limited experience with the former, no further details are presented on appropriate test methods and conformity criteria for the performance-based approach.

The prescriptive durability requirements of Eurocode 2 and EN 206 are somewhat crude as they do not consider the influence of different binder types and, being restricted to limiting strength classes, water/binder ratios, and cement contents, leave only very limited design options and little room for innovation. However, the NA of the individual member countries generally offer a larger range of design possibilities based on locally available materials and local experience. For example, the British NA (NA to BS EN 1992:1 – 2004 [2]), which was considered for the design of concrete mixes used in this research, accounts for different cement combination types for exposure classes XS (marine exposure) and XD (de-icing salts) and therefore accounts for the potentially superior chloride resistance of concretes made with blended cements. In addition, the British NA relates requirements for strength class, cement content and water/binder ratio to different minimum cover depths, which results in the option to “trade off” concrete quality against cover depth. Compared to previous codes and standards, the current Eurocode and its National Annexes present a more detailed list of prescriptive requirements for concrete composition and cover depth, which can be considered a positive development. However, many researchers argue that the prescriptive approach to concrete durability fails to present a rational design tool as it cannot account for the use of innovative materials and the influences of the construction process [6-9].

As stated above, EN 206 also includes the option to apply performance-based design approaches for concrete durability, however without giving guidance on appropriate test methods or related service life models. Researchers and practitioners in many countries are currently developing and evaluating appropriate test methods and service life models (e.g. [10-12]) and it can be expected that in future performance-based design for durability will increasingly be applied to concrete structures.

### **3. Performance-based design for durability**

#### **3.1 Principles**

Performance concepts should be based on quantitative predictions for durability from exposure conditions and measured material characteristics. The resistance of the structure, measured through durability parameters of the actual concrete used, is compared against the environmental load, similar to the approach for designing and controlling compressive strength for certain loading conditions. On this basis, deterioration of a concrete structure during its lifetime is quantitatively predicted using appropriate deterioration models. The obvious advantage over traditional prescriptive approaches is that the influence of mix design parameters and mix constituents can be individually assessed for different types of concrete, which allows rational, economic and innovative design of concrete mixes that are tailor-made for the specific project requirements and environmental conditions.

Various approaches and philosophies for performance-based specifications for concrete durability exist around the world. Most of these approaches include experimental investigations on relevant concrete properties such as diffusion coefficients, which can be used in service life models to predict the rate of deterioration. For reinforced concrete, chloride ingress and carbonation are the most important deterioration processes and a range of test methods exist to characterize the concrete's resistance against these processes (see for example [13]).

Some performance-based approaches are solely based on pre-qualification of concrete mixes in the design stage. In this case, concrete mixes specifically designed or chosen for a project are tested for their resistance against the environment-specific deterioration processes. In this way, suitable constituent materials and concrete compositions can be selected and specified for the project. The structures built with concrete specified in this way are assumed to be inherently durable but no testing is carried out on the actual structure to confirm this. Examples of recent approaches that follow this methodology include the method discussed in [12] and the European "Equivalent Durability Concept" [14].

Another school of thought postulates that durability cannot be achieved unless relevant properties of the cover concrete of the *as-built* structure can be assessed. Approaches that follow this viewpoint include conformity-assessment of the as-built structure, commonly using test methods for transport properties such as permeability and conductivity (or the inverse, resistivity). With this approach, the important influences that construction procedures such as compaction and curing have on the potential durability of the structure can be assessed. An example of performance-based approaches that include conformity assessment is the South African Durability Index (DI) approach.

### **4. The South African Durability Index Approach**

#### **4.1 General**

The South African Durability Index (DI) approach for specification and conformity assessment of concrete durability is based on durability indicators (so-called durability indexes) such as oxygen permeability, chloride conductivity and water sorptivity.

Similar to most service life prediction models for reinforced concrete structures, the South African model assumes that the service life duration corresponds to the corrosion initiation period. As such, the service life is assumed to end when the concrete has carbonated to the level of the steel or when the chloride concentration at the level of the steel has reached a certain threshold value. Two corrosion initiation models have been developed, related to carbonation - and chloride - induced corrosion. The models derive from measurements and correlations of short-term durability index values, aggressiveness of the environment and actual deterioration rates monitored over periods of up to 10 years. The models allow for the expected life of a structure to be determined based on considerations of the environmental conditions, cover thickness and concrete quality [3, 15]. The environmental classes are related to the EN 206 classes as modified for South African conditions, while concrete quality is represented by the appropriate durability index parameter. The oxygen permeability index is used in the carbonation prediction model, while the

chloride model utilizes chloride conductivity. The service life models can also be used to determine the required value of the durability parameter based on predetermined values for cover thickness, environment, and expected design life.

## **4.2 Prediction of chloride ingress**

The South African Chloride Conductivity Index (CCI) test involves the measurement of a sample's conductivity [3, 15]. A 30 mm thick, 70 mm diameter specimen is dried in an oven and vacuum pre-saturated with a 5 M NaCl solution. A migration cell is used, in which the sample is placed between two cells containing 5 M NaCl solution. A 10 V potential difference is applied across the sample, causing a movement of chloride ions, and the corresponding current is used to calculate the concrete's conductivity. The apparatus allows for rapid testing under controlled laboratory conditions and gives instantaneous readings.

An international study [10, 13, 16] revealed that the chloride conductivity test is able to detect differences in w/b ratio, binder type, and curing condition on a statistically highly significant level and that test results obtained with the chloride conductivity method generally correlate well with results obtained from other accepted test methods for chloride resistance, such as the Rapid Chloride Permeability Test (ASTM C 1202 [17]) and the Bulk Diffusion Test (NordTest NTBuild [18]).

Chloride ingress into concrete is modelled with the South African service life model for concrete in the marine environment [3, 15]. This model is based on Fick's laws of diffusion and uses chloride conductivity values to evaluate chloride diffusion coefficients. Correlations between 28-day chloride conductivity results and diffusion coefficients after several years marine exposure have been shown to be good over a wide range of concretes [15]. The philosophy behind examining the correlation between diffusivity and conductivity is that conductivity of saturated materials is linearly related to steady state diffusivity, while apparent diffusivity is a function of steady state diffusivity and the chloride binding capacity. Having established a correlation between the apparent diffusion coefficient and the chloride conductivity makes it possible for the designer to use the Fickian service life models directly and input the appropriate conditions (cover depth, environmental classification, desired life, and material) to give material specifications in terms of the diffusion coefficient value that should be achieved using the chloride conductivity test. The correlation between the apparent diffusion coefficient and the chloride conductivity can also be used to establish chloride conductivity index limits used in durability design.

## **5. Experimental work**

### **5.1 Aims and methodology**

In this research, the prescriptive design approach for reinforced concrete durability in the marine environment according to the British National Annex to the Eurocode (2004 [2]) is compared with performance-based design approaches used in South Africa. The aim of the study was firstly to evaluate if the prescriptive specifications of the Eurocode are generally more or less conservative than the performance-based approaches in South Africa. Secondly, it was assessed if the prescriptive requirements make sufficient allowance for the influence of various binder types on the durability characteristics of concrete.

A total of 12 different concrete mixes were designed to meet the durability specifications of the British National Annex to EN 1992:1 (2004 [2]) and tested according to the South African Durability Index method. The test results were used to model chloride ingress using the South African service life prediction model for the marine environment. The assessment and analysis of durability parameters using accepted test methods and service life prediction models allowed evaluating if the prescriptive requirements given in Eurocode, in combination with materials locally available in South Africa result in a rational concrete mix design. In this context, rational concrete mix design can be considered to result in concrete mixes that are neither potentially non-durable, nor vastly over-designed and therefore not economical.

## **5.2 Concrete mix design and binder type selection**

In the British National Annex to the Eurocode (2004 [2]), specifications of maximum water/binder ratio, minimum cement content and strength class are made in relation to binder type and cover depth, as discussed earlier. For the experimental work, the selection of appropriate design cover depths and binder types was made based on South African construction practice. The considered design service life was 50 years.

In agreement with South African construction practice, the design cover depths chosen for this research was 50 mm for exposure classes XS (marine environment). The common South African binder type combinations (pure CEM I, or CEM I plus either 10% condensed silica fume (CSF), 30% fly ash (FA), or 50% granulated slag (GGBS)) correlate to the binder combinations stipulated in the British NA to the Eurocode (2004) for environmental classes XS, which include CEM I, CEM IIA, CEM IIB-V, and CEM IIIA. All of the above four binder type combinations were therefore used in this research.

Mix design parameters and strength classes were selected in relation to the above mentioned design cover depths and binder types to meet the specifications of the British NA to the Eurocode (2004 [2]), as summarized in Table 1. For comparability reasons, the amount of coarse aggregate in all mixes was kept constant at 1050 kg/m<sup>3</sup>. The water content of the mixes ranged between 170 and 190 l/m<sup>3</sup> and if necessary, adjustments to the workability were made with superplasticiser (SP) to achieve a desired slump of 70±10 mm. In the mix design process, the authors tried to be as close as possible to the specified minimum cement contents. However, for some mixes, workability requirements demanded slightly higher water contents and therefore higher cement contents.

With mix parameters and compressive strength values meeting the requirements of the specifications, all 12 mixes would be considered durable for their design environment according to the British NA to the Eurocode [2].

## **5.3 Chloride conductivity measurements (chloride ingress prediction)**

Mixes 1 – 12 were assessed for resistance against chloride ingress using the chloride conductivity index (CCI) values as input parameters in the South African service life prediction model for concrete in the marine environment. The test specimens consisted of 30 mm thick core slices (68 mm diameter) that were removed from concrete cubes (28 days water-cured at 23°C) and preconditioned and tested according to the test method's specifications [19]. A total of 4 test results were obtained per mix and, following exclusion of outliers, the mean conductivity values used in the analysis.

The CCI results of the laboratory-cured samples were converted to the “equivalent in-situ concrete”, as suggested in [6], using a conversion factor of 0.90 so that  $CCI_{Lab} = CCI_{Site} \times 0.90$ . This conversion takes into account that measurements taken on real structures under site conditions have a higher statistical variability, compared to measurements taken in the laboratory on fully cured samples. The test results (measured and converted) are presented in Table 1. Using the equivalent  $CCI_{Site}$  values, as well as binder type and environmental conditions as input parameters in the South African service life prediction model allows to forecast the chloride contents in the structure (by mass of binder) at a certain depth and time.

For interpretation of the predicted chloride contents in structures made with Mixes 1 – 12 it was assumed that the service life ends with the beginning of the corrosion initiation phase at a chloride content of 0.4% by mass of binder. Table 1 and Figures 1-3 present the results of the analysis in relation to the following:

- Chlorides by mass of binder at a cover depth of 50 mm (corresponding to the design cover depth) (Figure 1)
- Depth at which the chloride content exceeds 0.4% by mass of binder (after 50 years), corresponding to the cover depth actually necessary for a design service life of 50 years (Figure 2)
- Expected service life, assuming a chloride threshold of 0.4% by mass of binder and a cover depth of 50 mm (Figure 3)

**Table 1:** Prescriptive recommendations according to EC2 (reference) for exposure classes XS1, XS2 and XS3, assuming a cover depth of  $(40 + \Delta c_{dev}) = 50$  mm; concrete mix design and selected properties

The South African service life prediction model for the marine environment uses Fick's law of diffusion to model chloride ingress into concrete and is therefore based on the model input parameters of chloride surface concentrations and time-dependent diffusion coefficients. The chloride surface concentrations are predicted based on binder type and environmental conditions, and the chloride diffusion coefficients are derived from chloride conductivity values, as discussed above.

Figures 1 – 3 show the results of the service life prediction model for mixes 1 – 12 and present an indication on how the prescriptive design approach of the British Annex to the Eurocode compares to the expected performance of the concretes in their respective design environments (based on the South African service life prediction model). It needs to be noted that the analysis presents a qualitative evaluation only, as the model is based on various assumptions and simplifications, such as a 0.4% threshold value for reinforcement corrosion and an estimated time-development of diffusion coefficients. A more accurate quantitative comparison of prescriptive and performance-based approaches in this way would need to be done based on long-term data of chloride ingress into concrete in real environments, which is currently not available. However, the service life prediction results shown in Figures 1 – 3 give a general indication on how conservative (or otherwise) the prescriptive durability requirements of the Eurocode are with respect to various binder types and environmental conditions in South Africa.

A limitation of the experimental research was that fully water-cured samples were used for the testing, which resulted in an upper-bound evaluation of chloride resistance. In real structures, where curing conditions influence the concrete quality, the chloride resistance can be expected to be lower. Nonetheless, the results allow identification of some interesting trends.

The results of the analysis indicate that the Eurocode specifications are on the conservative side with concretes made with blended cements. The predicted service life duration of all concretes made with silica fume, slag, or fly ash considerably exceeds the design service life of 50 years, even indicating a service life or more than 100 years, which was observed for all 3 exposure classes (Fig. 3). Correspondingly for these concretes, the predicted chloride contents at the level of the reinforcement after 50 years exposure are significantly below the threshold value of 0.4%, especially for environments XS1 and XS2 (Fig. 1).

The same trend, however less obvious, can be observed when the predicted required cover depths (the depths at which chloride concentration exceeds 0.4% by mass of binder) are considered (Fig. 2). The reason for the trend being less obvious in this case is that chloride ingress is fast in early years but slows down considerably with time. Considering, for example, Mix 7 (binder type II/B-V, exposure class XS2), the predicted chloride content at the level of the steel after 50 years is less than half that required for corrosion initiation but at 10 mm away from the steel, i.e. at 40 mm depth, the threshold has already been reached. This can be explained with the steep chloride profiles predicted in the model. A relatively small deviation from the specified cover (in the case of Mix 7, 10 mm, corresponding to 20% of the specified 50 mm) has therefore a significant influence on corrosion initiation and can reduce the service life duration by more than 50%.

**Figure 1:** Mixes 1 – 12: estimated chloride content at the reinforcement after 50 years

Figure 2: Mixes 1 - 12: estimated depth at which the chloride concentration reaches 0.4% (by mass of binder) after 50 years

Figure 3: Mixes 1 – 12: estimate of service life duration (>100 years for all mixes with blended cements)

Interpreting the experimental data based on Figures 1 and 3 alone creates the impression that the prescriptive approach is extremely conservative with blended cements, considering the “potential” durability measured on fully cured concrete. However, Figure 3 shows that the safety factor may actually be relatively small with respect to concrete cover for environment XS2 in particular, XS3 less so, and XS1 considerably less so.

In comparison to the concretes made with blended cements, the prescriptive specifications for the mixes containing CEM I are far less conservative or even inadequate. In case of environmental classes XS2 and XS3, the predicted service life durations are just above 20 years and 50 years, respectively. Figure 2 shows that the required cover depth for environmental class XS2 is close to 70 mm and that very little safety in terms of cover depth is built into the specifications for environmental classes XS1 and XS3.

To identify a trend with respect to different exposure classes, the mean values of the required cover depths of all blended cement concretes are considered, which are 22, 37 and 30 mm for exposure classes XS1, XS2 and XS3, respectively. This suggests that, in comparison to the South African performance-based service life models, the prescriptive requirements of the Eurocode are particularly conservative for exposure class XS1. In contrast, for exposure class XS2, the safety margin with respect to cover depth is relatively small.

## 6. Summary and conclusions

The 12 different concrete mixes used in this research were designed according to the prescriptive specifications of the British NA to the Eurocode and would therefore be considered durable for the chosen cover depth and design environment. However, the predictions of chloride ingress into these mixes, based on chloride conductivity results and the South African service life prediction model, indicate that the design specifications may not be adequate for concrete made with plain CEM I cement. In contrast, concretes made with blended cements generally showed that the prescriptive provisions for the marine environments are somewhat conservative, especially for environmental class XS1. However, mixes used in this study were water cured for 28 days and do therefore only indicate the full durability potential of the concrete mixes. In real structures, the chloride resistance of the concrete will be influenced by construction procedures and curing conditions.

The prescriptive requirements seem to not fully take into account that blended cements incorporating silica fume, slag or fly ash have a much better resistance against chloride ingress, compared to CEM I cements, which is a result of pore structure refinement and superior chloride binding characteristics.

Compared to older versions of prescriptive specifications for concrete durability, the Eurocode accounts for a larger range of design environments and various binder types used, which is a positive development. However, this research indicates that even with concrete made with conventional aggregates and binder combinations, the design specifications of the Eurocode may fail to result in safe or economical concrete mixes. The limitations of the prescriptive approach can be expected to be even more pronounced when innovative and new materials or construction methods are used. For projects where durability is of major concern, the use of performance-based design and specification methods should therefore be considered.

# Durability Performance of Crystalline-Modified Concrete Exposed to Severe Environment

Farhad Nabavi, BEng, MTech, PhD<sup>1</sup>

<sup>1</sup>Technical Manager, Xypex Australia

**Abstract:** This paper presents the effect of crystals formation on mechanical properties and durability performance of concrete exposed to severe environmental conditions. Durability of the concrete is directly related to the mass transport property of the concrete. Penetration of aggressive substances such as chloride ions and carbon dioxide into concrete can significantly reduce the service life of reinforced concrete (RC) structures. Mass transport in concrete is a function of interconnected pores and cracks in concrete. Crystalline structure blocks the pores and heals the cracks permanently. Results from laboratory tests and field investigations as case studies indicated that formation of crystals in pores and cracks can reduce the diffusion rate of aggressive substances into concrete and enhance the durability of concrete significantly.

**Keywords:** crystalline technology, concrete durability, chloride diffusion, service life, concrete sustainability.

## 1. Introduction

Premature deterioration of RC structures exposed to severe environment such as marine environment has become a worldwide problem due to high cost effect, environmental impact, and safety issues [1,2]. Penetration of aggressive agents such as carbon dioxide, chloride ion, and sulphates into concrete, through interconnected pores and cracks result in the degradation of the concrete materials.

Degradation processes which cause reduction in the service life of RC structures may influence both concrete and steel reinforcement depending strongly on diffusion processes and type of diffusive substances into the concrete. Chloride-induced corrosion of steel reinforcement in concrete has received increasing attention in recent years because it has been the dominant factor in deterioration of RC structures [3,4].

Steel reinforcement in concrete is protected by a highly alkaline protective passive layer. Accumulation of the chloride ions at the surface of reinforcing steel results in a local fall in the pH of the pore solution. The protective film can be destroyed if the concentration of chloride ions at the depth of the steel reaches to a critical level which is called chloride threshold level (CTL). Depassivation of the protective film causes steel corrosion which consequently reduces the service life of the RC structures. Therefore, preventing chloride penetration into concrete, by blocking the pores and sealing the micro-cracks, increases durability of the concrete and consequently extends the service life of RC structures [5,6,7].

This paper investigates the effect of crystal formation on transport properties and durability of the concrete. Sorptivity, water permeability, and chloride diffusion as durability assessment tests are investigated. In addition, the effect of crystalline technology on compressive strength of concrete is examined.

## 2. Crystalline Technology

Crystalline materials are dry powder compounds composed of Portland cement, silica sand, and many active and proprietary chemicals. Active chemicals in crystalline materials react with the moisture and cement hydration products to cause a catalytic reaction. This chemical reaction generates a non-soluble crystalline formation which permanently blocks the pores and capillary tracts; and seals the micro-cracks of the concrete. Scanning electron microscope (SEM) images (Figure 1 to 3) confirm the pore blocking and crack sealing properties of the crystalline technology.

**Figure 1. Crystals growth in concrete pores**

**Figure 2. Pore blocking by crystals formation**

**Figure 3. Crack bridging (a) and crack healing (b) by crystals formation**

### **3. Experimental Program**

The experimental program includes laboratories and field investigations.

#### **3.1 Test Methods and Standards**

The conducted tests and utilised standards are summarised as follows:

- Slump: AS1012.3
- Compressive strength: AS1012.9
- Drying shrinkage: AS1012.13
- Apparent Volume of Permeable Voids (AVPV): AS1012.21

- Water permeability: ACCI Method
- Rapid chloride ion test: ASTM1202/CSIRO Modified
- Chloride ion diffusion coefficient: NordTest (NT Build 443)
- Chloride content measurement: ASTM C1152-04.
- Half-cell potential measurement: ASTM C876-91.

## **3.2 Laboratory investigations**

### **3.2.1 Materials**

Since the durability performance was the main objective of laboratory investigation, all concrete specimens were cast using supplementary cementitious materials (Fly Ash and GGBF Slag). Crystalline material was used as admixture with two proportions of 0.8% (CA1) and 1.2% (CA2) by weight of cementitious materials in concrete. Crushed limestone aggregate with specific gravity of 2700 kg/m<sup>3</sup> and maximum size of 20 mm as coarse aggregate, and river sand with specific gravity of 2600 kg/m<sup>3</sup> and maximum size of 4.75 mm as fine aggregate, were used. According to the AS 4997-2005 recommendations, the minimum of 400 kg/m<sup>3</sup> of cementitious material content and maximum water to binder (W/B) ratio of 0.4 were considered in all types of concrete.

### **3.2.2 Sample preparation**

Three types of samples were prepared as follows:

- Type-GB cement with 25% Fly Ash-class F (AS3582.1), (FA) with and without Crystalline Admixture (CA)
- Type-GB cement with approximately 38% Slag (AS3582.2) (S1) with and without Crystalline Admixture (CA)
- Type-GB cement with approximately 60% Slag (AS3582.2) (S2) with and without Crystalline Admixture (CA)

Based on these codes, for instance, S2-CA1 means a concrete sample with 60% slag and 0.8% crystalline admixture.

### **3.2.3 Conducted Tests**

Slump (workability) test as plastic concrete property, compressive strength and drying shrinkage as hardened concrete properties, and water sorptivity AVPA, water permeability, rapid chloride test, and chloride diffusion coefficient as durability characteristics of the concrete were examined.

## **3.3 Field Investigations**

Case studies presented in this paper are related to the durability performance of crystalline modified concrete (CMC) incorporating crystalline admixture materials in two marine structures exposed to severe environment for 19 years.

### **3.3.1 Cronulla Marina Jetty**

The prestressed crystalline modified concrete (CMC) panels (jetty slabs) were cast at the Cronulla Marina jetty, NSW in October 1994. Each panel has a thickness of 100 mm and has foam flotation attached to the soffit. The top surfaces of the concrete panels have a nominal distance of 350 mm from the sea level. The Cronulla Marina structure, which is located in Gunnamatta Bay, has been subjected to most severe environmental conditions within tidal/splash zone. The condition survey and assessment of the structure was conducted in 2013 after 19 years of service (exposure time). Crystalline admixture proportion in the concrete mix was 4.2 kg/m<sup>3</sup> which would be 0.8% by weight of cement content.

### **3.3.2 Lascelles Wharf**

The precast CMC slab was cast at Lascelles Wharf – Geelong Ports, VIC in 1995. This concrete slab has been in service as a bulk chemical and grain dock and also exposed to marine

environment which is classified as the most severe exposure condition. The condition survey and assessment of the structure was conducted in 2014 after 19 years of service (exposure time). Crystalline admixture proportion in the concrete mix was 4.0 kg/m<sup>3</sup> which would be 1% by weight of cement content.

### 3.3.3 Concrete mix design

Concrete mix designs for both case studies are presented in Table 1.

**Table 1. Concrete mix designs for both structures**

Project	Cement	CA (20mm)	CA (10mm)	Coarse Sand	Fine Sand	Water	W/C
	[kg]	[kg]	[kg]	[kg]	[kg]	[kg]	
Cronulla Marina	530	730	340	480	120	170	0.32
Lascelles Wharf	400	420	620	90	660	150	0.37

### 3.3.4 Conducted Tests

Visual inspection, half-cell potential, and chloride content measurement were conducted as criteria for durability assessment of the structures.

In both projects, Copper/Copper Sulphate (Cu/CuSO<sub>4</sub>) Electrode (CSE) was used to measure the half-cell potential. The standard that is typically employed to interpret the half-cell potentials measurements is ASTM C876-91. This standard provides a very general guide for probability of corrosion based on the half-cell potential values.

At Cronulla Marina, the half-cell potentials were measured on 150 mm × 150 mm square grid over an area of 3.6 square meters. At Lascelles Wharf, the half-cell potentials were measured on 200 mm × 200 mm square grid over an area of 3.0 square meters.

Chloride content measurements were carried out for both projects to specify the chloride resistance of CMC exposed to chloride environment after 19 years. Concrete cores were extracted from the slabs to measure the chloride content. The chloride content was measured in different depths up to the thickness of the concrete cover. The minimum concrete covers at the Cronulla Marina and Lascelles Wharf were 40 mm and 51 mm, respectively.

## 4. Results and Discussion

Results and discussion are presented for laboratory investigations and case studies separately.

### 4.1 Laboratory Test Results

#### 4.1.1 Mechanical Properties

Test results of workability and hardened concrete properties are presented Table 2.

**Table 2. Concrete categories and properties**

Mix Code	W/B	Cementitious Content [kg]	CA [%]	Slump [mm]	Compressive Strength [MPa]			Drying Shrinkage [micron]
					3-day	28-day	91-day	
FA	0.4	435	Nil	95	21.9	36.2	46.7	719
FA-CA1	0.4	435	0.8	105	22.1	44.1	53.8	577
FA-CA2	0.4	435	1.2	100	28.0	47.5	58.0	562
S1	0.4	435	Nil	95	28.1	49.9	64.8	814
S1-CA1	0.4	435	0.8	100	28.6	52.7	65.7	689
S1-CA2	0.4	435	1.2	90	28.6	52.9	66.3	711
S2	0.4	435	Nil	100	14.2	38.1	49.3	803
S2-CA1	0.4	435	0.8	105	14.4	38.5	49.8	772
S2-CA2	0.4	435	1.2	95	15.7	42.0	53.4	772

All concrete mixes slump test results were within the normally acceptable range. 28-day compressive strengths for all types of concrete in this investigation are presented in Figure 4.

**Figure 4. 28-day Compressive strength of all types of concrete**

Concrete specimens with crystalline admixture showed higher compressive strength compared to the controls without CA. At age of 28 days, 31% improvement of compressive strength for FA series, 6% for S1 series and 10% for S2 series were observed.

In addition, drying shrinkage results indicated improved performance for all specimens with crystalline admixture. In particular, for FA series, results showed significant reduction in drying shrinkage up to 22%. This shrinkage reduction for S1 and S2 series was 15% and 4%, respectively

#### 4.1.2 AVPV Test

The AVPV test results are summarised in Table 3. Generally, crystalline modified concretes showed lower AVPV values than the control mixes under all curing conditions. Increasing the proportion of the crystalline materials decreases the AVPV value. Significant reduction in AVPV was found with concrete mix FA-CA2 with 11% lower AVPV than the control mix FA after 180 days limewater curing.

**Table 3. Summary of AVPV test results**

Mix Code	7d Lime + 49d Air AVPV [%]	Change [%]	7D Lime + 173d Air AVPV [%]	Change [%]	56d Lime AVPV [%]	Change [%]	180d Lime AVPV [%]	Change [%]
FA	13.06	Control	12.95	Control	12.71	Control	10.75	Control
FA-CA1	12.65	-3.1	12.05	-6.9	12.20	-4.0	9.87	-8.2
FA-CA2	12.80	-2.0	12.08	-6.7	11.54	-9.2	9.57	-11.0
S1	12.60	Control	12.44	Control	12.15	Control	10.22	Control
S1-CA1	12.05	-4.4	11.52	-7.4	11.24	-7.5	9.54	-6.7
S1-CA2	11.80	-6.3	11.25	-9.6	10.87	-10.5	9.32	-8.8
S2	12.05	Control	11.84	Control	11.37	Control	9.24	Control
S2-CA1	11.75	-2.5	11.20	-5.4	10.75	-5.45	8.64	-6.5
S2-CA2	11.55	-4.1	10.94	-7.6	10.47	-7.9	8.45	-8.5

The results confirmed that due to pore blocking by crystals formation, the overall volume of permeable voids decreased. This phenomenon is supported by water permeability test presented in next section.

#### 4.1.3 Water Permeability

All concrete types were tested for water permeability under 100 m water head. The concrete samples were cured in limewater for 90 days before testing. The test results have been summarised in Table 4 in terms of water permeability coefficient.

**Table 4. Water permeability coefficients of concrete types**

Mix Code	FA	FA-CA1	FA-CA2	S1	S1-CA1	S1-CA2	S2	S2-CA1	S2-CA2
Water Permeability Coefficient [ $\times 10^{-12}$ m/s]	1.76	0.98	NIL	1.14	0.31	0.12	0.82	NIL	NIL

Although, no visible water leakage was observed in FA-CA2, S1-CA2, S2-CA1, and S2-CA2 the water penetration depths of 22 mm, 16 mm, 14 mm, 11 mm, and 8 mm, respectively were measured. The results reveal, by increasing the dosage of crystalline material in the mix, water permeability of the concrete decreases. Considering the water permeability coefficient of crystalline modified concrete, this concrete can be categorised of high quality concrete in terms of mass transfer property which is suitable for structures exposed to severe environmental conditions.

#### 4.1.4 Rapid Chloride Test – ASTM C1202 / CSIRO Modified

The results of the rapid chloride ions test are presented in Table 5. As results show, crystalline formation can increase the chloride diffusion resistance of the concrete significantly.

**Table 5. ASTM C1202 / CSIRO Modified test results**

Mix Code	W/B	Cementitious Content [kg]	Crystalline Admixture [%]	ASTM C1202 [%]
FA	0.4	435	Nil	Control
FA-CA1	0.4	435	0.8	-76%
FA-CA2	0.4	435	1.2	-90%
S1	0.4	435	Nil	Control
S1-CA1	0.4	435	0.8	-71%
S1-CA2	0.4	435	1.2	-73%
S2	0.4	435	Nil	Control
S2-CA1	0.4	435	0.8	-47%
S2-CA2	0.4	435	1.2	-62%

#### 4.1.5 Chloride Diffusion Test – NT BUILD 443, Accelerated Chloride Penetration Test

The tests were conducted according to the Nordtest (NT Build 443) with exposure time of 35 days and 105 days. The test results are shown in Table 6.

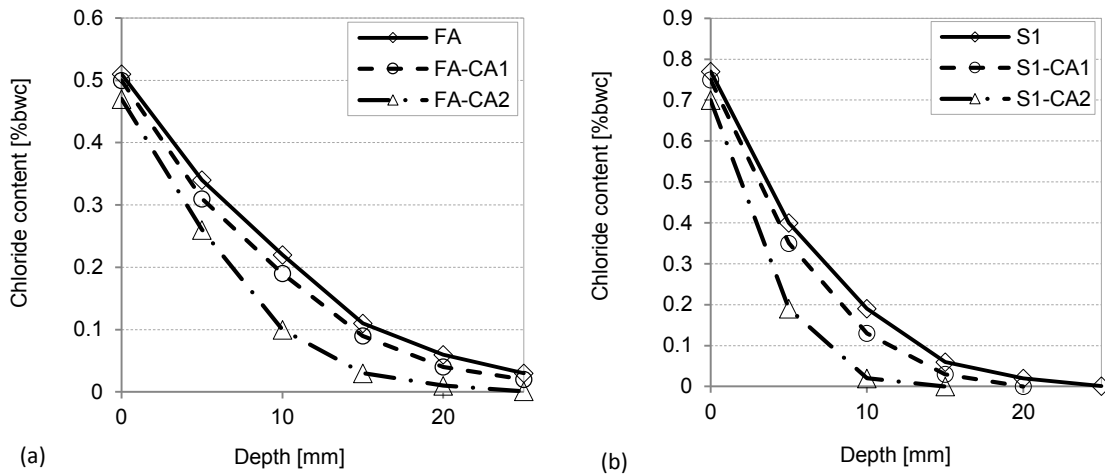

**Table 6. Chloride diffusion coefficient for all types of concrete**

Mix Code	CA [%]	Chloride Diffusion Coefficient [ $\times 10^{-12}$ m <sup>2</sup> /s]		Change (105 days) [%]
		35 days of Exposure	105 days of Exposure	
FA	Nil	15.0	8.0	Control
FA-CA1	0.8	8.5	6.8	-15%
FA-CA2	1.2	5.8	3.5	-56%
S1	Nil	4.0	3.5	Control
S1-CA1	0.8	2.2	2.5	-29%
S1-CA2	1.2	1.5	1.0	-71%
S2	Nil	3.0	1.7	Control
S2-CA1	0.8	3.5	1.2	-29%
S2-CA2	1.2	2.5	1.2	-29%

Crystalline modified concrete indicated significant chloride resistance property even compared to fly ash and slag concrete which are categorised as high quality concrete. Up to 56% and 71%

reduction in chloride diffusion rate in fly ash and slag concrete respectively proves that crystals formation can enhance the durability of the concrete significantly.

The chloride profiles of the different types of concretes are presented in Figure 5 and 6.

**Figure 5. Chloride profiles of FA (a) and S1 (b) series**

**Figure 6. Chloride profile of S2 series**

#### 4.1.6 Corrosion-Free Service Life

The prediction of corrosion-free service lives for S1 (38% slag) concrete samples have been estimated and are presented in Table 7. Concrete cover of 70 mm, chloride threshold level of 0.4% by weight of cement, and marine splash zone as environmental exposure were considered as assumptions in estimation of service life.

**Table 7. Prediction of corrosion-free service life**

Mix Code	S1	S1-CA1	S1-CA2
Crystalline Admixture [%]	0	0.8	1.2
Corrosion-Free Service Life [year]	42	59	147

## 4.2 Field Investigations, Case Study

### 4.2.1 Visual Survey

Site investigations conducted on both RC structures revealed that there was no sign of any concrete cracking, spalling or other defects and concrete slabs were in excellent conditions as shown in Figure 7.

Figure 7. Cronulla Marina (a) and Lascelles Wharf (b) current conditions

### 4.2.2 Half-Cell Potential Results

The results of half-cell potential measurements of both concrete slabs are summarised in Table 8.

Table 8. Half-cell potential measurements for both concrete slabs

Project	Total Points	Max. Potential [mV]	Min. Potential [mV]	Average [mV]
Cronulla Marina	189	-140	-280	-154
Lascelles Wharf	96	52.9	-243	-51.3

Results indicated no corrosion activity in the concrete slabs. In Cronulla Marina the minimum potential was related to the area influenced by the exposed fittings fix on the slab at that point.

### 4.2.3 Chloride Content

The results of chloride content measurements are presented in Table 9.

Table 9. Chloride content measurements

Average Depth [mm]	Cronulla Marina	Lascelles Wharf
	Chloride Content [% by weight of cement]	Chloride Content [% by weight of cement]
10	1.163	0.5
20	0.183	-
30	0.085	0.14
40	0.040	-
50	-	0.06

Considering the environmental exposure conditions, the chloride content measurements of both RC structures demonstrate a high quality of concrete after 19 years of exposure. For Cronulla Marina, to further quantitatively evaluate the resistance of crystalline modified concrete to chloride penetration, the chloride diffusion coefficient of the concrete was also calculated utilising Fick's second law and it

revealed an effective chloride diffusion coefficient of  $8.0 \times 10^{-14} \text{ m}^2/\text{s}$ . This chloride diffusion coefficient value is significantly lower than the high quality conventional concrete available in the literature. Chloride profile for the structures is shown in Figure 8.

**Figure 8. Chloride profiles for the structures**

## 5. Residual Service Life of the Structures

The free-corrosion service life for each structure has been calculated using chloride profiles and Fick's 2nd law. The design service life for both structures has been 50 years.

The free-corrosion service life of reinforced concrete structures is defined as the time required for the chloride concentration to reach to chloride threshold level (approximately 0.4% by weight of cement) at the steel reinforcement surface. The minimum concrete covers used in Fick's second law for Cronulla Marina and Lascelles Wharf were 40 mm and 51 mm, respectively.

The predicted residual corrosion-free service lives of structures are presented in Table 10.

**Table 10. Predicted residual corrosion-free service life for the structures**

Project	Residual Service Life [years]
Cronulla Marina	129
Lascelles Wharf	164

According to the calculations, crystalline technology increased the service life of the Cronulla Marina and Lascelles Wharf by approximately 100 years and 130 years compared to design service life, respectively.

## 6. Conclusions

This paper presented laboratory and field investigations on mechanical properties and durability performance of crystalline modified concrete. Compressive strength, AVPV, water permeability, and chloride diffusion characteristic of the concrete samples were examined as experimental investigation. Half-cell potential and chloride content were measured as the criteria for durability assessment of the reinforced concrete structures as case studies. Eventually, corrosion-free service lives for both experimental and case studies were calculated utilising Fick's second law. The conclusions of investigations can be summarised as follows:

- Non-soluble crystalline formation in concrete blocks the pores and heals the cracks permanently.
- Sorptivity and water permeability of concrete decreased by crystalline technology considerably.

- Crystalline modified concrete increased the compressive strength of concrete up to 31% for fly ash concrete and 10% for slag concrete.
- Crystalline modified concrete showed an excellent long-term performance in severe environmental exposure conditions.
- Chloride diffusion coefficient value in CMC confirmed that the interconnected pores in microstructure of the concrete have been blocked by crystals.
- By blocking the pores and healing the cracks by crystals formation in concrete, actual service life of the structure have been extended significantly.
- Increasing durability of the concrete can definitely reduce the maintenance and repair costs of the RC structures exposed to severe environment.
- Increasing service life of the structure will reduce the demand of raw materials such as aggregates, water, and cement in future which subsequently, will decrease the environmental impact. By enhancing the lifetime performance of the structure and environmental impact, concrete structure sustainability has been achieved.

# ISO 16204 and the Correct Solution to Fick

Norwood Harrison  
Humes Operations & Engineering

**Abstract:** In marine environments, chloride penetrates into concrete by diffusion, following a relationship known as Fick's second law. For a diffusion coefficient which varies with time, the Fick relationship differs from that applicable for a constant value, but there has nonetheless been widespread use of the constant-value form, with the diffusion coefficient (as would be measured by standard test) replaced by a related property having a different value. ISO 16204 presents guidelines for calculating chloride concentration at reinforcement depth, citing another publication as a source of input values. Both publications employ the alternative diffusion property, but values are easily converted to actual diffusion coefficients which can then be adopted in the correct Fick relationship. ISO 16204 does not endorse any model for estimating the remaining life after a threshold chloride level has been reached; in effect the threshold signifies the whole-of-life limit state and the resulting inherent conservatism is offset by relaxed target reliability. This development is taken here as an opportunity to re-asses values of the threshold to be used in design, referring to site investigations and the levels allowed by the provisions of Standards which reflect actual experience with marine exposure.

**Keywords:** concrete, chloride, marine, diffusion, fick.

## 1. Introduction

Modelling penetration of chloride into concrete has been through several phases, and is simplified in ISO 16204 "Durability – Service life design of concrete structures" (2012) to allow the concentration at chosen depth and time of exposure to be calculated from the initial chloride content, surface concentration during exposure and a time-dependent property of the concrete related to the diffusion coefficient. The International Standard does not itself provide representative or generic values for inputs, some of which are not obtainable from short-term measurements or observations but are nonetheless required in order to apply the model. For such data it nominates Concrete Society Technical Publication no. 61 (1), published prior to ISO 16204 and subsequently referred to here as TR61. Formulae in TR61 and ISO 16204 yield the same value for chloride concentration above the initial level, at any chosen depth or time of exposure.

## 2. ISO 16204 and the Correct Solution to Fick

TR61 introduces terminology "apparent diffusion coefficient" to denote a time-dependent property of the concrete related to diffusion, derived from measurements of chloride concentration in exposed concrete over an extended period of time. Quoting from TR61, "These values of apparent diffusion coefficient were then used in conjunction with the error function solution to Fick's second law of diffusion - - to predict rates of chloride ingress." At the time of publication of ISO 16204 it was known that the relationship given for calculating the concentration of chloride  $C(x,t)$  at any chosen depth and time of exposure is not in fact a solution to Fick's second law for a variable diffusion coefficient (2). To distinguish the "apparent diffusion coefficient" from actual values obtained by tests for this property. ISO 16204 provides explanation:

"The "apparent" diffusion coefficient after a period  $t$  of chloride exposure,  $D_{app}(t)$ , represents a constant equivalent diffusion coefficient giving a similar chloride profile to the measured one for a structure exposed to the chloride environment over a period  $t$ ."

This embodies the intention of obtaining values from exposed structures, but fails to clearly distinguish "apparent" from actual diffusion coefficients as obtained from tests such as Nordtest Build 443 (3), as this also assumes a constant value for the duration of the test. Such tests can be carried out on concrete at any age and as noted in TR61 (Figure 11.3 of that publication) yield widely different values from the apparent diffusion coefficient. TR61 shows the discrepancy but offers no explanation of its size. To some extent Nordtest Build 443 reflects early age exposure and so at early age the "apparent" coefficient is likely to be close to the value obtained from this test. Apparent diffusion coefficient applied using the ISO 16204 formula gives correct predictions only if values have been derived from long-term exposure, which in most instances will eliminate the use of this property for qualifying a new material.

The “apparent” diffusion coefficient is not in fact a diffusion coefficient at all in the context of Fick and is better referred to in a way which avoids any ambiguity, for which purpose it is suggested that the term “diffusivity” would be appropriate. Where the diffusion coefficient diminishes with time, diffusivity has a larger value than the diffusion coefficient.

The rate of change with time of either diffusion coefficient or diffusivity is denoted by an “age factor”  $n$ , which experimental data put in a range (approximately) from 0.25 to 0.7, higher values indicating a greater reduction in the property over time, as is obtained particularly with blended cements. The expression for  $C(x,t)$  using diffusivity has inputs of surface concentration of chloride, age factor and diffusivity at a chosen age. As well as replacing diffusivity with the diffusion coefficient, the solution to Fick has an additional input equal to the age of the concrete at the start of the exposure period, or an equivalent time depending on the curing treatment which the concrete has undergone. As it may be found elsewhere (2, 4), the algebraic expression of the solution to Fick is not reproduced here. However it is a property of the expression that when the time of exposure to the chloride environment greatly exceeds that prior to exposure, the effect of the pre-exposure time is diminished, allowing comparison with the relationship in ISO 16204 for which there is no input of this variable. If the ratio of diffusion coefficient to diffusivity is set at  $(1-n)$ , the two relationships converge. Conversely, data derived from exposure times long enough for the approximation to apply will yield the same value of  $n$ , whether fitted to the diffusivity relationship or the correct solution to Fick. Furthermore for the same inputs both relationships yield similar values of chloride concentration (identical if the pre-exposure time is set to zero), provided diffusion coefficient and diffusivity are set in a ratio  $(1-n)$ .

Table 1 shows values over time of the ratio of diffusion coefficient to diffusivity, this ratio being independent both of chloride levels and the depth at which concentrations are measured. It can be seen firstly that at high values of  $n$ , diffusivity has a much larger value than the diffusion coefficient; secondly that over time the ratio of the two measures converges to  $(1-n)$ , more rapidly with lower than higher values of  $n$ . At 20 years the ratio approximates to  $(1-n)$  even for the highest  $n$ -value encountered.

**Table 1. Convergence of the ratio diffusion coefficient / diffusivity**

n	(1-n)	Ratio diffusion coefficient / diffusivity for years exposure			
		0.3	1	5	20
0.3	0.70	0.80	0.74	0.72	0.70
0.5	0.50	0.64	0.57	0.53	0.51
0.7	0.30	0.52	0.43	0.37	0.34

Values for 7 days equivalent age prior to exposure.

TR61 provides typical or average values for diffusivity at 20 years, for a range of cement types and water/cement ratios. These are readily converted to 20-year values of diffusion coefficient simply by multiplying by  $(1-n)$ .

An explanation is provided immediately of the discrepancy between diffusivity and diffusion coefficient in the example from TR61 referred to above, which showed values of diffusivity more than double those of the diffusion coefficient. However it also shows up the possibility of gross error if diffusion coefficient should be used instead of diffusivity in the expressions set out in TR61 and ISO 16204. The spreadsheet provided with TR61 will accept either without distinction.

Replacing diffusivity with diffusion coefficient also removes an otherwise puzzling anomaly in the values for diffusivity provided in TR61 for portland cement (PC) and blended cement, in which contrary to the general understanding of properties blended cement exhibits higher diffusivity at an early stage of the exposure period. The effect is illustrated in Table 2, using fly ash blend as the example for blended cement.

At 1 year, PC concrete exhibits similar diffusivity to fly ash blend, while at 56 days the value is much lower; ie the diffusivity values would suggest that throughout most of the first year, chloride diffusion into PC concrete would be less than into concrete made with blended cement. With values of diffusion

coefficient derived from the same data the anomaly is removed, showing better chloride resistance for the blended cement throughout this period.

**Table 2. Representative values from TR61.**

Age of concrete	Diffusivity E-12 m <sup>2</sup> /s		Diffusion coefficient E-12 m <sup>2</sup> /s	
	PC	FA blend	PC	FA blend
56 days	2.7	5.0	2.0	1.7
1 year	1.6	1.5	1.2	0.5

Blend is fly ash 25%; w/c = 0.4 for both cement types  
 Values of diffusivity and age factor were obtained using the spreadsheet Ageddca in TR61.

Diffusion coefficients derived from TR61, obtained by multiplying the 20-year diffusivity by (1-n), can be applied directly for the purpose of design via the correct solution to Fick's second law, provided the cement (PC or blended) is known to be "typical or average" with regard to this property. A short-term diffusion test such as Nordtest Build 443 will indicate whether the cement proposed for a particular project does in fact have typical or average performance, provided other such short-term data are available for comparison. There are uncertainties associated with extrapolating 20-year diffusion coefficients back to a typical test age of 56 days, but the fly ash blend in Table 2 nonetheless provides a point of interest. In this example the extrapolated value for 56 days is 1.7E-12 m<sup>2</sup>/s. Results of this order are in fact obtained from fly ash blend using a good quality fly ash, reflected in a limit of 2.0E-12 m<sup>2</sup>/s (at 56 days standard cured) often specified for such a blend.

If it is impractical with locally available materials to achieve an initially specified 56-day diffusion coefficient there is the option of a revised design based on a higher w/c than would otherwise have been applied. Further to the fly ash example above, assuming that

- for cement materials of "typical or average" quality, w/c = 0.4 gives 2.0E-12 m<sup>2</sup>/s;
- the best achievable with local materials is 2.5E -12 m<sup>2</sup>/s;
- 2.5E -12 m<sup>2</sup>/s is obtained with the "typical or average" materials at w/c = 0.43;
- the design is revised to give the required performance with input w/c = 0.43,

local materials can be adopted, and the mix must then achieve a 56-day result of 2.5E -12 m<sup>2</sup>/s.

### 3. Threshold and progress of corrosion

#### 3.1 Threshold for corrosion

Immersed in air-saturated water containing chloride and having neutral pH, steel will rapidly corrode. If cement is dispersed into such a solution, the pH is raised to about 12.5, and immersed steel will remain uncorroded at surprisingly high concentrations of chloride – three times or possibly even higher than are found in sea water (5). Thus depassivation of reinforcing steel resulting from marine exposure depends on chloride from the seawater having at some stage become concentrated by evaporation. At average levels of surface chloride reported in TR61, moisture filling permeable voids (occupying a typical proportion of the concrete, as determined by the test for this property) has a concentration below what would be required in solution to depassivate the steel. One may conclude that, even if oxygen is present in the pore water, for corrosion to proceed there must be a further enhancement of the chloride concentration by some drying of the void space, and that whether or not the steel corrodes depends on the extent of such drying. A threshold level for initiation of corrosion then depends on other factors than just the concentration of chloride as a proportion of the concrete mass or of the cement. This is born out by observation, reported in TR61:

"Reported threshold levels vary from 0.25% to 2.5% (a tenfold difference), indicating that there is unlikely to be a fixed value for a given concrete."

and

“The commonly used value of 0.4% Cl (weight of cement) appears to be most applicable in conditions of wet/dry cycling of high (>0.6) w/c ratio mixes, whereas in mixes of low w/c ratios, under more stable moisture conditions, higher values may be tolerated.”

Some examples are included here for illustration.

Concrete ships (6):

The condition of reinforcement was examined in concrete ships moored or in service for 35 to 65 years. In two of the examples described, cover to reinforcement was in the range 10 to 25 mm, and chloride levels up to 1.2% of the cement were found at reinforcement depth. Reinforcement extracted from cores taken above and below the water line showed no evidence of corrosion.

Prefabricated harbour structures (7)

Harbour structures with pontoons made from reinforced concrete were deployed in northern France in June 1944 to offload cargo on beaches during the allied invasion of Normandy. The pontoons from one of these, Mulberry B, which came to be known as Port Winston, continued their exposure to the marine environment after the war and were inspected nearly 30 years later. It was reported that no corrosion of reinforcement was evident where cover exceeded 12 mm. Estimated chloride concentration at this depth is 0.9% of the cement.

Port Kembla swimming pool (8)

The Port Kembla seawater swimming pool, built in 1937, was exposed to a marine environment with some components permanently submerged, and others in the tidal or splash zone. The condition of concrete comprising the pool was assessed after 60 years of exposure. Of particular interest are reinforced concrete columns in the atmospheric zone, which exhibited concentrations of chloride essentially independent of depth from about 30 mm from the surface, and *lower* concentrations close to the exposed surface. The chloride threshold for steel corrosion was in the range 2.4 to 3.0% of the cement. Some of the stable interior chloride concentrations were as low as 0.6% of the cement, indicating that the levels leading to corrosion were derived from the exposure, not from chloride present in the concrete at the outset.

Concrete pipe (9)

Two cores were cut from a 900 mm diameter concrete pipe protruding through the sea wall into Hen and Chicken Bay, Sydney. Age of the installation was approximately 55 years. The concentration of chloride at the interior of the section including the reinforcement (cover in the range 8 to 18 mm) was about 4% of the cement. As with the Port Kembla swimming pool, there was a lower concentration, between 1.2 and 3.0%, at the surfaces of the concrete. As part of an overall petrographic investigation, reinforcement sections were examined, one showing no surface reactions and the other minor amounts of iron oxide and hydroxide.

### **3.2 Progress of corrosion and damage to the concrete**

TR61 also presents a model for calculating a further time following initiation of corrosion, at which the concrete will crack. This time is derived from the rate at which corrosion occurs and the ability of the concrete to accommodate rust formed from the corroded steel. It may be questioned whether the rate of corrosion after initiation can be calculated with any useful degree of accuracy and further where the rust will actually form, if at all. In the corrosion process, cathode sites formed where there is oxygen present draw electrons from the steel to form negatively charged hydroxyl ions in the electrolyte, also rendering the steel positively charged. Metallic iron is released into the solution at anode sites as ferrous ions  $Fe^{2+}$ . In the absence of oxygen ferrous ions may subsequently combine with hydroxyl ions from the electrolyte to form ferrous hydroxide, which is insoluble and non-expansive. Elsewhere, ferrous ions combine with oxygen and water to form (expansive) rust. The relevant equations are:

Cathode:

Anode:

In the electrolyte:

or if there is oxygen present,

the ferric ions together with oxygen and water being subsequently converted to rust.

Concrete in which steel is corroding will often exhibit highly visible rust staining on the surface, showing that ferrous ions or soluble compounds containing iron are able to diffuse in quantity away from the steel surface, and that some proportion of the metallic iron released at anode sites is only converted to the expansive, insoluble rust where oxygen is encountered at the surface.

The mechanism is illustrated in Figure 1, in which a piece of reinforcing wire, wrapped in cotton tape to simulate embedment in concrete, is immersed in a weak solution of sodium chloride. The first two photos (a) and (b) show the immersed sample, with rust formed outside the cotton wrap, near the water surface. In (c), the tape has been removed from the wire, revealing black hydroxide, but not rust, extending to the full depth to which the steel surface was in contact with the solution.

- (a) Immersed sample & twin piece of wire. Epoxy coating extends about four diameters (20 mm) from the lower end. Water level is at mid-height of the white paper strip.
- (b) Close-up of rust formation outside the cotton wrap.
- (c) Tape unwrapped from the steel wire.

**Figure 1. Reinforcing wire wrapped in cotton tape, immersed in dilute salt solution**

There are no doubt situations where rust forms on the surface of steel embedded in concrete, when passivity is lost either due to carbonation, chloride, or both, and cracking will be induced as a result, but the situation is by no means universal. Corroded steel in concrete commonly exhibits a black rather than red appearance and in these circumstances the expansive rust model described in TR61 simply will not apply.

The process has been described here as an explanation in part of the broad conclusion expressed in ISO 16204, Clause B.7:

“As with carbonation, there were no available models with broad international consensus available for predicting the length of the corrosion period till cracking, spalling or collapse of the structure occurs when this Standard was published. For this reason service life designs are normally based on the limit state of depassivation (reaching a critical a chloride concentration at the rebar

surface). As with carbonation, this rather conservative limit state is then normally linked with a relaxed target reliability level for failing, often in the order of  $10^{-1}$  to  $10^{-2}$ .”

In effect the design procedure treats the time for chloride to reach a threshold value as the whole-of-life for the structure. This by itself could be sufficient reason to adjust the threshold to a higher value than the level of 0.4% of the cement commonly applied. The above examples indicate that in some types of concrete the steel remains passive at much higher levels of chloride – in fact to equilibrium levels for at least the milder class of marine exposure, corresponding for example to C1 in AS 3600. For this situation the required depth of cover is not related to the ability of the concrete to slow ingress of chloride, but to maintain a stable moisture environment at reinforcement depth. For this purpose the crucial property is impermeability, low values depending on low w/c and being achievable with any cement type. Improved performance in marine exposure is obtained with concrete containing a high level of available alkalinity from calcium or magnesium (10), presumably because these are able to neutralise acidity generated by hydrogen ions released near anode sites at the steel surface. Calcium or magnesium carbonates may be present in aggregates while calcium is contributed by the cement. It can be assumed in the examples described in 3.1 above that the binder was portland cement, which for a given cement content will contribute a greater amount of alkalinity than blended cements (with fly ash or silica fume) in which no calcium is provided by the SCM.

#### 4. Chloride threshold for whole-of-life design

In its discussion of threshold values for chloride TR61 has reservations as expressed above about tangible evidence for a universal limiting value, but the point remains that where surveys of structures take no account of the composition or quality of the cover concrete, lower concentrations of chloride are associated with lower probability of corrosion. At 0.4% of the cement there is a low probability even of initiation; however achieving this level at the end of the design life may be expensive or even impractical and if the life can be achieved with a higher terminal level of chloride, the design method should allow this option.

Using the method set out in Section 2 above, with 20-year typical or average diffusivity from TR61 converted to diffusion coefficient and calculation using the correct solution to Fick, chloride concentrations at the end of the design life can be derived for examples encompassed by Standards or specifications. For any well-founded and widely accepted such specification, such calculations provide chloride threshold values which may then be applied elsewhere in design. Table 3 shows chloride concentrations at the end of design life, within the scope of the two generic Australian Standards, AS 3600 and AS 5100.5, and the corresponding British Standard BS 8500-1.

**Table 3. Chloride concentrations at design life**

Source	Exposure Class	Design life (y)	Chloride at minimum cover depth (% cem) for cement type	
			PC	FA blend
AS 3600	C1	50	0.92	0.27
	C2	50	1.09	0.20
AS 5100.5	C	100	2.07	0.33
BS 8500-1	XS3	50	1.30	0.33
	XS3	100	1.28	0.26

Blend is fly ash 25%; w/c = 0.4 & total cement 400 kg/m<sup>3</sup> for both cement types.

For AS 3600 & AS 5100.5, strength grade is 50 MPa and covers are those applicable to rigid formwork & intense compaction.

For BS 8500-1, selected cover is that allowed for maximum w/c 0.4.

For exposure class C1, surface chloride is the “typical” value from TR61; for other classes, those described as “characteristically high”.

Initial chloride 0.03% of the concrete, 0.19% of the cement.

The most striking pattern shown by this table is the contrast between levels allowed for PC and the example of blended cement. Even so, the highest for PC, 2.07% of the cement, is below levels in examples above (section 3.1) exhibiting no corrosion after exposure for up to 60 years. A reasonable

design limit for PC would be 1.5% of the cement. Given the margin between this and the nominally applied 0.4% for any cement type, there no longer appear to be any grounds for requiring such a low value for blended cement either and the limit for this type could be increased to 0.5 or even 1.0%. However both these proposals require qualification. The examples apply to situations where the specification limits the water/cement ratio to about 0.4 and also specifies a minimum cover. If either of these were relaxed the result could be a greater effect from the chloride at the allowed threshold values. Thus there is no immediate prospect of lower cover or grade of concrete. The effect of higher thresholds is to allow a wider choice of materials, where a limit is imposed on the diffusion coefficient as well as other requirements of the specification.

## 5. Conclusion

For long periods of exposure, as apply to the design life of a structure, inputs required for calculating chloride concentrations using the correct solution to Fick are provided by a simple adaptation of data from TR61. ISO 16204 does not acknowledge any model for life following a threshold level of chloride at reinforcement depth, in effect treating the time to reach the threshold as the design life of the structure. Observations of structures reveal concentrations of chloride required to initiate corrosion over too wide a range (more than an order of magnitude) for a single value to be used in design, and for this purpose the best indication of acceptable limits is obtained by estimating the end-of-life concentrations allowed by well-founded existing Standards. However the effect of chloride depends on other factors including alkali content of the cement and aggregate, and ability of the concrete to stabilise moisture at cover depth. Specified cover cannot be reduced just because a nominated threshold of chloride is not reached within the required service life.

# *k*-value for carbonation of concretes with supplementary cementitious materials

Christina Nobis<sup>1</sup> and Anya Vollpracht<sup>2</sup>

<sup>1</sup>Research Assistant, Institute of Building Materials Research, RWTH Aachen University, Germany

<sup>2</sup>Junior Professor for Environmental Compatibility of Building Materials, Institute of Building Materials Research, RWTH Aachen University, Germany

**Abstract:** The performance of supplementary cementitious materials (SCM) such as fly ash (FA) or ground granulated blast furnace slag (GGBS) in concrete can be assessed by the *k*-value concept according to the Technical Report of the European Committee for Standardization CEN/TR 16639. This prescriptive method determines the performance of SCMs as concrete additives of type II in terms of concrete compressive strength. In recent years, the importance of durability aspects has become more apparent. Carbonation is generally one key issue for concrete with GGBS or FA. The integration of durability aspects into the *k*-value concept is a promising approach to the performance assessment of SCMs. This study presents results from a data evaluation of about 290 concrete mixtures with and without GGBS or FA. The analysis of the data is carried out based on the *k*-value concept and determines *k*-values for carbonation (*k<sub>c</sub>*) in relation to the SCM-content of the binder.

**Keywords:** carbonation, durability, granulated blast furnace-slag, fly ash, blended cement.

## 1. Introduction

Carbonation is one key aspect for the durability of reinforced concrete structures as it may induce steel corrosion. The pore solution of uncarbonated concrete with OPC usually exhibits a pH value in the range of 13.0 to 13.8 [1] due to the dissolution of alkali ions and OH<sup>-</sup>. Calcium hydroxide (Ca(OH)<sub>2</sub>) which was formed during cement hydration acts as a buffer for the alkalinity. Under these conditions, the steel forms a surface oxide layer, termed passive film. The atmospheric carbon dioxide (CO<sub>2</sub>) diffuses into the pore structure of the concrete, either dissolved in water or as gas. It dissolves in water and forms carbonate ions in the highly alkaline pore solution (equations (1) and (2)). The carbonate ions react with calcium ions in the pore solution to calcium carbonate (CaCO<sub>3</sub>) (equation (3)). This process reduces the calcium ion content in the pore solution and thus leads to the dissolution of crystalline Ca(OH)<sub>2</sub>, which has a lower solubility than CaCO<sub>3</sub> (equation (4)) [2].

This process continues until all Ca(OH)<sub>2</sub> in the affected area is consumed. The pH value of the pore solution will decline to a range of 8 to 9. In this condition the protective passive film of the steel reinforcement dissolves and, in the presence of water, corrosion may occur. The precipitation of the CaCO<sub>3</sub> will lead to a densification of the pore structure of the cement matrix due to the increase in volume when Ca(OH)<sub>2</sub> is transformed into CaCO<sub>3</sub>. The permeability of the carbonated area is reduced. Carbonation also effects the calcium-silicate-hydrate phases (C-S-H). When the Ca<sup>2+</sup> content in the pore solution is reduced, calcium ions will be released from the Ca-OH bonds of the C-S-H phases. Eventually this will convert part of the C-S-H phases to porous hydrated silica gel (ySiO<sub>2</sub> · tH<sub>2</sub>O) (equation (5)) [3, 4].

However, the carbonation of concrete is generally a slow process due to the low carbon dioxide content of about 0.03-0.04 vol.-% under natural environmental conditions. In general, concrete with OPC is more resistant to carbonation than concrete with GGBS or FA. The carbonation depth increases as cement replacement by SCM increases [5, 6, 7]. This is due to the reduced amount of Ca(OH)<sub>2</sub> in concrete with GGBS or FA. The Ca(OH)<sub>2</sub> content decreases in proportion to the replacement ratio and furthermore to the extent of the pozzolanic reaction (in case of FA). Therefore, the coarsening mechanism based on C-S-H modification outweighs the densification mechanism caused by CaCO<sub>3</sub> precipitation. This may

negatively affect other concrete properties such as freeze and freeze-thaw resistance [8] or chloride diffusion coefficient [9]. However, in concrete with OPC it is assumed that the formation of  $\text{CaCO}_3$  causes pore blocking which reduce further carbonation. On the other hand, concrete with GGBS or FA usually exhibits a refined pore structure and thus improved permeability [9, 10].

To assess the performance of SCMs in concrete such durability aspects have to be accounted for. In Germany, the efficiency of SCMs in concrete is determined via comparative analyses of concretes with and without SCM. The compressive strength is considered a proxy for durability. The principle method behind this is the prescriptive  $k$ -value concept. The concept was introduced by Iain A. Smith in 1967 for the design of fly ash concrete and has been further developed [11]. The  $k$ -value concept was established for FA (EN 450-1) and silica fume (EN 13263-1) in the European concrete standard EN 206-1 in 2000. The principle for the determination of the  $k$ -value is described in the Technical Report of the European Committee for Standardization CEN/TR 16639 [12]. It is used for the calculation of the equivalent water/cement ratio ( $w/c_{\text{eq}}$ ) according to the following formula (equation (6)):

$$w/c_{\text{eq}} = w/(c + k \cdot \text{SCM}) \quad (6)$$

$w$  = water content in  $\text{kg/m}^3$ ,  $c$  = cement content in  $\text{kg/m}^3$ , SCM = SCM content in  $\text{kg/m}^3$ .

The efficiency factor  $k$  indicates the contribution of a type II concrete additive to the compressive strength of concrete with OPC.  $k$  reaches values between 0 (no contribution) and 1 (OPC-equivalent contribution) or even higher. The durability of the concrete with SCM designed using the  $w/c_{\text{eq}}$  must be assessed in subsequent tests. Based on extensive studies the National Annex DIN 1045-2 gives a default  $k$ -value of 0.4 for FA in combination with specific cement types and other restrictions. Most recently, a  $k$ -value of 0.6 for GGBS was introduced to the European Standard that shall cover the minimum quality for GGBS according to EN 15167-1. The integration of durability aspects into the  $k$ -value concept is a promising approach to the performance assessment of SCMs. Based on this analysis it can be determined to what extent the carbonation resistance is a limiting factor for the applicability of GGBS or FA concrete.

## 2. Materials and Methods

### 2.1 Database

The Institute of Building Materials Research in Aachen has an extensive database concerning the carbonation of concretes with and without supplementary cementitious materials collected from internal reports of material testing and from literature. In particular, the database includes data on the carbonation of concrete with OPC, GGBS and FA under laboratory conditions. In the analysis no differentiation was made between SCM as additive or main cement constituent for the calculation of  $w/c_{\text{eq}}$ . The concretes differ considerably concerning their water/binder ratio ( $w/b$ ) and composition. To that end, the concretes presented in the database were divided into different categories according to their GGBS/clinker and FA/clinker ratio, respectively. The database is summarised in table 1. However, given the amount of the data only the key information will be shown in this paper.

**Table 1. Summary of the database on carbonation of concretes with OPC, GGBS and FA**

category	No. of concretes	SCM/clinker		range of w/b		binder content ( $\text{kg/m}^3$ )			
		min	max	min	max	clinker <sub>min</sub>	clinker <sub>max</sub>	SCM <sub>min</sub>	SCM <sub>max</sub>
0 no SCM	70	0/100		0.50	0.75	235	320	-	
1 low	23	20/80	39/61	0.50	0.75	162	248	68	96
2 medium	37	40/60	49/51	0.53	0.75	122	174	95	146
3 high	36	50/50	59/41	0.50	0.75	105	165	120	190
4 very high	16	> 60/40		0.50	0.67	46	127	178	276
1 low	18	10/90	24/76	0.44	0.67	240	300	30	70
2 medium	33	25/75	29/71	0.43	0.75	169	270	60	90
3 high	60	30/70	40/60	0.36	0.75	159	321	70	241

w/b: water/binder ratio ( $b$  = clinker content + GGBS or FA content as concrete additive and cement constituent)

### 2.2 Materials

The cement types used in the concretes and the combinations with GGBS or FA are listed in table 2. In order to ensure better comparability only cements with a strength class of 32.5 were selected for this

analysis as there are no sufficient data sets for the assessment of concretes with cement types of higher strength. The Blaine fineness of the used GGBS differed considerably and ranged from 2675 to 5050 cm<sup>2</sup>/g. Both, GGBS and FA, were obtained from several European countries. All concrete mixtures were prepared using quartzitic sand and coarse aggregates from the river Rhine. The maximum aggregate size was in the range of 8 to 16 mm. The specimens investigated were concrete beams with different dimensions (100 · 100 · 500 mm<sup>3</sup> and 70 · 70 · 300 mm<sup>3</sup>).

**Table 2. Summary of the cement types and additives used for the concretes of the database**

SCM	category 0	category 1	category 2	category 3	category 4
GGBS	CEM I 32.5 R	CEM I 32.5 R + GGBS CEM II/B-S 32.5 R CEM III/A 32.5 N	CEM II/B-S 32.5 R + GGBS CEM III/A 32.5 N	CEM I 32.5 R + GGBS CEM III/A 32,5 N	CEM I 32.5 R + GGBS CEM II/B-S 32.5 R + GGBS CEM III/B 32,5 N
FA		CEM I 32.5 R + FA	CEM I 32.5 R + FA CEM II/B-V 32.5 R	CEM I 32.5 R + FA CEM II/B-V 32.5 R	-

See table 1 for definitions of the categories.

## 2.3 Methods

### 2.3.1 Testing of the carbonation depths

All concretes with few exceptions were stored under water until an age of 7 d. Afterwards the concrete specimens were kept in laboratory conditions at 20 ± 3 °C and 65 ± 5 % RH during the experimental period. For the analysis only concrete specimens with a storage period longer than 1 year were chosen. The oldest specimens were tested up to eight and a half years. The specimens were tested at different times (e.g. 7, 14, 28, 56, 90, 180, 365, 730, 1825 d). The carbonation depths of the concretes were measured using a solution, which consists of 1 % phenolphthalein in 70 % ethanol. The indicator appears pink in pH values above 9 and colourless at lower levels. Hence, concrete pieces with a thickness of 30 mm were split off at testing time and the indicator was sprayed on the freshly exposed surface. After 24 h the carbonation depth was measured as the average thickness of the uncoloured carbonated layer.

### 2.3.2 Determination of the $k_c$ -value

In order to assess the performance of the SCMs in concrete, an efficiency factor  $k_c$  for carbonation similar to the  $k$ -value according to CEN/TR 16639 [CEN European Committee for Standardization, "Use of  $k$ -value concept, equivalent concrete performance concept and equivalent performance of combinations concept (CEN/TR 16639)", CEN/TC 104, 2014, Brussels, Belgium.] for compressive strength must be defined. The carbonation rate  $v_k$  was chosen as a substitute for compressive strength. To calculate the carbonation rate the carbonation depths of each concrete mixture was approximated as a function of the square root of the exposure time (equation (7)):

$$x = x_0 + v_k \cdot \sqrt{t} \quad (7)$$

- $x$ : depth of carbonation in mm,
- $x_0$ : initial carbonation (usually very small or zero),
- $v_k$ : carbonation rate in mm/ $\sqrt{t}$ ,
- $t$ : exposure time in d.

This function was determined by linear regression for each concrete mixture. To ensure comparability, only the carbonation depths up to an exposure time of 1 year were included in the analysis. The rate of carbonation was plotted against the w/b ratio of the concrete mixtures for each category. Next, the correlation between carbonation rate and w/b ratio was determined for each category via linear regression (equation (8) and (9)).

$$\text{reference concrete without SCM: } v_{k,0} = A_0 + B_0 \cdot (w/c)_0 \quad (8)$$

$$\text{tested concretes with SCM: } v_{k,SCM} = A_{SCM} + B_{SCM} \cdot (w/b) \quad (9)$$

- $v_{k,0}$ : carbonation rates of concretes without SCM in mm/ $\sqrt{t}$ ,
- $v_{k,SCM}$ : carbonation rates of concretes with SCM in mm/ $\sqrt{t}$ ,

$(w/c)_0$ : w/c ratios of concretes without SCM,

w/b= w/b ratio with b = clinker content + GGBS or FA content as concrete additive and cement constituent.

Figure 1 highlights, by way of example, the linear regression for the carbonation rates of the concrete mixtures without SCM and with GGBS of category 3. From the left picture it is obvious that the GGBS concretes have higher carbonation rates and carbonation rates increase with w/b ratio. In the right figure the w/b ratio is replaced by  $w/c_{eq} = w/(clinker + k_c \cdot SCM)$ . The  $k_c$ -value is varied until the performance of GGBS concretes is equal to the OPC concretes. This is the case if the two regression graphs are aligned. A  $k_c$ -value of 1 represents an OPC-equivalent performance of the SCM in regard to carbonation, whereas a value of 0 would imply that the SCM has no effect. In the example shown in figure 1 the best alignment was found for a  $k_c$ -value of 0.70.

Figure 1. Exemplary illustration of the  $k_c$ -value determination

## 2.4 Results and Discussion

Figures 2 and 3 illustrate the spread of the measured carbonation depths of all concretes with and without GGBS and FA respectively up to an exposure time of 8.5 years. Since the process of carbonation is controlled by diffusion, the x-axis is shown in square root scale. The carbonation depths of all specimens increase almost linearly with square root of time. At the beginning of the testing period the carbonation rate is usually a bit higher than the carbonation rate at the end. In the database the majority of the concretes showed this behaviour. The reason for this is that the equation  $x = x_0 + v_k \cdot \sqrt{t}$  is based on a steady state performance with a constant carbonation rate over time. In reality, the carbonation process changes the microstructure of the affected concrete area and may cause a reduction of gas diffusivity. The carbonation depths of the concretes with SCM tend to be greater than those of the concretes with OPC. However, some concretes with GGBS or FA perform even better. Whether this might be ascribed to a refined pore structure or the concrete composition cannot be assessed.

Figure 2. Carbonation depths for concretes with and without GGBS

Figure 3. Carbonation depths for concretes with and without FA

The values show a rather big spread due to the wide range of concrete compositions and the different raw materials. To evaluate the influence of the SCM on the carbonation performance the carbonation rates are correlated with the  $w/C_{eq}$  ratio. A greater  $w/C_{eq}$  ratio produces a higher carbonation rate. This relation was plotted as a linear regression according to equations (8) and (9) for each category. The parameters of the linear regression and the determined  $k_c$ -value are shown in table 3 for each category. Figure 4 highlights the correlation of the carbonation rates and  $w/C_{eq}$ .

Figure 4. Correlation between carbonation rates and  $w/c_{eq}$  for concretes with and without GGBS (left) and FA (right)

Table 3. Summary of the database on carbonation of concretes with OPC, GGBS and FA

category	linear regression parameters			$k_c$ -value
	$A_0$ or $A_{SCM}$	$B_0$ or $B_{SCM}$	$R^2$	
0 none SCM	-0.23	0.82	0.66	-
1 low	-0.32	1.02	0.69	0.80
2 medium GGBS	-0.41	1.22	0.74	0.77
3 high content	-0.25	1.02	0.65	0.70
4 very high	-0.07	0.85	0.13	0.60
1 low	-0.17	0.84	0.63	0.30
2 medium FA	-0.26	1.05	0.86	0.35
3 high content	-0.19	0.98	0.74	0.34

See equation (8) and (9) for definitions of the linear regression parameters.

The coefficients of determination for all linear regressions graphs are not particularly high because of the large spread of data points. The comparison of the carbonation rates is only possible to a limited extent due to the differences in mixture composition and SCM quality. Since the focus of this analysis was to find a trend of the carbonation performance of blended concretes the poor coefficients of determination were considered sufficient, except for the GGBS blended concrete with more than 60 % GGBS in the binder. Nevertheless, the  $k_c$ -value for this category is included in the evaluation to indicate the trend.

In general, the efficiency factor for carbonation tends to decrease as the replacement percentage increases. This is particularly the case for GGBS blended concretes. The  $k_c$ -value ranges from 0.80 to 0.60 with increasing slag content. In comparison to the  $k$ -value of 0.6 that was introduced by EN 206 based on the 28 d compressive strength  $k_c$  is higher for categories 1 to 3.

Variation in FA content did not seem to have much effect on the  $k_c$ -value. This could be due to the small range of the investigated FA contents in present study. The  $k_c$ -value was found to be lower than the GGBS  $k_c$ -values. The  $k_c$ -value for concretes with a very low FA content (10 to 24 % of the binder) was 0.30 and for higher contents 0.35 and 0.34. Since the difference is very small it can be assumed that a constant  $k_c$ -value of approximate 0.3 complies for the investigated FA blended concretes. However, this efficiency factor seems to be low in comparison to the  $k$ -value of 0.4 which is used for the application of FA as concrete additive type II in Germany (DIN 1045-2). On the other hand, it is reasonable that the carbonation resistance of FA blended concretes is poorer than those blended with GGBS. The pozzolanic reaction of FA consumes  $Ca(OH)_2$  and thus may increase the carbonation rate.

### 3. Conclusions

In this paper, an efficiency factor  $k_c$  for carbonation was determined for concretes with GGBS and FA respectively based on the  $k$ -value concept described in CEN/TR 16639. To that purpose, a database of the carbonation performance of 290 concrete mixtures was evaluated.

- The  $k$ -value concept was initially linked only to the compressive strength. With the revision of the European concrete standard EN 206, durability aspects now have to be accounted for. However, no proposals were made for a concrete assessment method. The implication of the carbonation rate as a substitute for compressive strength in the well-known  $k$ -value concept is a promising tool to quantify SCM performance as concrete additive.
- The carbonation rate tends to slightly decrease over the testing period. Prognoses based on the carbonation rate of concrete measured very early, i.e. before one year, might lead to an overestimation of the carbonation depths.
- The performance of all concretes, even with equivalent binder concrete composition, exhibits a large spread. Some concretes with SCM perform even better than concretes without. This might be attributed to a refined pore structure due to the latent hydraulic or pozzolanic reaction.
- In general, the carbonation rate of concrete with GGBS or FA is higher compared to OPC concrete. This is expressed in the determined  $k_c$ -values  $< 1.0$  for all SCM concretes.
- The  $k_c$ -value ranges from 0.80 to 0.60 for GGBS concrete depending on the slag content. The carbonation rates for GGBS concrete are increased due to the lower amount of CH.
- The  $k_c$ -value of FA concrete does not differ appreciably with increasing FA content. However, the  $k_c$ -value of 0.3 is considerably low in comparison to the GGBS blended concretes. This might be attributed to the lower quality of the FA included in the database or to the consumption of CH in the pozzolanic reaction.
- The implementation of a durability based efficiency factor can be used for the assessment of blended concrete performance and proportioning of SCM. However, the efficiency factor might change with age, cement type, SCM content and curing conditions.

**Abstract:** To ensure safety and serviceability, it is essential to assess the residual capacity of corroding structures. For this assessment, it is essential to evaluate the residual mechanical properties of the embedded reinforcement bars (rebars) that are experiencing corrosion. Literature reports substantial difference of opinion on corrosion-induced changes in the residual mechanical properties. These differences could be due to the limitations of conventional techniques that are used to measure the strain (say, extensometers) and residual cross-sectional area (say, using Vernier calipers, average mass loss, etc.) and/or the methods to calculate mechanical properties of the corroded rebar specimens. The adoption of Digital Image Correlation (DIC), a non-contact, image-based deformation measurement technique, can overcome these limitations. In this study, mechanical properties measured using fixed gauge lengths (using virtual extensometer) and the Two-Dimensional Digital Image Correlation (2D-DIC) technique are compared. The data obtained using physical or virtual extensometers can be used only to obtain the 'average' strain along the gauge length and not the local strains at various locations within the gauge length. This study shows that 2D-DIC can capture the local strains and thereby the variations in strain along the entire gauge length of corroded rebars, which are very crucial in the assessment of residual mechanical properties. It is concluded that 2D-DIC is a feasible technique to estimate the residual mechanical properties of the corroded rebars extracted from concrete structures.

**Keywords:** steel, corrosion, concrete structures, residual mechanical properties, digital image correlation, extensometer, gauge length, strain, cross-sectional area

## 1 Introduction

The corrosion of embedded steel reinforcing bars (rebars) can adversely affect the safety and serviceability of concrete structures. It is essential to assess the residual mechanical properties of the rebars in order to assess the residual structural capacity and formulate timely structural repair/rehabilitation strategies, which in turn can help in assuring safety and serviceability. Researchers have attempted to characterize the residual mechanical properties of corroded rebars for several decades. The effect of the degree of corrosion on the elastic modulus, yield strength, ultimate strength, and ductility have been reported in literature (Almusallam 2001, Palsson and Mirza 2002, Du et al. 2004, Cairns et al. 2005, Apostopoulos and Papadakis 2007, and Francois et al. 2013). Because corrosion is a random phenomenon resulting in highly uneven surfaces, the evaluation of corroded specimens poses several challenges. Past studies vary from one another with respect to the type and diameter of steel rebars used, the measurement of residual cross-sectional area, the gauge length adopted, etc. These variations may be responsible for the difference of opinion among researchers on the effect of corrosion on the mechanical properties of rebar. The currently available information about the mechanical behavior of corroded rebars is not sufficient to model the behavior of structures with different levels of corrosion. Hence, there is a need for a precise estimation of the residual mechanical properties of corroded rebars, which can only be achieved by adoption of advanced methods of evaluation. In this study, Digital Image Correlation, an advanced non-contact, image-based deformation measurement methodology, is used to evaluate the residual mechanical properties of corroded rebars.

Following is a section on the significance of this study. Following this, a critical review on the contradictory findings in literature on the effect of corrosion on the yield strength, ultimate strength, and ductility of corroded bars is provided. Then, the probable reasons for these contradictions are discussed. Following this is a discussion on the experimental program to study the feasibility of 2D-DIC in evaluating the mechanical properties of corroded rebars, comparison of stress-strain graphs obtained from virtual extensometer and 2D-DIC, and the conclusions drawn from this study.

## 2 Research Significance

Characterizing the stress-strain behaviour and estimating the residual mechanical properties of corroded rebars are essential to reliably assess the residual capacity of the corroding structures. However, current techniques of evaluating corroded rebars using typical laboratory extensometer and currently adopted methods of measuring residual cross-sectional area are not sufficient to assess the mechanical behaviour of corroded rebars. This has led to difference of opinion among researchers who have studied the effect of corrosion on mechanical response of rebars. This work assesses the feasibility of a more advanced, non-contact 2D-DIC technique in (1) overcoming the limitations of conventional evaluation techniques (say, using contact extensometers) and (2) estimating the residual mechanical properties of corroded rebars in a more realistic and accurate manner.

## 3 Effect of corrosion on the mechanical properties of steel rebar

As mentioned earlier, the differences in the opinions on the effect of corrosion on the changes in the mechanical properties of rebars could be due to the differences in the type of test specimens and experimental techniques adopted. The specimens tested by various researchers varied with respect to the type of steel (ToS), pattern of corrosion (PoC) and degree of corrosion (DoC). The experimental techniques varied in the selected gauge length ( $L_0$ ), the method of inducing corrosion (MoIC), basis of estimating the degree of corrosion (DoC) and the method of measurement of residual cross-sectional area (RCSA). A summary these experimental features reported in literature is provided in Table 1. The following sub-sections discuss the key findings from the literature.

### 3.1 Yield strength of corroded rebars

Researchers have studied the effect of corrosion on the 'nominal' and 'actual' strength properties calculated using the original and residual cross-sectional areas, respectively. Herein, the term 'strength' indicates a parameter with units of stress (i.e., in MPa). Cairns et al. (2005) and Apostolopoulos and Papadakis (2007) concluded that corrosion does not significantly affect the 'actual' yield strength of the rebars; however, the 'nominal' yield strength of the rebars reduces significantly with increasing degree of corrosion as reduction in cross-sectional area of the specimens is not considered while calculating the strength. On the other hand, Palsson and Mirza (2005) and Francois et al. (2012) have observed a marginal increase in the 'actual' yield strength. The reason behind this difference in opinion is mainly due to the differences in the length over which the area is assumed to be uniform, which vary from 10 mm to 250 mm in the previous studies. (see Table 1 for details).

### 3.2 Ultimate strength of corroded rebars

Palsson and Mirza (2002) and Apostolopoulos and Papadakis (2007) reported that corrosion does not significantly reduce the 'actual' ultimate strength (in MPa) of the rebars, calculated using residual cross-sectional area. However, Du et al. (2004) concluded that the 'actual' ultimate strength reduces with increasing degree of corrosion. This difference in opinion could be due to the difference in the method of measurement of cross-sectional area (see Table 1 for details). On the other hand, Francois et al. (2012) reported a marginal increase in the 'actual' ultimate strength of corroded rebars with increasing degree of corrosion. Francois et al. (2012) reasons this behavior as "...Almost all the corroded bars failed at a pit location and the increase in the true ultimate strength at the pit can be explained by the fact that the failure path is imposed by the pit and does not correspond to the weakest point of the steel rebar as in the case for non-corroded bar...". Cairns et al. (2005) have provided a reason for this apparent increase in ultimate strength with section loss as "... if the position of the pit does not coincide with the location where steel is the weakest, an apparent increase in strength (which is based on the minimum cross-sectional area) will be measured...". This indicates the influence of the measured residual cross-sectional area on the calculated strength properties of the corroded rebar; the differences in opinion regarding the residual 'actual' ultimate strength of the rebars are likely due to the use of the average cross-sectional area over a specific length, which does not give an actual estimate of the cross-sectional area at the location of failure.

### 3.3 Ductility of corroded rebars

Almusallam (2001), Palsson and Mirza (2002), Cairns et al.(2005), Apostolopoulos and Papadakis (2007), and Francois et al. (2012) have unanimously concluded that corrosion has more impact on the ductility of the rebar than the strength properties. In this paper, 'ductility' is expressed quantitatively as 'ultimate strain' (i.e., the strain exhibited by the specimen at fracture point). Du et al. (2005) have concluded that

non-uniform distribution of cross-section along the length of a corroded rebar significantly reduces the measured ultimate strain, area under the stress-strain graph, and elongation. This is because the researchers have used the deformations over the entire gauge length for these calculations. Du et al. (2005) conducted a numerical analysis of the experimental results and showed that an average value of more than 10% corrosion can reduce ductility of the corroded rebars to a value less than the minimum requirement specified for Class S reinforcement. Class S reinforcement is defined as rebars with a strength ratio  $\geq 1.15$  and ultimate elongation  $\geq 6\%$ , as specified in CEB Model Code 90. Almusallam (2001) conducted a study on rebars conforming to ASTM A 615 Grade 60 steel and concluded that the rebars would exhibit brittle behavior if corrosion exceeds 12.6%. Francois et al. (2013) have concluded that the ductility is more influenced by the shape of the cross-section than both the cross-sectional area loss and pit depth. Cairns et al. (2005) and Apostolopoulos and Papadakis (2007) found that the strength properties decrease linearly with the mass loss; however, the ductility decreases exponentially with mass loss. Palsson and Mirza (2002) compared the ultimate strain measured using gauge lengths of 25 and 75 mm on the same specimens and concluded that the strain measured using 25 mm gauge length showed a higher value than that measured using 75 mm gauge length.

a: 'Effective diameter'  $\neq$  the average diameter over a certain length of the corroded specimen.

b: 'Uneven'  $\rightarrow$  corroded sections randomly distributed along the length of the specimen.

c: 'Localized'  $\rightarrow$  corrosion concentrated at one location of the specimen

Though the researchers unanimously agree that ductility is reduced due to corrosion, they have used different the gauge lengths (a very crucial parameter influencing the measured ductility) to measure the ultimate elongation. Table 1 lists out the variations in the gauge length selected in the previous studies.

## 4 Influence of experimental techniques on the measured values of mechanical properties

Section 3 identified the limitations in evaluating the mechanical properties of corroded rebars using the conventional tension testing and data acquisition methods. The first challenge is to predict (prior to the testing) the failure location of corroded rebars, because the cross-sectional area generally varies randomly along the length. The second challenge is to select an appropriate gauge length. The third challenge is to appropriately define the length over which the residual cross-sectional area is assumed to be uniform. Ideally, the pattern of corrosion (PoC) must be considered to determine these experimental parameters, for which suitable standardized procedures do not exist. Therefore, researchers have been adopting various methods using engineering judgment, which are discussed in the following sections.

### 4.1 Gauge length

The strain,  $\epsilon$ , can be calculated as  $\Delta L / L_0$ , where,  $\Delta L$  is the change in length and  $L_0$  is the original length. In case of tension test specimens, the gauge length is considered as  $L_0$ . The ASTM E6-09 (2009) defines the gauge length as “the original length of that portion of the specimen over which strain, elongation or change of length are determined”. The total elongation of the rebar specimen is the sum of the elastic and plastic elongations. According to ASM, ‘...When a gage section that is very long (compared to its diameter), the necking elongation converted to percent is very small. In contrast, with a gage section that is short (relative to its diameter), necking elongation can account for most of the total elongation. For round bars, this problem has been remedied by standardizing the ratio of gage length to diameter as 4:1. Within a series of bars, all with the same gage-length-to-diameter ratio, the necking elongation will be the same fraction of total elongation...’. 5:1 as per ASTM E8M (2013) and IS 1608 (1995). This is to ensure that the necking elongation would be a constant fraction of the total elongation for all diameter specimens.

For corroded rebars, because the cross-sectional shape and size (and hence the effective diameter) varies along the length of the rebar, gauge length is not selected as per any code recommendations. The difficulty in predicting the failure location on the corroded specimens compels researchers to select a convenient gauge length that would also ensure that the failure will occur within the gauge length. Hence, the gauge length selected for testing the corroded rebars depends mostly on the test setup/fixtures and the number of probable failure locations and their distribution along the length. The measured ultimate strain (say,  $\epsilon_{max}$ ) is inversely proportional to the gauge length ( $L_0$ ) and hence the selection of the gauge length determines the measured ultimate strain (and therefore, the estimated ductility). Also, the typical laboratory extensometers assume that strain is uniformly distributed along the entire gauge length. However, the stress distribution is generally not uniform due to the variation in the cross-sectional area along the gauge length, and hence, the strain distribution is not uniform either. Hence, extensometers will not be able to capture the heterogeneity in the strain distribution and the actual elongation behaviour of the corroded rebars.

### 4.2 Residual cross-sectional area

Du et al. (2004) and Cairns et al. (2005) reported that the material properties of steel remain the same for the residual material obtained after the removal of corrosion products. Hence, the residual cross-sectional area is used for calculating the stress in the specimen. The cross-sectional area used to calculate the stress influences the ‘calculated’ residual strength of the rebar. The residual cross-sectional area of the corroded specimens are usually measured by two common techniques - (a) measuring the mass of the whole length or a specific part of the rebar specimen before and after corrosion, and (b) calculating the cross-sectional area from the volume of remaining steel measured using liquid displacement. These methods give an average cross-sectional area over the length considered for volume displacement or mass loss. For specimens with highly uneven cross-section, these methods may not capture the reduction in cross-sectional area at the weakest location and may underestimate the effect of corrosion.

Other than these methods, Vernier calipers are also used to measure the residual diameter of the corroded specimens. While calipers can measure the residual diameter at exact locations rather than over a length, this method is very tedious and does not give an actual estimate of the residual cross-sectional area, as the shape of the cross-section is not circular for a corroded bar. Figure 1 illustrates the schematic diagram of the conceptual cross-section of a corroded rebar. The white portion at the periphery of the cross-section indicates the loose corrosion products which can be easily removed by cleaning. The grey portion to the interior of this outer portion represents the corrosion products adhered to the residual steel which cannot be easily removed with acid. But this portion of the cross-section may not assist in carrying load. It is difficult to visually assess the area of the intact steel which is capable of carrying load.

Due to difficulty in predicting the exact failure location on the corroded specimen, the commonly adopted technique is to measure the ‘average’ cross-sectional area over the possible region of failure. The variability in the cross-sectional area along this considered length of the failure region influences the measured residual cross-sectional area. The strength properties – the ‘actual’ yield strength and ultimate strength of the corroded rebars – depend upon the residual cross-sectional area at the failure location. The closeness of the value of the ‘average’ residual cross-sectional area to the residual cross-sectional area at the failure location depends on the length over which the residual cross-sectional area is assumed to be uniform and the variability in the cross-sectional area in this considered length.

**Figure 1. Conceptual cross-section of a corroded rebar**

In short, there is a need for a more advanced method to evaluate the behaviour of corroded rebars. The 2D-DIC technique is an image analysis technique that can be used for studying the mechanical behaviour of materials. This paper aims at assessing the feasibility of 2D-DIC as a method of evaluating the mechanical behaviour of corroded reinforcing bars.

## **5 Two Dimensional Digital Image Correlation (2D-DIC) Technique**

Digital Image Correlation (DIC) is a versatile, non-contact image-based technique for estimating full-field displacements. When a single camera is used to capture in-plane deformations over a predefined planar area on the object, the technique is specifically called two-dimensional Digital Image Correlation (2D-DIC). DIC has been gaining acceptance in the field of civil engineering, especially to monitor live structures. This method has been employed to measure displacements in the longitudinal truss girder of a steel railway bridge in Nieporet, Poland (Malesa et al. 2010). Gencturk et al. (2013) have compared full-scale testing of prestressed concrete structures using DIC and conventional technique using LVDT. They found that DIC can produce more accurate strain measurements, can clearly identify the load path in the structures and provide a better understanding of the behavior of full-scale prestressed concrete structures. DIC is also being increasingly used to measure strain in the laboratory studies as well. McCormick and Lord (2010) have used DIC to measure crack opening in a loaded reinforced concrete bar. De Wilder et al. (2014) have used DIC to measure the shear capacity of the I-shaped prestressed concrete beams, as this technique can capture the brittle mode of failure due to shear.

The measurement of the deformation of an object using DIC involves tracking the change in position of the points on the surface of the object across the subsequent images of the specimen, captured using a suitable camera at different time intervals (i.e. *frame rate*). For a better understanding of the procedure of computation of the strains using 2D-DIC, an example of a simple tension test is chosen. The specimen is decorated with a stochastic pattern, composed of a distribution of light or dark blobs called speckles, to enable the identification of the pixel subsets across the images. The experimental setup consists of a UTM, a Charge Coupled Camera (CCD), illuminations such as fluorescent or LED lamps and the test specimen as shown in Figure 2. The camera is focused on the speckled specimen and during the test, a series of images is acquired at a suitable frame rate. The region of the specimen captured in the images is called the Area Of Interest (AOI). The image corresponding to the undeformed state of the specimen is labelled as the reference configuration and images of the intermediate deformed state are labelled as the current configurations at particular time instances. After the test is completed, these images are analysed with a 2D- DIC software, *VIC-2D<sup>TM</sup>* to obtain the full-field displacements and strain evolution with time. In the DIC algorithm, the displacement at a given pixel location in the reference image is computed by first choosing an image subset centred at this point and then finding its location in a subsequently acquired image (i.e. a deformed configuration) by minimizing a sum of squared intensity differences cost function. Typically, displacements can be accurately computed down to 1/100th of a pixel. Once the full-field displacement maps are computed, these are differentiated with respect to spatial coordinates and strain measures of interest are computed by the software.

Figure 2. Experimental setup for the tension test of corroded rebar specimen

## 6 Experimental Design

This section outlines the details of the experiment and the data analysis using 2D-DIC technique.

### 6.1 Specimen Preparation and Experimental Test Setup

Naturally corroded Cold-Twisted Deformed (CTD) steel rebars embedded in concrete were collected from a 10 year old building in Chennai, India. Chennai has a tropical wet and dry climate, with temperature varying from 15°C to 40°C and average annual rainfall of about 140 cm. The CTD steel rebars were introduced in the Indian construction industry in 1967 (Basu et al. 2004) and were discontinued from use in 1990s, due to their high vulnerability to corrosion. Rebars with different degrees of corrosion, ranging from mild to severe corrosion, were available in this lot of rebars collected. Sampling was done from this lot by cutting 420 mm long pieces such that the relatively weaker corroded section is at the middle of these pieces and the ends are relatively less corroded. This is done to ensure that failure occurs at the centre of the specimen and not inside the grips. These specimens were cleaned as per guidelines given in ASTM G1-90. Two rebars were selected for tension testing and were cut longitudinally into half for 60 mm at the centre, as shown in Figure 3 (a), using an Electric Discharge Machine (EDM) method, to get a smooth, planar surface for 50 mm long region, which can be speckled and images acquired. The two specimens selected were such that one is of fairly uniform reduction in cross-sectional area, while the other has an uneven reduction in cross-section along the length of the specimen, as shown in Figure 3 (b) and (c).

The cross-sectional area of the specimen was calculated by the liquid-displacement method. Primarily water was used for the measurement of the cross-sectional area. The cross-sectional area of the half-cut specimen to be measured was very small (less than 56 mm<sup>2</sup>). Liquid displacement technique using water did not give sufficiently accurate measure of the volume of the rebar because of the error due to the meniscus formed by water inside the container. Hence, water was replaced with kerosene to measure the cross-sectional area, which has a surface tension of 0.032 N/m compared to 0.072 N/m of water. This helped to minimize the error due to the meniscus formed by the liquid. To improve accuracy of the readings a micropipette was used to pour the liquid into the container containing the specimen. The area profile obtained is as shown in Figure 4. The average cross-sectional area was calculated for every 5 mm length of the 50 mm long longitudinally cut section of the specimen (named 'R1' to 'R10'). This half cut region of the specimens, which is the AOI, is speckled with white paint over a black background using spray paints, forming a pattern that is recognizable using a high resolution camera. It is kept undisturbed for 24 hours for the spray paint to dry.

The test setup is as shown in Figure 2. Tension test is conducted on the longitudinally half cut corroded specimen in a 100 kN capacity machine. The test was conducted at a displacement rate of 0.0125 mm/s, as per the lowest strain rate recommended in IS 1608:1995. Images were acquired using a high resolution camera at a rate of 1 image/sec till breakage of the specimen.

**Figure 3. Longitudinally half-cut specimens**

## 6.2 Data analysis using 2D-DIC

After completing the tension test (till fracture) on the two corroded specimens, each one of the images of the intermediate deformed states is correlated with the respective reference image (undeformed state), thus forming an image pair, to compute the full-field deformations in the AOI across all the images, acquired during the test for the specimen (1 or 2) under consideration. The commercial 2D-DIC package VIC-2DTM is employed for the DIC computations with the input parameters such as a) the AOI size (specimen 1 – 120 pixels x 700 pixels and specimen 2 - 125 pixels x 709 pixels), AOI is identified as the enclosing region of a polygon, defined by tracing the boundaries of the region of interest on the specimen, b) the subset size of 25 pixels x 25 pixels and the step or increment size of 3 pixels for both the specimens, c) Zero Normalized Sum of Square Differences (ZNSSD) optimization function. Using the mentioned parameters, VIC-2DTM estimated the displacements in unit pixels. To convert the displacements in the metric units (mm), a calibration is performed by first estimating the scaling factor (mm/pixels) and then multiplying it to the pixel displacements. Finally, full-field strains are computed using a filter size of 15 pixels x 15 pixels, the filter size defines the local region which is approximated by a smooth polynomial surface to compute the displacement gradients and hence the strains. VIC-2DTM can also compute linear one-dimensional (1D) strain (virtual extensometer), where the 1D element is defined by selecting the two (Top/Bottom) pixels spanning the undeformed length.

All the VIC-2D™ outputs are recorded and as the next step, each image is then correlated with the machine load applied at that instant corresponding to the time of image capture, to obtain the **load-displacement** or **stress-strain** plot of the specimens. To meet the objectives of this study, the data analysis involves:

- a) Comparison of the strain values measured by virtual extensometer and the strain computed using 2D-DIC.
- b) Comparison of the stress-strain curve plotted using residual cross-sectional area at the fracture location and the average residual cross-sectional area assumed to be uniform over the gauge length.

The conventional technique of strain measurement using typical laboratory extensometers was simulated using a virtual extensometer utility in VIC-2D™. Desirable gauge length can be selected on the images over which VIC-2D™ computes the strain, assuming strain distribution to be uniform over this length. 50 mm was selected as the gauge length for strain measurement using virtual extensometer. To

understand the heterogeneity in the strain distribution over the 50 mm long AOI, the AOI was sub-divided into 10 regions, each of 5 mm length as shown in Figure 4, and strains in each of these regions were computed using 2D-DIC. These regions are named 'R1', 'R2', and so on up to 'R10' with the region with the fracture location as 'RF'. It is assumed that the residual cross-sectional area in this 5 mm long sub-divided regions is uniform. This is a more accurate estimate than assuming the average cross-sectional area over the entire gauge length to be uniform over that length.

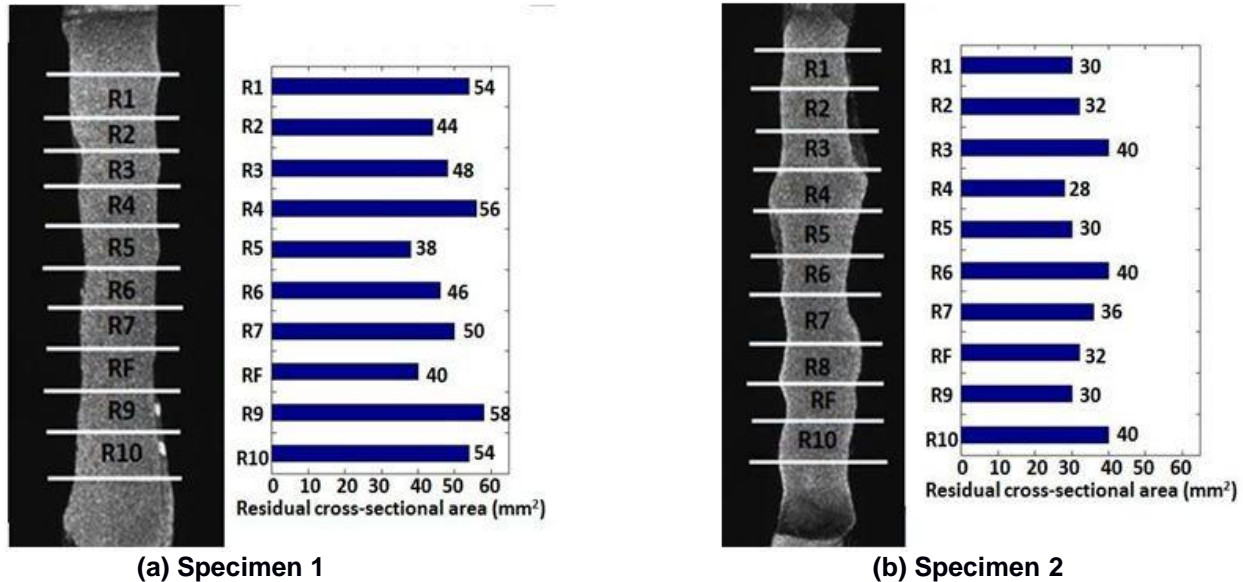

Figure 4. Variations in the cross-sectional area along the length of AOI

## 7 Results and Discussions

The following section details the results of the comparative analysis carried out on the two corroded rebar specimens tested.

### 7.1 Influence of the gauge length on measured mechanical properties

Figure 5 shows the stress-strain curves plotted with strain measured using virtual extensometer of 50 mm gauge length (the thicker curve labelled as 'G50') and strains computed for the regions 'R1' to 'R10' using 2D-DIC. The stress-strain plots for the regions 'R1' to 'R10' exhibits the non-uniform strain distribution over the AOI. Regions 'R1' to 'R10' exhibit dissimilar strain distribution due to the variation in the cross-sectional areas of these regions. The virtual extensometer measures the average strain over the AOI by means of the relative displacement of the two points 50 mm apart, assuming uniform strain distribution along the gauge length. The ultimate strain measured using the virtual extensometer is significantly lower than the ultimate strain exhibited by the 'RF' and adjacent regions. Table 2 shows the differences in ultimate strains measured using virtual extensometer and 2D-DIC.

Another observation is that, for specimen1, the region 'R1' exhibits a sudden decrease in the stress at a strain value of about 0.02 (the vertical line in the stress-strain curve in Figure 5. Similar behaviour is exhibited by regions R2, R3, R4, and R5, with a sudden reduction in the stress at about strains ranging between 0.02 and 0.05. Similarly, regions R1 to R6 of Specimen 2 exhibit a reduction in stress when strain is between 0.01 and 0.02. These reductions in stress exhibited by some regions that are away from the 'RF' and adjacent regions indicate that regions away from the RF are not influenced by the elongation due to necking. This shows that there can be significant variations in the strains experienced by the different regions within the gauge length. Thus, assuming uniform strain over a specific gauge length does not capture the actual mechanical response of the corroded rebars. Hence, an appropriate gauge length for corroded specimens would depend upon the variation in the cross-sectional area profile in the proximity of the probable failure location with least cross-sectional area. The 2D-DIC technique can help to determine appropriate gauge length for a corroded specimen by observing the strain distribution in the adjacent regions to the failure location. The computations involve a posterior analysis of the data (i.e., image analysis) collected during the tensile test.

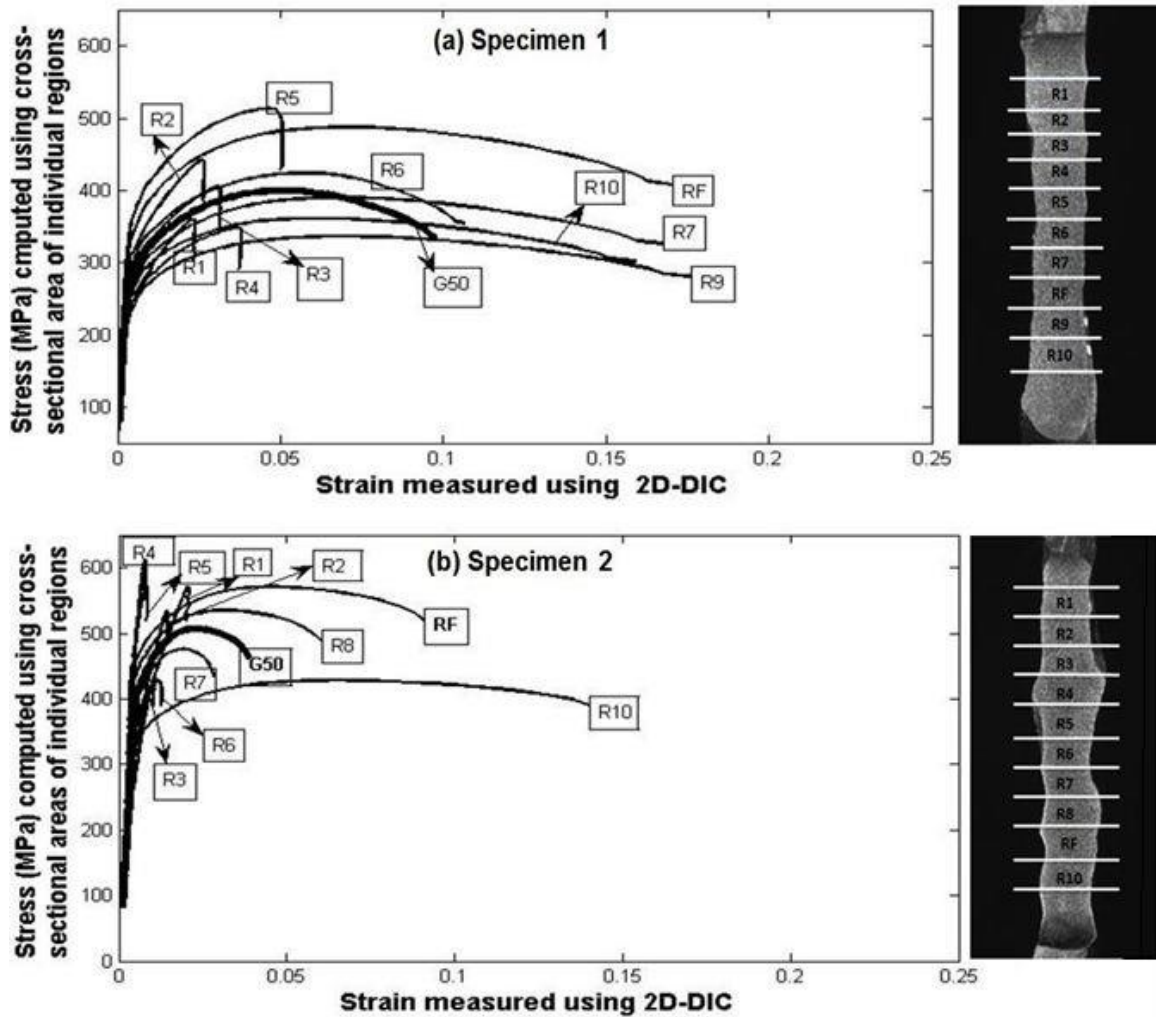

Figure 5. Comparison of stress-strain plots obtained using virtual extensometer and 2D-DIC

Table 2. Measured Mechanical Properties

Length over which residual cross-sectional area is assumed to be uniform (i.e., 'Gauge Length')	Specimen 1			Specimen 2		
	Yield strength (MPa)	Ultimate strength (MPa)	Ductility (%)	Yield strength (MPa)	Ultimate strength (MPa)	Ductility (%)
50 mm	300	400	10	400	500	4
5mm (RF)	340	490	17	450	580	8

## 7.2 Influence of the measured residual cross-sectional area on the measured mechanical properties

The length over which the average residual cross-sectional area is measured influences the calculated strength properties of the corroded rebars. The stress-strain curve plotted using 50 mm gauge length virtual extensometer and the average cross-sectional area measured over 50 mm is represented by the thicker line labelled 'G50' in Figure 5. The yield strength and ultimate strength values exhibited by this curve is significantly lower than the corresponding value calculated for the region 'RF' using the residual cross-sectional area measured over the region 'RF' (5 mm). Table 2 presents the strength properties measured using the average residual cross-sectional area measured over 50 mm and 5 mm for both the specimens. This indicates that the calculated strength properties assuming the residual cross-sectional area to be uniform over the gauge length are lower than those calculated using residual cross-sectional area at the region 'RF'. This is because the 'average' residual cross-sectional area over larger lengths cannot capture the actual local reduction in the cross-sectional area at the fracture location.

### **7.3 Influence of the pattern of corrosion on the measured mechanical properties**

Two specimens, one with uniform corrosion, (i.e., nearly uniform cross-sectional area along the length), and the other with highly uneven corrosion pattern, as shown in Figure 4 (a) and (b) respectively, were selected to study the influence of the pattern of corrosion on the mechanical behavior of corroded rebars. Figure 5 exhibits the variations in the stress-strain curves for different regions ('R1' to 'R10'). For Specimen 1 with uniform corrosion pattern over the AOI, the adjacent regions to the 'RF' (i.e., 'R7', 'R9' and 'R10'), exhibit similar ductility behavior, while strength properties are considerably different for these regions. However, for Specimen 2 with uneven corrosion pattern over the AOI, the adjacent regions to the 'RF', (i.e., 'R8' and 'R10') exhibit very different ductility as well as strength properties. This indicates that rebars with larger variation in the cross-sectional area along the gauge length exhibits higher heterogeneity in the strain distribution compared to the ones with uniform corrosion pattern. Hence, the measurement of strain using a typical laboratory extensometer for specimens with non-uniform cross-sectional area along its length cannot capture the actual stress-strain behaviour of the specimen. Also, assuming uniform residual cross-sectional area over the gauge length for the corroded rebars with uneven cross-sectional pattern (say, pitting corrosion) may fail to capture the actual residual cross-sectional area at the fracture location. Hence, the pattern of corrosion (i.e., the variability in cross-sectional area over the length) is an important parameter that would help in deciding an appropriate gauge length and the length of the specimen over which the residual cross-sectional area can be assumed to be uniform.

## **8 Conclusions**

Previous studies on the evaluation of the corrosion-induced changes in the mechanical properties of the rebars exhibit considerable differences in opinion among researchers. The reason for these differences is mainly the variations among the adopted test methods and the limitations of the conventional techniques of evaluation. This study has compared the mechanical properties measured using the virtual extensometer and the 2D-DIC technique and arrived at the following conclusions. The mechanical behavior of corroded rebars cannot be determined using an extensometer as there is considerable heterogeneity in the strain distribution along the gauge length. Also, the average cross-sectional area measured over a length may underestimate the actual reduction in cross-sectional at the failure location. The conventional techniques of evaluating corroded rebars have limitations in taking into account the effect of pattern of corrosion on their mechanical behavior. However, a posterior analysis of the images captured during the tensile test using DIC can capture the heterogeneity in the distribution of strain over the AOI for corroded rebars. DIC analysis can take into account the pattern of corrosion on the specimens and study its effect on the mechanical properties of rebars. Thus, evaluation of the corroded rebars using DIC can facilitate an accurate estimate of the mechanical properties and a better understanding of the mechanical behavior of corroded rebars.

## **9 Future Work**

An extensive experimental program is ongoing on a set of corroded CTD steel rebar specimens, with different levels of corrosion. This study aims to develop an improved methodology for the evaluation of the mechanical characteristics of corroded rebars using DIC. Mild and moderately corroded specimens are evaluated using 2D-DIC, which requires polishing a narrow region (planar) on the surface of the specimen. For severely corroded specimens, with highly reduced cross-sectional area, achieving a planar surface is not always feasible. In that case, a three-dimensional (3D) variant of the DIC, usually called as 3D-DIC is employed. It is a stereovision based technique, which employs two cameras to capture the same region of interest on the specimen. In recent years, 3D-DIC has emerged as an accurate technique for estimating both the in-plane and out-of-plane motion or displacement fields. This study also attempts to categorize specimens according to the corrosion pattern and define gauge lengths for each category. Instead of conventional methods of measurements, the 3D-laser scanning technique, is being adopted to obtain a better estimate of the residual cross-sectional area of the specimens, which would significantly help in identifying the potential failure locations.

# Determination of Chloride Diffusion Coefficient of Concrete: Comparison of Bulk Diffusion and Electrical Field Method

Aimin Xu<sup>1</sup> & Ahmad Shayan<sup>2</sup>

<sup>1</sup> Senior Research Engineer, ARRB Group, Melbourne, Australia

<sup>2</sup> Chief Research Scientist, ARRB Group, Melbourne, Australia

**Abstract:** Chloride Diffusion coefficient of concrete is of prime importance in the service-life prediction for concrete structures, and it can also be used as a parameter for the concrete quality control. This paper presents the results of chloride diffusion tests in which the diffusion coefficient was determined by the two most commonly used acceleration methods; the bulk diffusion in solution of high chloride concentration, and the electric field accelerated migration test.

Two types of concrete mixes were used, one being of 40 MPa strength grade, containing plain Portland cement as binder, and the other of 50 MPa strength grade which contained blended cement as binder. This paper shows that the value of diffusion coefficients determined by the bulk diffusion test is considerably higher than that obtained on concrete structure exposed to seawater, and the value of diffusion coefficient determined by migration test under electrical field is even greater.

The paper discusses the possible reasons for the discrepancies including chloride binding, specimen age, and the appropriateness of using the diffusion coefficients so determined for concrete quality control.

**Keywords:** accelerated diffusion, chloride binding, chloride diffusion coefficient, concrete, electrical field.

## 1. Introduction

Chloride contamination of concrete can cause damage to concrete structures through alteration of chemical properties of concrete and chemical-electrical property of reinforcing steel which induces steel reinforcement corrosion. The latter occurs more rapidly in structures subjected to chloride containing sources, such as seawater, deicing salts and saline soil. The chloride ions enter concrete and gradually reach steel reinforcing bars which causes steel to corrode, when the concentration at steel is high enough. The duration since concrete is exposed to the chloride source till corrosion of reinforcing bar commence depends on the concentration of chloride in the source and the rate to transport through the concrete. This duration has been generally taken as the "service-life" of the component, which is a conservative approach.

There are several mechanisms for chloride transport in concrete and a few methods have been developed to evaluate the rate of chloride transport, as reviewed by Nilsson et al.<sup>1</sup> The most commonly encountered mechanism is the diffusion of ions, and the most tested property is the diffusion coefficient. The diffusion coefficient is a fundamental parameter for evaluating the service-life of the structural member, and can also be used for concrete quality control. However, the chloride ion diffusion in concrete in natural environment, such as normal seawater (about 3.5% NaCl by mass of water) is a very slow process, and the test will need a very long time to yield results, e.g. the ponding test by ASTM C1543 requires 6 months<sup>2</sup>. It is well known that concrete properties such as pore structure and strength improve with age, and that the improvement results in a reduction in the diffusion coefficient. For quality control, diffusion coefficient is determined at a designated exposure age which needs to be practical such as 28 days.

Therefore, accelerated test methods have been developed and used for testing the diffusion coefficient. The mechanisms and test methods are elaborated in Nilsson et al.'s comprehensive review<sup>1</sup>. The methods that have been adapted by standard organizations are NT Build 443 by Nordtest<sup>3</sup> which has also been designated as ASTM C1556 with minor change<sup>4</sup>, and NT Build 492 which uses basically the same test principle as ASTM C1202.<sup>5,6</sup>

NT Build 443 tests the natural diffusion of chloride ions into concrete at the age of 28 days (if it is for quality control) exposed to a strong chloride solution (NaCl 165 g/L) with exposure time of at least 35 days, and NT Build 492 tests migration of chloride under an electric field of 30 Volts across a 50mm thick slice of concrete for a period of 24 hours (the field strength and purging time can vary according to the anticipated migration speed). The experience of the present author is that neither test methods yields values of diffusion coefficient comparable to those obtained from concrete cores extracted from actual

structures<sup>7</sup>. In addition, the diffusion coefficient obtained by NT Build 443 will certainly be influenced by the exposure age.

Investigations have been conducted at ARRB to evaluate and compare the diffusion coefficients obtained by these methods. This paper discusses mechanisms of the transport process in the three methods and presents results of diffusion coefficients determined for two concretes; Grade 40 MPa made with GP cement and Grade 50 MPa made with blended cement. Particularly, the effect of specimen age on the magnitude of diffusion coefficient is investigated. The free chloride ion diffusion coefficient and chloride binding capacity, which can be evaluated from the results of these tests, are also discussed.

## 2. Transport Mechanisms Involved in the Test Methods

### 2.1 Bulk Diffusion

Diffusion of ions occurs where there is a concentration difference over a distance, i.e. the gradient is not zero. The distribution of a substance as a function time and space  $C(t,x)$  in a body exposed to a constant environment with a constant concentration can be described by the “Second Law of Diffusion” (or Fick’s Second Law). This law was originally derived for ion diffusion in solution. Nilsson<sup>8</sup> theorized that the diffusion law can be applied to the diffusion in concrete and that it can be expressed as:

$$C(t, x) - C_i = (C_s - C_i) \left[ 1 - \operatorname{erf} \left( \frac{x}{\sqrt{4D_a t}} \right) \right] \quad (1)$$

where  $C=C(t, x)$  is concentration of chloride ions which is a function of time ( $t$ ) and distance ( $x$ ),  $C_i$  is the original chloride content and  $C_s$  the content at surface of concrete, and  $D_a$  is the apparent diffusion coefficient. Values for  $C_s$  and  $D_a$  are obtained by curve fitting, i.e. by plotting the chloride content versus depth ( $x$ ) and fitting the data to Eq.(1), using trial values of  $C_s$  and  $D_a$  until the distribution in theory fits the data. The relationship between  $D_a$  and the diffusion coefficient of free moving ions ( $D_0$ ) can be expressed by the equation<sup>7</sup>:

$$D_a = D_0 / (1 + \partial C_b / \partial C_f) \quad (2)$$

where  $\partial C_b / \partial C_f$  is termed as “binding capacity” to describe the change of bound chloride ( $C_b$ ) with the change in equilibrium solution concentration ( $C_f$ ).<sup>8</sup>

In theory, there is no difference between the process of diffusion in seawater and that in NT Build 443 condition. However, the  $\partial C_b / \partial C_f$  is large at low concentration and becomes small at high concentration. This means that with increase in concentration, the change in chloride binding becomes relatively smaller and the  $D_a$  will be larger according to Eq.(2). Consequently,  $D_a$  obtained by NT Build 443 method will be larger than that of structure exposed to seawater. Comparative experimental tests have confirmed this.

Xu and Shayan<sup>7</sup> pointed out that all chloride ions must enter the specimen through the boundary ( $x=0$ ), therefore the total free chloride ions diffused into the specimen is the same as the bulk diffusion and that the diffusion coefficient of free chloride,  $D_0$  can be estimated in the bulk diffusion test by:

$$D_0 = [C(t)_{total} / A]^2 \pi / (4t), \text{ or } D_0 = \left[ (C_s - C_i) / (C_{ENV} - C_{i,free}) \right]^2 \quad (3)$$

where  $C(t)_{total}$  is the total amount of chloride ions entered the concrete at time  $t$ ,  $A$  is the area;  $C_{ENV}$  is the concentration of chloride in the solution (with the same unit as  $C_s$ ). The binding capacity,  $\partial C_b / \partial C_f$  can be estimated through the relationship shown in Eq.(2), i.e.  $\partial C_b / \partial C_f = D / D_a - 1$ .

### 2.2 Migration in Electrical Field

Under an electrical field ions at one surface are pushed into the specimen by the electrical potential difference. The distribution of free chloride ions (those that did not chemically react with cement paste during the process) in the specimen under such a condition before they break through the other side of the specimen can be described by<sup>9</sup>:

$$C(t, x) - C_0 = \frac{C_{ENV} - C_0}{2} \left[ e^{\frac{v}{D}x} \operatorname{erfc}\left(\frac{x+vt}{\sqrt{4D't}}\right) + \operatorname{erfc}\left(\frac{x-vt}{\sqrt{4D't}}\right) \right] \quad (4)$$

where  $C_{ENV}$  is the solution concentration at boundary ( $x=0$ ) and  $v$  is the velocity of the ions moving due to the electrical field. Under electrical potential of  $\Delta E$  across a specimen of thickness  $L$ , the velocity is:

$$v = \frac{zF}{RT} \frac{\Delta E}{L} D' \quad (5)$$

where  $F=96484.56$  C/mol,  $R=8.31441$  J/mol/K,  $T$  is the temperature (K), and  $z=1$  for chloride ions. It can be shown that Eq(4) is dominated by its second term (about 95% for a test of 6 hours). If the concentration at a depth  $x_d$  is known, the value of  $D'$  can be calculated by the relation derived by Tang,<sup>10</sup> which is:

$$D' = \frac{1}{vt} \left[ x_d + \frac{2\xi}{v} (1 - \sqrt{\xi^2 + vx_d}) \right] \quad (6)$$

where  $\xi$  is the invert of the error function complement, i.e.  $(C(x,t)-C_0)/(C_{ENV}-C_0)=\operatorname{erfc}(\xi)$ .  $D'$  is named as "non-steady state migration" coefficient by NT Build 492, and denoted as  $D_{nssm}$  which will be used in this paper.

The depth of chloride migration can be revealed by spraying a silver nitrite solution onto the cross section of the tested specimen, which results in a whitish zone (AgCl). The concentration of chloride that is revealed by 0.1 M AgNO<sub>3</sub> solution is believed to be 0.07 M.<sup>5,10</sup> If  $C_0 = 0$  and  $C(x_d, t) = 0.07$  M, then  $\xi$  equals 1.281214 and 0.842741, for the test using 2 M solution (NT Build 492) and 0.6 M (seawater), respectively.

It should be pointed out that 0.1 M AgNO<sub>3</sub> is a relatively strong solution with excess silver at the migration front, which turns black with exposure to sunlight and masks some of the AgCl formed. Therefore, the revealed depth is shorter than that if a diluted AgNO<sub>3</sub> solution is used.

## 2.3 Influences of Temperature and Time on Diffusion Coefficient

### 2.3.1 Temperature

Generally, diffusion coefficient increases with the increase in temperature and decrease in solution viscosity, as described by the Stokes-Einstein relation<sup>11</sup>:

$$D = k_B T / (6\pi\eta a) \quad (7)$$

where  $k_B$  is the Boltzman constant ( $1.38 \times 10^{-23}$  JK<sup>-1</sup>),  $T$  is the temperature (K),  $a$  is the effective dynamic radius of the diffusing particle (sphere) and  $\eta$  the viscosity of water. This leads to a simple relationship for evaluation of diffusion coefficients at different temperatures:

$$D(T_1) / D(T_2) = (T_1 \eta_1) / (T_2 \eta_2) \quad (8)$$

During the migration under an electrical field test the temperature of concrete specimen increases due to the electrical current induced heat. For comparison, the as-determined diffusion coefficient is to be expressed as that at a reference temperature by using Eq.(8) and the published values of water viscosity (CRC Handbook<sup>12</sup>).

### 2.3.2 Age of Concrete

Concrete properties improve with curing time because of the hydration of cement, e.g. strength increases and porosity decreases. Similarly the diffusion coefficient which is a function of porosity and cement hydration degree will decrease with time.

The diffusion coefficient has been found to decrease with concrete age, and a power function used by Poulsen<sup>13</sup> is typical:

$$D_a(t) = D_{ref} (t_{ref} / t)^m \quad (9)$$

where  $D_{ref}$  is the coefficient determined at “reference age”  $t_{ref}$ , and  $m > 0$  is a constant depending on cementing materials composition which is also termed as the “age factor” in the service life prediction softwares<sup>14,15</sup>. In the literature, the starting age of the test, e.g. 28 days has been denoted as  $t_{ref}$ .

This fact raises a question about the representatives of the diffusion coefficient obtained by the bulk diffusion test. Because the diffusion coefficient decreases with age, which is particularly true for a young concrete, and that the test is run from age of 28 days to 63 days (exposure duration 35 days) or later, the as-determined diffusion coefficient would be smaller than that at the starting age, e.g. 28-day. In another words, the common practice of using the diffusion coefficient determined by the bulk diffusion test as  $D_{ref}$  would be incorrect. Furthermore, the standard immersion duration is “at least 35 days”, which will result in further reduction in the diffusion coefficient.

Nilsson et al.<sup>1</sup> demonstrated that diffusion equation, Eq.(1) is valid even though the diffusion coefficient is time dependent, and during the period in which the diffusion coefficient is a continuous function of time, diffusion equation can be expressed as:

$$C(t, x) - C_i = (C_s - C_i) \left[ 1 - \operatorname{erf} \left( \frac{x}{\sqrt{4 \int_{t_1}^{t_2} D(t) dt}} \right) \right] \quad (10)$$

Clearly,  $D_a$  in Eq.(1) is an average value of the diffusion coefficient defined by

$$D_a(t_2 - t_1) = \int_{t_1}^{t_2} D(t) dt = \int_{t_1}^{t_2} D_{t_1} (t_1 / t)^m dt = D_{t_1} \frac{t_1^m}{1-m} \frac{t_2^{1-m} - t_1^{1-m}}{t_2 - t_1} (t_2 - t_1) \quad (11)$$

Eq.(11) can be rearranged to explicitly express  $D_a$  as function of age as shown by Tang and Gulikers.<sup>16</sup> For testing and quality control, the as-determined  $D_a$  by NT-build 443 (and ASTM C1556) must be recalculated to that at a certain reference age, e.g. 28-day. The values of diffusion coefficient at different ages during the test will be elaborated on in the following sections.

### 3. EXPERIMENTAL WORK

#### 3.1 Concrete Mix and Specimens

The investigation was conducted on two grades of concrete, 40 MPa concrete made with GP cement, and 50 MPa concrete made with blended cement (75% GP cement, 6.25% fly ash and 18.75% slag). Standard concrete cylinders (diam.100 mm, length 200 mm) were made and cured in a fog-room at 23°C until the age of 28 days, when three cylinders of each mix were tested for compressive strength and others for the diffusions. The mix proportions and the compressive strength at 28 days are shown in Table 1.

**Table 1. Concrete mixes and the strength and VPV at 28 days**

Code	Cementing material (kg/m <sup>3</sup> )	Mix proportion Cement : water : aggregate : sand	Strength at 28-day (MPa)	VPV (%)
VR40 (40 MPa)	400	1 : 0.450 : 2.775 : 1.725	59	11.8
VS50 (50 MPa)	480	1 : 0.375 : 2.188 : 1.437	70	12.2

Each cylinder for diffusion tests was sawn into three disks (cast/trowelled surface as top): top 90 mm for the bulk diffusion tests, middle and bottom 50 mm for the electrical field accelerated migration test. The side surface of the specimens was coated with epoxy glue.

### 3.2 The Bulk Diffusion Test

The test was carried out according to ASTM C1556. Two specimens were tested for each concrete. The cut face of the specimen was exposed to NaCl solution of concentration 165 g/L (2.82 M) and stored at 23°C. The tests were started at age of 33 days due to some practical problems encountered. The exposure time was 37 days and 49 days for the 40 MPa Grade and 50 MPa Grade concrete, respectively. The diffusion of chloride ions into concrete will inevitably reduce the solution concentration, therefore the concentration of the exposure solutions was determined at one week and three weeks since the start of exposure, and salt (NaCl) was added to the solutions to maintain the original concentration.

In the last day of the test, each specimen was ground from surface down by using a “profile grinder” (Germman Instruments, Denmark), which allows accurate incremental sampling (area of about 70 mm in diameter). For each specimen, the primary sampling depth was about 10 mm, and the sample from 10 mm depth used to determine its chloride content. The specimens after the primary sampling were stored at 5°C. Further sampling was done if the chloride content in this sample was much higher than the initial chloride content (tested on non-contaminated concrete). The total chloride content was determined by dissolving the concrete powder in nitric acid solution, heating the solution to boiling, filtering the acid-heat treated sample and then using potentiometric titration technique to determine the chloride ion content in the solution.

### 3.3 The Migration Test

The test was carried out following ASTM C1202 test method. That is, a specimen (50 mm disk) was placed between two cells, each cell with a metal mesh which is connected to an electric terminal. The potential across the specimen was maintained constant by the instrument. The cell connected to negative terminal contains NaCl solution (0.6 M) and the cell to positive terminal contains NaOH solution (0.3 M). The test was run at 60 Volts for 6 hours. The current and voltage across specimen were automatically recorded and the total charge passed through the specimen during 6 hours was calculated and reported by the instrument. After the completion of the ASTM C1202 test procedures, the tested specimens were split along the migration direction. The depth of chloride penetration was revealed by spraying a solution of 0.1M AgNO<sub>3</sub> on the exposed surface which forms a whitish AgCl zone, and the depth of AgCl ( $x_d$ ) was measured. The value of  $x_d$  is inserted into Eq.(6) to find a primary value of  $D'$  which is then inserted into Eq.(4).  $D_{nssm}$  is obtained by varying  $D'$  so that Eq.(4) gives  $C(t, x_d)/(C_{ENV}/2) = 0.6/0.035$  ( $C_0=0$ ).

To evaluate the age effect, the migration test was so planned that three sets of tests were conducted in relation to the time of bulk diffusion: (1) the starting day, (2) about the middle of the exposure duration, and (3) the finishing day. Two disks from the same cylinder were tested for each concrete at each age.

NT Build 492 standard indicates that the actual potential difference between the electric terminals is 2 volts less than the nominal potential, i.e.  $\Delta E = V - V_0$ , and  $V_0 = 2$ . In this investigation,  $V_0$  was measured for each specimen by using 10 volts and 30 volts (each for a minute) before setting the instrument to 60 volts. The current changes at the start and becomes stable after a few seconds.  $V_0$  (0-amp potential) is found by plotting the initial current (using the value recorded at 1 minute) against potential  $V$  (Figure 1). The extra time used for this determination was calculated as equivalent time under 60 volts and added to the purging time for the calculation of  $D_{nssm}$ .

Figure 1. Initial current vs. potential to determine the 0-amp potential (all test results).

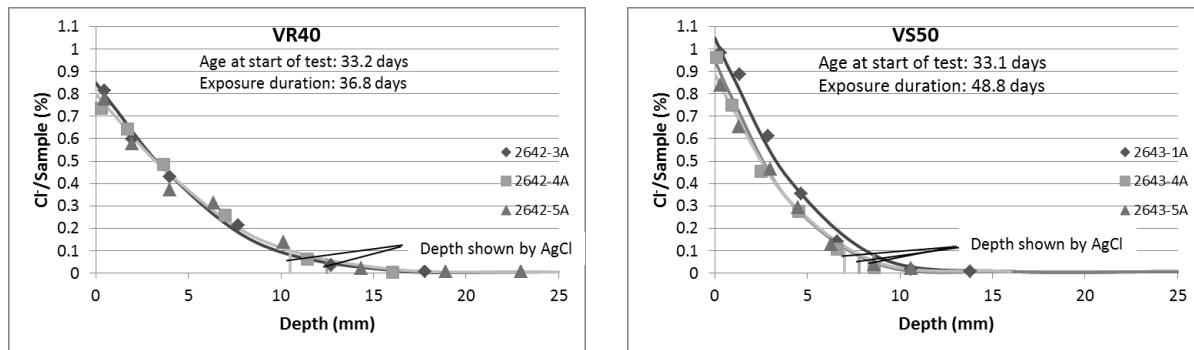

## 4. Results and Discussion

### 4.1 The Bulk Diffusion Test

The diffusion parameters,  $C_s$  and  $D_a$  of the two concretes are shown in Table 2, and the chloride profiles with fitted theoretical curves are shown in Figure 2.

**Table 2 – Results of bulk diffusion test**

Concrete type	Age during test	$C_s$ , Cl <sup>-</sup> per concrete (g/g)	$D_a$
VR40	33 – 70 days	0.81%, cv=0.05	$6.7 \times 10^{-12}(\text{m}^2/\text{s})$ , cv=0.07
VS50	33 – 82 days	0.96%, cv=0.08	$2.3 \times 10^{-12}(\text{m}^2/\text{s})$ , cv=0.12

**Figure 2. Chloride profiles.**

The as-tested apparent diffusion coefficient for Grade 40MPa concrete is about  $6.7 \times 10^{-12} \text{ m}^2/\text{s}$  and that for Grade 50MPa concrete is about  $2.3 \times 10^{-12} \text{ m}^2/\text{s}$ . These values are much higher than those tested on the actual concrete structures exposed to seawater. Besides, the as-tested diffusion coefficients do not represent those at the starting age due to the age effect. To present the results at 28 days and find out the actual age that these results represent, it is necessary to evaluate the age factor.

### 4.2 The Migration Test and Age Factor

The results obtained from the migration test include: the initial current (under 60 V), total charges passing through the specimen after 6 hours (calculated to that for the standard specimens: diameter 95 mm and length 50.8 mm), the class of resistance to chloride penetration specified by ASTM C1202; the 0-amp potential, depth of migration,  $D_{nssm}$  at 23°C. The results are shown in Table 3.

**Table 3 – Results of migration test (average of two specimens unless noted)**

Specimen code	Age at test (days)	Thickness $L$ (mm)	Initial current $I_i$ (mA)	Charge (Coulombs) & Class	0-amp volt $V_0$ (V)	Cl <sup>-</sup> depth $x_d$ (mm)	Coefficient $D_{nssm}$ , 23°C (m <sup>2</sup> /s)
VR40-1	33.4	52.0, 53.7	130, 103	2817 (M)	2.10	18.3, 14.3	$14.0 \times 10^{-12}$
VR40-2	49.9	51.0, 51.1	125, 100	2460 (M)	2.23	17.3, 12.8	$12.9 \times 10^{-12}$
VR40-3	69.9	51.7, 51.7	105, 96	2149 (M)	1.95	12.4, 11.8	$11.3 \times 10^{-12}$
VS50-1	33.4	53.8, 50.6	78, 74	1739 (L)	1.96	7.2, 6.7	$6.1 \times 10^{-12}$
VS50-2	55.9	50.5, 51.5	61, 54	1201 (L)	2.23	5.4, 5.8	$5.4 \times 10^{-12}$
VS50-3	82.1	51.0, 51.2	49, 42	1001 (L)	2.04	5.3, 4.2	$4.5 \times 10^{-12}$

Class of resistance to chloride penetration: M= moderate (2000– 4000 Coulombs); L= low (1000 – 2000 Coulombs)

The data obtained by the migration tests can be used for estimation of the “age factor”. To do this, the values to use must be comparable on the same base, i.e. not influenced by the change in temperature, actual size of specimens, and human errors (e.g. measurement of depth of chloride) and uncertainty in assumptions (e.g. assuming the free chloride concentration at the chloride front is 0.07 M). The best choice is the conductivity calculated from the initial current and specimen’s dimensions:

$$\kappa = \frac{I_i}{V - V_0} \frac{L}{\pi r^2} \quad (12)$$

where  $I_i$  is the initial current (mA),  $V - V_0$  is the effective potential (V),  $L$  and  $r$  are the thickness and radius of specimen (cm) respectively. The age factor estimated by the initial conductivity (Figure 3) is  $m=0.2$  for VR40 (Grade 40 MPa concrete) and  $m = 0.6$  for VS50 (Grade 50 MPa concrete). From the pattern of the conductivity decrease with age shown by Figure 3, one can predict that such decrease would be very little in the future, e.g. after 1 year. These results indicate that the chloride diffusion coefficient of concrete may not change significantly after a few years of construction.

Figure 3. Estimation of the age factor.

#### 4.3 The Bulk Diffusion Coefficient at Different Ages

The diffusion coefficient at each age during the test can be calculated by using Eq.(9) when the age factor is known.

For the two concretes, the as-determined  $D_a$  represents that at an age between starting and end of the exposure, i.e. it was 42.4 days for VR40 (tested during age 33.2 to 70 days), and 54.6 days for VS50 (tested during age 33.1 to 82 days). The value of  $D_a$  at 28 days will be  $6.9 \times 10^{-12} \text{ m}^2/\text{s}$  and  $3.5 \times 10^{-12} \text{ m}^2/\text{s}$  for VR40 and VS50, respectively. The average values of the apparent diffusion coefficient for the two concretes are shown in Table 4 and Figure 4.

It can be calculated that if the test were started at age of 28 days and duration was 35 days,  $D_a$  would be  $6.9 \times 10^{-12} \text{ m}^2/\text{s}$  and  $2.7 \times 10^{-12} \text{ m}^2/\text{s}$  for VR40 and VS50, respectively. It is clear that the practice of using the starting age (e.g. 28 days) as the reference age for the determined  $D_a$  is imprecise for the newly made concrete. This is because the change in the diffusion coefficient during the test is significant.

Table 4 – Average apparent diffusion coefficient at various ages during testing

Concrete	Age (days)	$D_a$ ( $\text{m}^2/\text{s}$ )	Note
VR40	33.2	$7.3 \times 10^{-12}$	Start of test
	42.4	$6.7 \times 10^{-12}$	The test result (average)
	70.0	$6.3 \times 10^{-12}$	End of test
	28.0	$7.5 \times 10^{-12}$	Reference age
VS50	33.1	$3.1 \times 10^{-12}$	Start of test
	54.6	$2.3 \times 10^{-12}$	The test result (average)
	82.0	$1.8 \times 10^{-12}$	End of test
	28.0	$3.5 \times 10^{-12}$	Reference age

Figure 4. The diffusion coefficient at different ages during test, “Average” is the test result.

#### 4.4 Diffusion Coefficient of Free Chloride Ions

As described earlier, the diffusion coefficient of free chloride ions,  $D_0$  can be calculated using Eq.(3), and the mean chloride binding capacity,  $\partial C_b/\partial C_f$  can be evaluated. The environmental chloride is calculated by:

$$C_{ENV} = \frac{C_f}{m_{conc}} = \frac{C_f}{w} \frac{w}{m_{conc}} = \frac{C_f}{w} A_i \quad (13)$$

where  $m_{conc}$  is the mass of concrete,  $C_f/w$  the chloride content in the solution, and  $A_i$  is the concrete absorption. The solution used for the test (2.82M) gives  $C_f/w = 0.0905$ .  $A_i = 5.2\%$  and  $5.6\%$  for the VR40 and VS50 respectively. The average results for the two concretes are shown in Table 5.

Table 5 – Diffusion coefficient of free ions and chloride binding capacity

Concrete	$D_0$ (m <sup>2</sup> /s)	$D_a$ (m <sup>2</sup> /s)	$D_0/D_a$	$\partial C_b/\partial C_f$
VR40	$19.64 \times 10^{-12}$	$6.71 \times 10^{-12}$	2.93	1.94
VS50	$8.47 \times 10^{-12}$	$2.32 \times 10^{-12}$	3.64	2.60

The chloride binding capacity determined for in-situ concrete structures tested by the author was higher than 10. Published data on the chloride binding<sup>17, 18</sup> demonstrate that the slope of the curve of chloride content versus concentration of chloride in solution, i.e. the binding capacity, becomes smaller with increase in solution concentration, especially in the range where the environmental chloride ions concentration is above 0.6M. The reduction in the binding capacity may be the main reason for the high diffusion coefficient shown by concrete exposed to high chloride concentration.

On the other hand, this fact indicates that concrete exposed to environments with high chloride concentration would exhibit a higher chloride diffusion coefficient than that exposed to normal seawater.

#### 4.5 Comparison of $D_a$ and $D_{nssm}$

The second group of the migration tests had similar age as that of the average age of the bulk diffusion test, so that the results could be used for comparison. As shown in Table 6, the values of  $D_{nssm}$  are about twice that of  $D_a$  and 60% of  $D_0$ . This is likely because that the binding of chloride during the test was very limited.

Table 6 – Comparison of diffusion coefficients obtained from the two methods

Concrete	$D_a$ (m <sup>2</sup> /s)	$D_0$ (m <sup>2</sup> /s)	$D_{nssm}$ (m <sup>2</sup> /s)	$D_{nssm}/D_a$	$D_{nssm}/D_0$
VR40	$6.71 \times 10^{-12}$	$19.64 \times 10^{-12}$	$12.92 \times 10^{-12}$	1.9	0.66
VS50	$2.32 \times 10^{-12}$	$8.47 \times 10^{-12}$	$5.35 \times 10^{-12}$	2.3	0.63

Concrete powder samples were taken from the surface and near the AgCl boundary (migration front) of the specimens, one for each concrete, and the chloride content was analyzed. The distribution of chloride (Figure 5) demonstrates that the chloride content at the migration front was about 0.1%, and that at the it surface was much higher, which indicates that chloride binding occurred only in the near-surface zones. Note that the chloride content in the solution (0.6M), i.e.,  $C_f/w = 0.0208$ , which would result in 0.1% chloride in the concretes if chloride binding did not occur.

The maximum chloride content at concrete exposure surface is about 2/3 of that occurred during the bulk diffusion test (e.g. it is about 0.6% for the 40 MPa grade concrete) and becomes less toward the migration front. These indicate the binding of chloride by the concrete during the migration test could not complete due to the limited time (Figure 5). More comparative experiments are needed to establish the correlation between  $D_{nssm}$  and  $D_a$ .

Figure 5. Chloride content in specimens tested for  $D_{nssm}$ . Dash lines represent free chloride ions distribution by theory.

## 5. Conclusions

This work has confirmed that the apparent diffusion coefficient,  $D_a$  determined by the bulk diffusion test method depends on the age of concrete and exposure duration. Its value decreases with age of concrete, especially for the newly made concrete.

The value of  $D_a$  at different ages can be estimated once the age factor is known. For quality control purpose, the reported  $D_a$  should be that for a specified age, but not a universal value.

The results of electrical field induced migration test can be used to estimate the age effect. The results presented in this paper indicate that the conductivity of the concrete at the start of the test, i.e. the initial conductivity is the best parameter to use to evaluate the age effect.

The estimated mean binding capacity of concrete,  $\partial C_b/\partial C_f$ , under the bulk diffusion test condition (exposed to 2.82M NaCl solution at 23°C) is 1.9 and 2.6 for the VR40 and VS50 concrete respectively, which are lower than that of concrete exposed to normal seawater.

For the two concrete mixes investigated in this work, the following results were obtained:

VR40: age factor  $m$  was 0.2,  $D_a$  at 28-day was  $6.9 \times 10^{-12} \text{ m}^2/\text{s}$

VS50: age factor  $m$  was 0.6,  $D_a$  at 28-day was  $3.9 \times 10^{-12} \text{ m}^2/\text{s}$

# Frost test and the significant influence of small amounts of ions dissolved in surface water

Max J. Setzer<sup>1</sup>

<sup>1</sup>Professor em. of Civil Engineering, University Duisburg-Essen, presently WISSBAU, Essen

**Abstract:** The scaling of concrete during a freeze-thaw attack is dramatically increased by dissolved ions – not only as well known by de-icing agent (e.g. 3% NaCl = 513 mmol(eq)/l) but also even by small ion concentrations as found in tap or surface water (below 30 mmol(eq)/l). This is proved by outdoor exposure and in modified RILEM CIF-test. Effects of macroscopic physics or chemistry are too small to explain the phenomenon. The solution is found in the disjoining pressure relevant in the gel pores (typical pore diameter 2 nm to 30 nm). Additionally, it describes the following experimental results: (1) The gel-pore-water is prestructured by the surface interaction; (2) its density is increased to values between 1.15 g/cm<sup>3</sup> and 1.25 g/cm<sup>3</sup>; (3) its heat of fusion is reduced by app. 30% (1 to 3) depending on the type of cement; (4) the freezing point of gel-pore-water is lowered far below triple point – down to -45 °C. Since ice Ih is formed in the larger pores of concrete triple point condition – i.e. the coexistence of ice, gel-pore-water and vapor – is only fulfilled by additional high negative pressures in the gel-pore water; its value is increasing with falling temperature by app. 1 MPa/K. Experiments show that ice expansion is not relevant during the first freeze-thaw-cycles due to empty pores formed by self-desiccation. Freeze-thaw-cycles act as frost pump increasing the degree of saturation until ice damage sets in. Frost-test procedures – RILEM recommendations - should be modified on the basis of these results.

**Keywords:** Frost action, RILEM CDF/CIF recommendation, surface physics, dissolved ions, frost pump.

## 1 Introduction

Two principal questions concerning durability of concrete against freeze thaw attack are in the focus of this article. (1) Why concrete survives many freeze-thaw cycles even if it is saturated by isothermal capillary suction? (e.g. in ASTM C 666 it are 300 cycles, in Swedish test and CIF-test 56) In comparison a completely water filled steel container with much higher strength is destroyed during the first frost attack. (2) Why even small amounts of dissolved ions as found in surface water or tap water increase the scaling of concrete dramatically and this in a strength which cannot be explained by microscopic physics or chemistry (e.g. by depression of freezing point of chemical attack)?

The first question can be answered by a semi-macroscopic explanation. Starting point is that there exists a remarkable amount of unfrozen gel pore water even far below bulk freezing point. This aspect has already been pointed out by Powers [15]. He and Helmuth [23] used the hydraulic pressures and transport for the explanation. Fagerlund [6] claimed that if a critical degree of saturation is surpassed damage sets in. Already in 1977 calculated the author [28] the pressures and mass transport arising from surface tension of sub-microscopic ice crystals of different size in the gel structure which are trapped in submicroscopic pores and separated from the solid surface by an unfrozen molecular water-layer. Later the author [29, 30] used semi-macroscopic thermodynamics to calculate the temperature dependent negative frost-pressure in unfrozen gel-pore-water necessary to maintain the triple phase condition. Scherer [17] and Penttala [16] adopted similar pressures for the water ice interfaces. Scherer used it especially for his percolation model. The frost pressure generates frost shrinkage and a transport from unfrozen pore water to ice. As shown in [30] this effect generates macroscopically during a freeze-thaw cycle a frost-suction. It will be shown below that frost suction is by far more efficient than any other transport like isothermal capillary suction and of course than diffusion. For frost resistance it must be kept in mind that due to self-desiccation during the hydration of cement empty pore room is generated which is sufficiently large to balance the expansion of ice.

However, experiments proof that the macroscopic values for the properties of water deliver wrong values for the generated pressures. It is apparent from the experimental results that gel pore water deviates

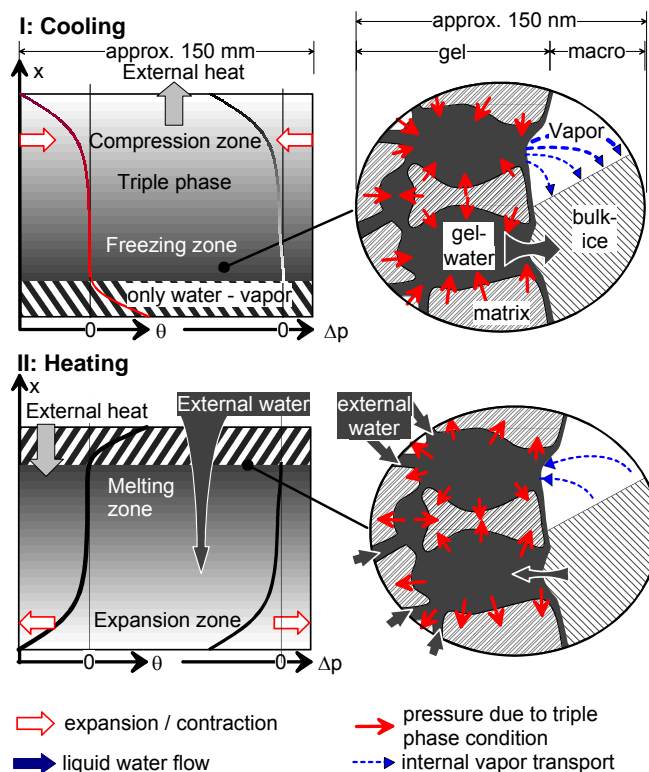

significantly from macroscopic bulk water. The heat of fusion and the density of gel-pore-water vary with the type of cement. Additionally, microscopic physical and chemical laws do not cover the influence of dissolved ions. To explain the impact of dissolved ions the disjoining pressure has to be introduced - a phenomenon which is only effective in the nanoscopic region i.e. far below  $1 \mu\text{m}$ . Especially the electrostatic part of the disjoining pressure is essentially changed by the concentration of dissolved ions and herewith important for the explanation of scaling.

At this point we should also keep in mind that we have to distinguish different sources of internal pressure. The micro-ice lens model and the negative pressure in the unfrozen gel pore water due to triple point conditions are strictly related to the pore water and its equilibrium with ice. A dry system will not show the effect. In contrast to this the disjoining pressure is primarily an interaction between the walls of the gel pore. It would be acting even in a dry system. However, it is significantly changed by the pore water and its dissolved ions.

Finally it must be taken into account that the frost phenomena act on different geometric scales. While disjoining pressure and all surface scientific aspects are most relevant around  $1 \text{ nm}$  and decay to become insignificant around  $100 \text{ nm} = 0.1 \mu\text{m}$ . The transport from gel pore water to the micro ice lenses takes place in the region around  $0.1 \mu\text{m}$  to  $100 \mu\text{m}$ . Here both thermal and thermodynamic equilibrium is reached much faster than any external change takes place. In the real structures above this we have as a rule transient thermal and hygral changes become more and more decisive i.e. no equilibrium is reached during normal cooling or heating process.

## 1. Micro-ice-lens model

### 1.1 Microscopic part and semi-macroscopic theory

**Figure 1:** The micro-ice-lens model. Comparison of microscopic / sub-microscopic scale (right) and transient macroscopic scale (left).

The micro-ice-lens model – figure 1 - describes the pumping effect leading to frost suction. It has three levels linked to scales – submicroscopic or nanoscopic, microscopic and macroscopic. In [29, 30] the author deduced the criteria for a thermodynamic equilibrium on the basis of the classical thermodynamics. Two criteria were derived: (1) a chemical stability criterion and (2) a mechanical stability criterion. Below bulk freezing point and after ice has formed in larger pores (above  $\approx 0.1 \mu\text{m}$ ) due to heterogeneous nucleation the macroscopic triple point condition is violated i.e. any unfrozen water has the tendency to

migrate to the ice. The triple point criterion can only be fulfilled in porous media if a high negative pressure can be generated in the unfrozen water. This is the chemical stability criterion. It bases on the equality of chemical potential of water. For unfrozen, liquid pore water (index L) and ice (index S) the equilibrium is established by equal chemical potential given by:

$$\int_{T_0}^T (s_S - s_L) d\tilde{T} = -v_L \Delta p_{LS} + (v_S - v_L)(p_S - p_0) \quad (1)$$

with the temperature T, the molar entropies s, the molar volumes v and the pressures p. In our context the second term is negligibly small giving

$$\Delta p_{LS} = -\frac{1}{v_L} \int_{T_0}^T (s_S - s_L) d\tilde{T} \quad (2)$$

As a rule the entropy changes with temperature and pressure (see [29]). However, the correction terms are small. The macroscopic properties and values of water are not applicable for gel pore water as found from detailed experimental results [19]. Its entropy and molar volume (density) is given in table 1.

The equation (2) can be simplified to a numerical relation between the pressure difference and the temperature  $\theta$  in Celsius scale with the coefficient  $\kappa$  dependent from the type of cement.

$$\Delta p_{LS} = \kappa \cdot \theta \quad (3)$$

Since  $\theta < 0$  and  $\kappa > 0$  the pressure in the liquid is negative. In table 1 data for bulk water and pore water are compiled. The value of pressure difference increases with falling temperature!

**Table 1: Data for prestructured gel pore water - from Setzer, Liebrecht [19]**

	Heat of fusion	Density	$\kappa$	$\bar{\gamma}/\kappa$
bulk	333 J/g	1000 kg/m <sup>3</sup>	1,22 MPa/K	27 nm*K
CEM I	186 J/g	1206 kg/m <sup>3</sup>	0,82 MPa/K	40 nm*K
CEM III A	238 J/g	1085 kg/m <sup>3</sup>	0,95 MPa/K	35 nm*K
CEM III B	226 J/g	1209 kg/m <sup>3</sup>	1,00 MPa/K	33 nm*K

The mechanical stability criterion defines until which temperature gel pore water remains unfrozen. For details see [29,30]. Here it is shown in a reduced way and combined with equation (3):

$$-\bar{\gamma} \frac{\partial \bar{A}}{\partial V} = -\frac{\bar{\gamma}}{R_H} = \Delta p_{LS}; \text{ and with (3): } R_H = -\frac{\bar{\gamma}}{\kappa \cdot \theta} \quad (4)$$

$\bar{\gamma}$  is the mean value of interfacial energy between ice and pore water. The value of the interfacial energy is quite uncertain in literature even under macroscopic aspects. Values are found between 20 and 44 mJ/m<sup>2</sup>. The value of Hobbs 33±3 mJ/m<sup>2</sup> is based on more direct experiments with interfaces and is used in table 1. In any case the given value gives only an approximation – however, a valuable guess for the magnitude and region.

$R_H$  is the hydraulic radius of the changing ice front. It is different during freezing and melting and depends from the pore geometry. During freezing it defines the progress or percolation of the ice into a pore; during melting the collapse of a pore-ice particle. In good approximation it is  $R_H(\text{percolation}) = R_H(\text{melting})/2 = d/4 = D/2$  where d is the diameter of a cylindrical pore and D the distance between the surfaces of a slit-pore.

At this point it is worth to note that the most relevant gel pore maximum in hardened cement paste is near to d=2 nm. Even if we consider the worst-case of bulk water in the table 1 and use as minimum temperature - 20° C as in most test procedures and especially in the RILEM recommendations than this gel pore water will not freeze.

## 1.2 Definition of size range – transition to macroscopic part and transient phenomena

The macroscopic range starts where the time of the externally generated temperature change faster than the necessary time to reach the thermal equilibrium this macroscopic volume of characteristic dimension length L. Following [12] the temperature within a slab of thickness L can be calculated by:

$$\theta(x,t) = \frac{4}{\pi} \theta_0 \sum_{n=0}^{\infty} \left\{ \frac{1}{(2n+1)} \exp\left(-\left[\frac{(2n+1)\pi}{L}\right]^2 a \cdot t\right) \sin\left(\frac{(2n+1)\pi}{L} x\right) \right\} \quad (5)$$

with:  $\theta(x,t) = T(x,t) - T_0$ ;  $\theta_0 = T_e - T_0$  and  $a = \frac{\lambda}{\rho c}$

where  $a$  is the thermal diffusivity of the material defined by the thermal conductivity  $\lambda$ , the density  $\rho$  and the heat capacity  $c$ . In equation (5) the exponential term is the dominant factor. It becomes less than 1% if the exponent falls below a value of  $-5$ . If we now consider a region of  $L_e$  then equilibrium is reached if it is:

$$\left[ \frac{(2n+1)\pi}{L_e} \right]^2 a \cdot t_e > 5; n=1 \Rightarrow t_e > \frac{5L_e^2}{3 \cdot a \cdot \pi^2}; \quad (6)$$

where  $t_e$  is called equilibrium time.

For wet concrete good approximations are  $\lambda = 2 \text{ W/(m}^*\text{K)}$ ,  $\rho = 2400 \text{ kg/m}^3$  and  $c = 1 \text{ kJ/(kg}^*\text{K)}$  and with that  $a = 0.83 \text{ mm}^2\text{/s}$ . Freezing is a phase transition; the situation is a moving boundary condition (Stefan problem) and equation (5) is not strictly correct. However, for our task to find an estimate for the region where quasi-equilibrium conditions change to a transient situation we can smear the heat of fusion over a temperature range where freezing takes place.  $0.1 \text{ K}$  is certainly a reasonable value. The heat of fusion in  $1 \text{ kg}$  of concrete we need the relative amount of freezable water in it which is until  $-10^\circ \text{ C}$  the bulk water. For a well hydrated concrete (degree of hydration app.  $0.9$ ) and a  $w/c$  of  $0.5$  we find approximately  $40$  liters of freezable water in one cubic-meter or  $0.017 \text{ kg(water)/kg(concrete)}$ . With an heat of fusion of  $333 \text{ kJ/kg}$  this gives  $5.5 \text{ kJ/kg(concrete)}$ . This smeared over  $0.1 \text{ K}$  the new  $c_{\text{frost}}$  is  $56.6 \text{ kJ/(kg}^*\text{K)}$  and  $a_{\text{frost}} = 0.0145 \text{ mm}^2\text{/s}$ . If we take as characteristic length  $L_e = 120 \mu\text{m}$  then the equilibrium time is  $t_e = 0.17 \text{ s}$  and at  $L_e = 300 \mu\text{m}$   $t_e = 1.05 \text{ s}$ . These equilibrium times are sufficiently below the values of a transient frost impact (typical  $10 \text{ K/h}$ ) and the length sufficiently above gel particle and pore size ( $\ll 1 \mu\text{m}$ ). At  $L_e = 4 \text{ mm}$  the equilibrium time is already a app.  $3 \text{ min}$ . This is critical even if external temperature changes are mostly slower than  $1 \text{ hour}$ . Therefore, we can now safely distinguish several regions:

1. ( $>4 \text{ mm}$ ) In the **macroscopic scale** we have transient conditions where a frost-front is penetrating the object during freezing and a melting-front during heating.
2. ( $<4 \text{ mm}$  and  $>120 \mu\text{m}$ ) A **transition scale** where transient effects are still important. It is equivalent with the region of macro-capillaries. Here macroscopic transport of water etc. takes place.
3. ( $<120 \mu\text{m}$  and  $>4 \mu\text{m}$ ) In the **microscopic scale** local thermal equilibrium can be assumed. The mass transfer caused either by pressure or temperature gradients or by pressure differences between water and ice have time constants which are larger than the time constants of temperature waves without freezing. However, they are still significantly smaller than the macroscopic time constant. Therefore, in the submicroscopic scale we can assume a thermal equilibrium as well as a thermodynamic equilibrium.
4. ( $<4 \mu\text{m}$  and  $>0.120 \mu\text{m}=120 \text{ nm}$ ) **Submicroscopic scale**. Only local transport is significant. Region of micro-ice lenses, meso-capillaries and empty pores due to self-desiccation.
5. ( $<120 \text{ nm}$  and  $>4 \text{ nm}$ ) The **scale of gel** where the freezing point of pore-water is decreased by the surface interaction with the solid. It starts at meso-gel level (typical dimension  $d < 0.12 \mu\text{m}=120 \text{ nm}$ ) the upper diameter of meso-capillaries – hydraulic radius  $R_H = d/4 = 30 \text{ nm}$  - as given in [27])
6. ( $<4 \text{ nm}$ ) The **nanoscopic scale** where the natural law of surface physics and chemistry dominate over macroscopic bulk laws. The disjoining pressure as discussed below is dominant. Region of gel pores.

### 1.3 Macroscopic part of micro-ice-lens model

As pointed out above and can be seen in figure 1 gel pore water is transported during cooling to the micro ice particles until a sufficiently high negative pressure is generated in the unfrozen gel pore water following the equation (3); this transport is increasing with falling temperature. The phenomenon is called frost shrinkage. During heating the inverse effects takes place i.e. the value of the negative pressure in the unfrozen gel pore water is falling with temperature. However, ice remains unfrozen. A distinct hysteresis is observed between freezing and melting. Therefore, if external water is available it will be sucked in. The effect is called frost suction. This is by far the most efficient suction process. (See figure 1 for the description and in figure 5 for experimental results.) problem is proved by some thousand test results in CDF/CIF test [13, 14] and numerically modelled by Kruschwitz [9, 8].

## 2 Simulation of real conditions during a frost attack in laboratory by the RILEM CIF test – frost suction and internal damage

It is clear that this transient process of frost suction highly depends on the boundary conditions. Since any test procedure should simulate the real conditions as good as possible the boundary conditions of the real concrete structure shall be analyzed first – see figure 3. In real structures the heat and moisture transport takes place predominantly over one outer surface which can be called “surface of attack”. As long as they are laterally “infinitely” extended the heat and moisture flux are vertical to this surface. The horizontal heat transport is negligible as well as the water transport. A test specimen can be treated like a small cut out of such a structure. However, now additional surfaces lateral are generated. Any transport of both liquid and heat over these new surfaces would generate a deviation from the transient process in the real structures. Experimental data showed that in this case the effect of the micro-ice lens pump would be shortcut. Frost suction and herewith the result of the test and the durability prediction would deviate essentially from real situations. It is worth to keep in mind that 1 mm of liquid water on top of the surface of attack consumes as much heat during freezing as 10 mm of concrete. Therefore, a transport over any other surface of the specimen must be suppressed. This substantial requirement has been violated in nearly all test procedures (ASTM, ÖNORM, and even Swedish slab test) known to the author. CDF [13], CIF [14] test as proposed in the RILEM recommendations solve this problem - for a better understanding see figures 3 and 4. Since in the test procedures the relevant boundary conditions are adequately fixed the tests have a high precision as proved by several international round robin tests and evaluated following ISO 5725 (details see Auberg [1]). It is not reached by any other freeze-thaw tests taken into account.

**Figure 3. Comparison real structure and laboratory test.**

**Figure 4. Test set-up during RILEM CDF / CIF test procedure.**

In the CIF/CDF test (figure 4) each specimen is in an individual container immersed in a liquid temperature controlled bath which allows both precise control of the freeze thaw cycle (<0.5 K) and an efficient heat transport. Lateral heat exchange by convection is suppressed due to the small distance between specimen and container wall and exchange by radiation by the use of metal surfaces.

In a frost test the degree of saturation is increased by frost suction until a critically and damaging degree is reached. Therefore, it is important to start the freeze thaw test is a well-defined degree of saturation. In CDF/CIF test the specimens are saturated by capillary isothermal suction during 7 days. Two freeze-thaw cycles are passed per day. Results are reached after 28 cycles or 14 days. For further detail it is referred to the RILEM recommendation.

## 2.1 Experimental results of CIF test

**Figure 5.** CIF Test results. Water uptake and rel. dyn. E-modulus as function of time / freeze thaw cycle ftc. Negative values relate to capillary suction.

**Figure 6.** Length change measured during CIF test. Abscissa has been cut to collect the data during contraction (1st cycle - negative!) and during expansion (28th cycle) in one graph. Data by Setzer, Kasperek

In figure 5 both internal damage characterized by the reduction of the relative dynamic elastic-modulus, and water uptake are plotted. It is seen: (1) The saturation by frost suction (positive values) is substantially larger than the saturation by the isothermal capillary suction. (2) The CIF test is able to distinguish even relatively small changes in concrete quality (here between w/c 0.55 and 0.61). The acceptance criterion RDM=80 % is transgressed with wc= 0.55 at the 29th freeze-thaw cycles (14.5 days) and for wc=0.61 at the 24<sup>th</sup> ftc (12 days). Since German regulations for waterways demand a minimum of 28 cycles before the RDM=80% is transgressed the wc=0.55 meets the test even if scarcely and 0.61 fails it. (3) Damage sets in after nearly the same amount of suction is reached in both cases as marked by arrows.

The thermal expansion during CIF test figure 6 reflects the length change measurement in figure 2: (1) At start of test – 1st cycle – frost shrinkage (negative values) dominates since apparently there is sufficient space due to autogenous shrinkage that ice expansion is not relevant here. The result also shows that even isothermal capillary suction cannot saturate the specimen sufficiently. However, due to frost suction ice expansion dominates at the end (28th cycle) where the critical degree of saturation is reached.

For durability of frost resistance the speed of frost suction is the decisive parameter. It should be noted that following our data entrained air is protective since it inhibits the suction process comparable to air in mechanical a hydraulic pump. This must be kept in mind when designing air content especially for high performance concrete with a dense matrix.

### 3 Scaling and the influence of dissolved ions

#### 3.1 Scaling experiments with changing concentration of solution including simulation of surface water

Figure 7. Change of scaling dependent from concentration of de-icing salt (NaCl) concentration – 28 ftc. 1% NaCl = 0.171 mol/l<sub>eq</sub>.

Figure 8. Influence of minor concentrations of dissolved ions (eq. surface water) on scaling after 28 freeze-thaw-cycles – ftc – with concrete.

It is well known that deicing chemicals increase the frost damage dramatically. In the RILEM technical committee TC 117 FDC recommendation the CDF test - has been proposed [13]; its precision has been assessed in several international round Robin tests and evaluated by ISO 5725. In a big additional research program [22] we found an acceptance level of 1500 g/m<sup>2</sup> after 28 freeze thaw cycles (ftc) for durability against frost and de-icing salt attack (In European Standard concrete class XF3). In this project more than 400 different types of concrete have been tested covering good and bad concretes. The selection of the mix design was advised by industrial representatives.

In another program we checked how a change of the concentration of deicing chemicals influences the scaling - figure 7. The 3% concentration as demanded in CDF test has been used as reference. It is clearly seen that at 3% - the CDF-value - the maximum damage is reached. From the macroscopic point of view this is astonishing since at this concentration neither the depression of freezing point nor a chemical attack are sufficiently strong to explain this maximum.

Even more astonishing was an experience during a round Robin test of RILEM TC 176 for the recommendation of CIF test [14] of frost resistance of concrete with **pure** water: It was found that already the different type of tap water in the different laboratories caused significantly different results. Auberg [1] reproduced the composition of the test-water in laboratory and could explain the differences in scaling by the influence of dissolved ions. However, since the precise causes were not understood sufficiently well to give clear recommendations RILEM TC 176 used demineralized water as test liquid in the RILEM recommendation for CIF test [14]. We were aware that for scaling these are minimum conditions.

Therefore, Bevanda studied the effect of dissolved ions systematically [2, 3]. She proved as well that the laboratory test results with well-defined ion concentrations can exactly be related to scaling under outdoor conditions with surface water. In figure 8 it is clearly seen that small concentrations dramatically change scaling. The “non-linear” progress of scaling can be attributed to the difference between carbonated and non-carbonated zone. The concentrations of test liquid are far below the well-known maximum condition for de-icing chemicals. Surface or tap water has a concentration of some milimol-equivalent/liter and is in the lower part of figure 8. This effect definitely cannot be explained by a microscopic physics or chemistry.

### 3.2 Explanation by the electrostatic part of disjoining pressure

Figure 9. Disjoining pressure  $\Pi$  – electrostatic and molecular part - as function of the ionic strength (I.S.) and the pore diameter.

Figure 10. Disjoining pressure  $\Pi$  – electrostatic and molecular part - as function of the ionic strength (I.S.) – for a pore diameter of 2 nm.

A fair explanation of the rather high impact of even highly diluted dissolved ions on the surface scaling of concrete during a freeze thaw attack can be given by nanoscopic surface science. For this one must keep in mind (1) that hardened cement paste has a nanoscopic gel structure and (2) that in this structure special surface scientific laws become dominant. They are described best by the disjoining pressure  $\Pi$  which was published first by Derjaguin (1936) and which describes the interaction between two internal surfaces in the distance of a few nanometers. The disjoining pressure is characterized thermodynamically by the distance  $h$  of the two solid interphases.

$$\Pi(h) = - \left( \frac{\partial G}{A \cdot \partial h} \right)_{p, T, \mu_i} \quad (7)$$

It becomes relevant when the surface forces between the interfaces overlap. A precise description would go beyond the scope of this article. The background is found in the excellent text books by Israelachvili [7], by Derjaguin, Churaev and Muller [5] and by Churaev [4]. Three different types of disjoining pressure must be distinguished: the dispersive or molecular term (index  $m$ ) which is attractive in our case and compared to the other two relatively small, the electrostatic term (index  $e$ ) which is the most interesting here and the structural term (index  $s$ ) which is rather important and large in pre-structured and structured gel-pore water [25] but will not be treated here.

$$\Pi = \Pi_m + \Pi_e + \Pi_s$$

The molecular term decays with the distance by a power of six and ranges to the largest distance under the disjoining pressure terms i.e. until approximately 100 nm. The electrostatic term decays with distance  $d$  exponentially -  $\propto \exp(\kappa \cdot d)$  where  $1/\kappa$  is the Debye radius. It highly depends on the type of electrolyte and the electrolyte concentration.

$$\frac{1}{\kappa} = \begin{cases} 0.304 / \sqrt{[NaCl]} \text{ nm} & 1:1 \text{ elektrolyte} \\ 0.176 / \sqrt{[CaCl_2]} \text{ nm} & 2:1 \text{ elektrolyte} \\ 0.152 / \sqrt{[MgSO_4]} \text{ nm} & 2:2 \text{ elektrolyte} \end{cases} \quad (8)$$

The electrostatic and molecular part of the disjoining pressure following by DVLO theory and taking into account pore solution and distances as found in hardened cement paste has been calculated and is plotted in figure 9 and 10. In the plot the concentration is given by the ionic strength as defined by

$IS := \frac{1}{2} \sum_i z_i c_i$  where  $z$  is the valence and  $c$  the concentration of the ion type  $i$ . It must be emphasized

here that the electrostatic part of disjoining pressure is dominant and repellent. From squeezed out pore solution – Xu [32] - we can state that the ionic strength of the pore solution is near to 0.1 mol/l. The figure 9 and 10 show that this is near to a maximum of the electrostatic disjoining pressure. During freezing the concentration in the unfrozen pore water is increased since ice does not solve ions. The disjoining pressure is diminished.

This drop-down of disjoining pressure is added to the pressure discussed above in the micro-ice lens model. In contrast to the micro ice lens pressure which acts in the unfrozen water and is related to this water the change of disjoining pressure is related to the interaction of the solid gel particles even if this interaction is highly affected by the medium between the particles especially by the dissolved ions.

If by frost suction water with dissolved ions is sucked in the effect of electrostatic part of disjoining pressure is enhanced. For concentrations as found in deicing solutions this effect becomes detrimental as known from practical experience. However, the recent findings show as well that even small amounts of dissolved ions cannot be neglected.

## Conclusions

1. **Frost suction:** During the first freeze-thaw cycles a saturation process of concrete is observed which is caused by frost action and which significantly exceeds the usual saturation for instance by an isothermal capillary suction. The frost suction process is generated by the micro-ice-lens pump.
  - (1) Microscopically it bases on water in nanoscopic gel pores which is hindered from freezing by surface forces and which deviates from properties of bulk water (prestructured, density, heat of fusion). Below freezing point it is in equilibrium with ice due to negative pressure. This generates frost shrinkage during cooling and frost swelling during melting.
  - (2) Ice expansion is not observed during the first cycles since sufficient pore space has been generated due to autogenous shrinkage during hydration.
  - (3) Macroscopically there is a transient process. During cooling water is transported from gel to ice. During heating it remains trapped. The frost swelling sucks in external water if available.
  - (4) The degree of saturation increases with every freeze thaw cycle.
2. **Internal damage:** Only after a damaging degree of saturation is reached destruction by ice expansion and hydraulic pressures sets in as it is explained by the existing models of frost damage. The pure ice expansion effect is restricted to the inner part of concrete i.e. internal damage.
3. **Surface scaling** is highly dependent from dissolved ions in the pore solution. The electrostatic term of disjoining pressure is changed due to this especially during ice formation. Dissolved ions in the sucked in water increase the effect. Even small amounts are relevant as found in surface water. Concentrations like in de-icing solutions are detrimental.

# Durability Planning – a Formalised Approach in Concrete Institute of Australia Recommended Practice

Rodney Paul <sup>(1)</sup> and Frank Papworth <sup>(2)</sup>

<sup>1</sup>Materials Technology Service Line Leader GHD Pty Ltd, Perth, Australia,

<sup>2</sup> Managing Consultant BCRC, Perth, Australia

**Abstract:** This paper provides an overview of the Concrete Institute Australia (CIA) Recommended Practice Z7/01 Durability Planning (CIA Concrete Durability Series – Durability Planning. Concrete Institute of Australia Recommended Practice Z7/01. Sydney 2014.). Durability planning is cost-effective selection and usage of materials combined with design processes, construction methods and detailing to achieve the asset owner intended service life without premature unexpected operational maintenance.

CIA Z7/01 (1) provides information on durability planning during design, construction and operational service life phases for all concrete construction stakeholders. It is intended to inform and inspire designers about the benefits of durability design so they can inspire asset owners to elevate durability planning to a position alongside structural and architectural design. The planning process can be equally applied to all construction materials and this is commonly adopted by durability consultants in Australia.

Durability knowledge is available for engineering analysis but formal durability processes in design, construction and operational maintenance are missing. Durability planning as outlined in this technical paper and CIA Z7/01 (1) is the recommended change to formalise durability complementary with structural design.

A durability assessment report will explain the durability requirements and provide details to be included in the project design reports, specifications, design drawings, asset maintenance plans and/or operation and maintenance manuals. This report may be a page for simple structures or detailed for complex, critical or uncertain structures. Durability checklists in tabular form provide useful project guidelines complementary to the durability assessment report.

**Keywords:** Concrete, Durability Planning, Durability Assessment Report, Durability Consultant

## 1. Introduction

Information on processes involved in concrete deterioration are available for engineering analysis but a formal process for achieving durable structures in design, construction and operational maintenance is missing. Durability planning outlined in CIA Z7/01 (1) is a system to formalise the process of achieving durability through appropriate design, construction and maintenance.

The CIA durability series will provide the tools for managing durability through design, construction and maintenance. The series will comprise:

- Z7/01 Durability – Planning (published in 2014).
- Z7/02 Durability - Exposure Classes (in progress).
- Z7/03 Durability - Deemed to Comply Requirements (in progress).
- Z7/04 Durability – Good Practice through Design, Concrete Supply and Construction (published in 2014).
- Z7/05 Durability – Modelling (in progress).
- Z7/06 Durability - Cracks and Crack Control (in progress).
- Z7/07 Durability – Testing (to be published in 2015).

CIA Z7/01 (1) sets out the process of planning to achieve the required level of durability. The durability planning outcomes will be delivered in a durability assessment report or durability plan (alternative names for a durability deliverable report) specific for the project. This will describe how the desired level of durability will be achieved and ensured using appropriate tools and recommendations given in Codes and Recommended Practices (e.g. CIA Z7/02-07).

A durability assessment report provides a continuous link in durability objectives between design, construction and maintenance. Durability planning evaluates, explains and provides solutions for all stakeholders. Greater confidence is provided for the design and required service lives to be achieved.

Durability is provided with improved confidence when the concrete structure asset owner is actively involved starting from the project brief stating specific durability requirements. Designer and/or contractor provided durability without adequate asset owner defined formal requirements has uncertainty that an optimum whole of life cost will be achieved. In a worst case scenario of reduced structural adequacy and/or functionality, asset owner maintenance cost funding and resources may be excessive to keep the asset operational or the asset owner may face rapid premature depreciation.

Concrete structures recommended to use durability planning will have durability design requirements that are complex, critical or uncertain. Durability planning is not expected for simple structures in exposure conditions excluding moderate or severe (e.g. house slab and paths).

The durability assessment report issued will explain the durability requirements and provide details to be included in the project design reports, specifications, design drawings, asset maintenance plans and/or operation and maintenance manuals. This report may be a page for simple structures or detailed for complex, critical or uncertain structures. Durability checklists in tabular form provide useful project guidelines complementary to the durability assessment report.

## 2. Why Durability Planning

All capital works, whether government or privately owned assets, must achieve the design life intended, operational functionality, acceptable return on capital investment, safe operational environment (e.g. durability provides acceptable serviceability and ultimate risk to the community) and environmental sustainability. An appropriate durability philosophy throughout the project delivery will provide this.

In engineering terms, durability planning is cost-effective selection and usage of materials combined with design process, construction methods and detailing to achieve the asset owner intended service life without premature unexpected operational maintenance. A technical analysis determines the nature and rate of materials deterioration for given macro and micro environmental conditions, which is used to influence the design, construction and operational maintenance during the service life.

Design and construction to National or International Standards may not achieve the asset owner's required design life in aggressive exposure conditions. Significant premature maintenance and/or repair could be necessary. A durability review is required as Codes do not cover all environmental exposure conditions and specific location micro exposure conditions can be more severe than the general exposure conditions.

Asset owners may require a design life of 20, 50, 70, 100, 150 or 300 years whilst Standards may state 40 to 60, 50, 100 or not comment on design life. Owners may have specific desires for the performance of the structure at the end of the design life so that rehabilitation and extended life can be achieved. Future different owners may have upgrade requirements. They may also have views on reliability required through the design life. Durability planning allows owners to give specific design life requirements. Durability planning evaluates, explains and provides solutions to all parties and provides greater confidence that the design life will be achieved.

Durability design is expected by all construction parties but formal design by durability consultants is not a common specified requirement. The common informal expectation is someone completes the durability design within the design process and, in the absence of a named person, the structural engineer is deemed to have completed the task. This is not a reasonable obligation for the structural engineer who does not have durability training and /or experience. An alternative view is that Australian Standards take full account of durability such that structural design being acceptable equates to acceptable durability design.

However, Australian Standards state that compliance with the durability provisions of the standards is not sufficient given the complexity of the subject. For example, AS 3600: 2009 Section 4.1 Note 2 [4] "Durability is a complex topic and compliance with these requirements may not be sufficient to ensure a durable structure."

Furthermore, reliance on durability provided by a current Standard is not an acceptable legal defence for premature durability damage to a structure where a reasonable engineer is expected to have awareness of more recent related Standards or other technical society publications that require additional durability provisions.

Is premature deterioration or unacceptable maintenance a present day problem? Yes, in some aggressive environments where materials selection or construction techniques are inadequate, or design agreed maintenance is not implemented. Therefore acceptable durability is not always being achieved to the level expected.

It is recommended that asset owner project briefs include the requirement that design and non-compliance reports that effect durability are reviewed by a durability consultant. On projects where the contractor's construction method is different to the design or influences durability a durability consultant review is required. The durability planning process benefits all parties:

- The asset owner is likely to have a structure that more closely matches expectations in terms of reliability through the design life. The contribution to the proactive maintenance approach will lead to a lower maintenance cost.
- For the designer, inclusion of high level materials expertise reduces the risk of premature failure and over design.
- An unexpected outcome on some projects is contractors utilise the durability consultant expertise for advice on materials and methods even where not strictly required. Consequently they reduce the risk of not using optimal materials and this reduces the risk of failures and can lead to cost savings.
- For the operator of the structure it leads to reduced maintenance which means lower cost and less interference.

Examples of concrete structures recommended to use durability planning are listed below:

- Major civil and building structures, including:
  - Airport infrastructure.
  - Bridges and culverts, elevated viaducts, tunnels.

- Buildings for commercial, industrial, government and residential use, including weatherproof exterior façade and below water level basements.
- Mining and industrial structures, including material processing and handling.
- Power stations, including seawater structures.
- Structures of cultural, heritage, national or world significance.
- Transmission towers.
- Wharves, piers and jetties.
- Water retaining or excluding structures including dams, desalination plants, pipelines, pump stations, tanks and treatment plants.
- Wastewater treatment plants.
- Precast panels with complex metal arrangements and tight covers.
- Buildings with applications that lead to unusual exposures (e.g. where leakage with contaminants occurs like swimming pools in hotels or aquariums in restaurants).
- Industrial sites where elements or structures might be exposed to contaminated ground or air.
- Elements with critical leakage requirements.
- All concrete structures in corrosive exposure environments.

### 3. Formal Durability Planning

The need to incorporate durability into design, construction and maintenance to prevent premature deterioration of concrete structures has been identified in many international documents over a long period of time. Examples of technical concerns and improvement approaches for durability in the design, construction and maintenance of concrete structures are listed below from 2001 back to 1968. Technical society publications by the American Concrete Institute (ACI) in the 1960's and RILEM in the 1980's were state-of-the-art at that time, however, formal durability planning to coordinate technical improvements was missing.

- Australia: CIA: Z7 Durable Concrete Structures (2, first published in 1990 and second edition in 2001) states: "The aim of this Recommended Practice is to provide designers, specifiers and users of concrete with guidance on the provision of durable concrete structures by alerting them to potential problems that may occur at any phase from concept to completion." CIA Z7/01 (1) provides durability planning that is not given in CIA Z7 (2).
- Europe: CEB RILEM Durability of Concrete Structures (3, published in 1983), with the latter stating: "The international concrete profession is, therefore, challenged by acute demands to develop and implement rational measures of solving the present twofold problems of durability, namely: 1) Find measures to ensure a satisfactory remaining lifetime of existing structures threatened by premature deterioration; 2) Incorporate in new structures the knowledge, experience and new research findings, in order to monitor the structural durability, thus ensuring the required service performance of future concrete structures." And "Furthermore, an efficient voluntary coordination of activities in order to develop the proposed rationale 'Durability Technology' on a higher professional level than the present, would be welcomed by all parts of the concrete profession." This workshop brought together about 80 international leaders in concrete technology and durability who presented on the topics of state-of-the-art, deemed to satisfy rules and future work, which provided technical papers with references that was truly "state-of-the-art" for concrete durability at that time. Transfer of knowledge from theory to practice summary comments included, "...important task now is to use our already existing knowledge regarding materials technology, and transfer this knowledge in useable form to the structural engineer, i.e. to the designer and the contractor, as in practice a design engineer will ask for a certain type of concrete, not a certain type of cement or aggregate, etc." and "...one of the objectives of explicitly stated for this workshop, i.e. bridging the communications gap between materials science and engineering descriptions" and "...structural engineers should have a general understanding of what the materials scientists are doing – or could achieve – in order to ask the right questions to the materials science".
- United States of America: ACI Durability of Concrete Construction (4, published in 1968) states, "...is written for the intelligent engineer who wants to make or specify durable concrete, but who needs to be alerted to possible deterioration under various circumstances, and for students who wish to learn something about the subject" and "It will be assumed the reader is not a physicist, or chemist, or petrographer. This poses something of a problem because most of the properties and behavioural aspects of concrete of practical importance to engineers are very largely consequences of its microstructure and chemical nature, and detailed study of these matters lies mostly in the realm of the physical sciences. Furthermore, practical measures to achieve durable concrete usually comprise suitable control of microstructure or chemical properties, or both, although practitioners may not think about it in these terms. Yet they would be able to act more intelligently and with greater confidence if they had some general understanding of them."

CIA Z7/01 (1) has major sections on the formal durability planning process through the various stages of the structures life that include:

- Asset Owner brief.
- Project tender.

- Durability planning
- Concept design.
- Detailed design.

- Construction.
- Maintenance during operation

#### 4. Terminology

Definition of terms commonly used for durability is variable in Australian Standards with some important terms having different words or not being defined, which is a consequence of the many people involved in difference standards. In the absence of an Australian Durability Standard, CIA Z7/01 (1) provides in terminology that takes account of international durability use and can be referenced for common definition understanding in Australia. Definitions of durability and durability consultant CIA Z7/01 (1) are important for Australian future use and are given below.

- Durability: The capability of structures, products or materials of continuing to be useful after an extended period of time and usage. In the context of performance-based design of structures, durability refers to the fulfilment of the performance requirements within the framework of the planned use and the foreseeable actions, without unforeseen expenditure on maintenance and repair.
- Durability consultant: Person or group who completes the durability assessment and is the author of the durability assessment report and durability checklists. Intent is a person or group who can apply materials deterioration knowledge to construction materials and construction processes, additional to more common structural, civil, geotechnical and other engineering knowledge of design, construction and maintenance. Maybe an in-house employee of the design team, or an independent consultant engaged for the purpose. Intended to have a close working relationship with the asset owner, design team and construction team to ensure durability is provided to achieve the asset owner required service life. Practical experience is essential to ensure the durability assessment report and durability checklists do not become a research exercise. Contractor reviews are included to achieve a buildable final design for the asset owner service life. The durability consultant may be a person with relevant technical qualifications other than a qualified engineer (e.g. materials scientists), with the asset owner client (or authorised representative) responsible to approve the durability consultant for a project

Design life is one of the most important durability parameters yet this is not always clearly identified in codes and specification and definition are not always clear and consistent. CIA Z7/01 (1) provides some clear definitions which are also shown in Figure 1. The term “design life” is often used to convey the same intent as “design service life” and both terms are acceptable to convey the same intent. It is the period in which the required performance shall be achieved, used in the design of new structures construction. Service life (operational) however is the period in which the required performance of a structure or structural element is achieved, when it is used for its intended purpose and under the expected conditions of use. It comprises design service life and prolonged service lives.

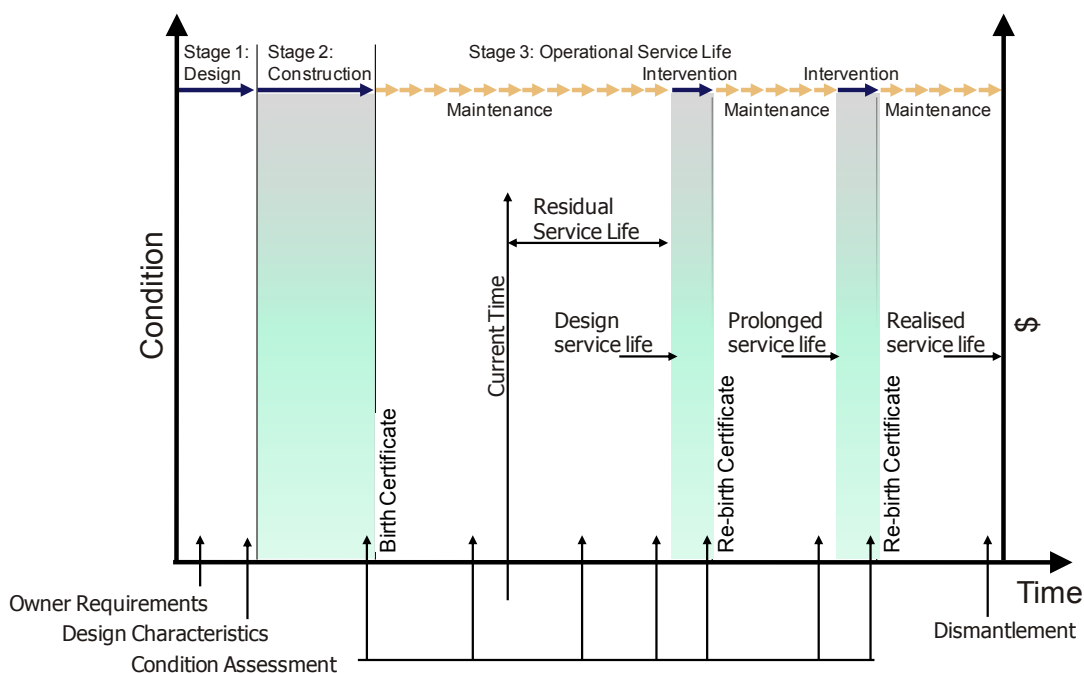

Figure 1 : Phase in the Life of a Structure (5)

## 5. Durability Tasks Through the Asset Life

An asset owner project brief is recommended to include service life, reliability, maintenance strategy, required condition at end of design life, durability requirements and who is to complete durability tasks and who is to review.

The contractor's tender should show that the contractor understands the project durability requirements, exposure conditions, mechanisms of deterioration, any issues with construction materials, workmanship requirements and maintenance after construction is completed. The scope of works should require that tender documents include an outline durability plan

It is recommended that the scope of works require that a durability assessment report be prepared at the detailed design stage. This should include the following:

- Modelling of deterioration mechanisms to determine future service life of materials where necessary.
- Assessment of durability requirements according to national codes, identification of where these requirements are deemed inadequate based on current state of the art and requirements that will be in accord with state of the art requirements.
- Durability audit of final design.
- Evaluation of proposed materials that will meet the required performance criteria.
- Review detailed material specifications for project elements with design and construction teams.
- Design details to minimise and/or avoid effects of aggressive environment (e.g. seals, flashings, waterproofing, cladding, etc.).
- Durability review of materials specifications.
- Proposed inspection, monitoring and testing programs that will ensure early identification of any premature deterioration, to be complemented by pro-active operational maintenance actions.
- QA/QC requirements for durability sensitive critical elements of materials and workmanship.
- Maintenance procedures to ensure the structure will remain in the required condition at the optimum whole-of-life cost.

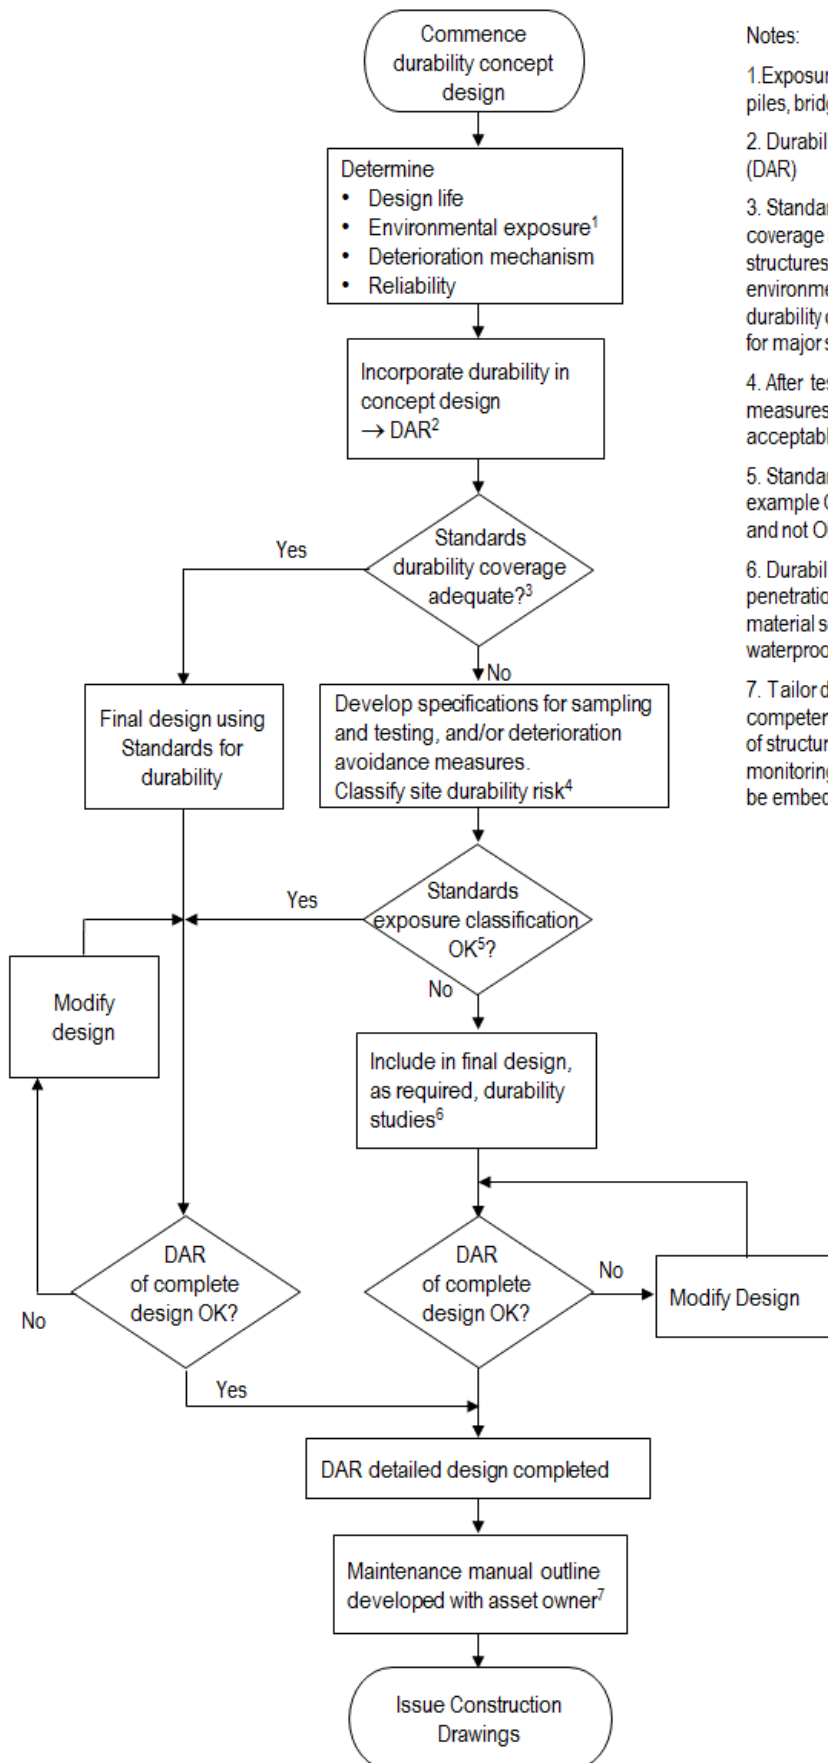

The process of durability planning through design, construction and maintenance phases is included in CIA Z7/01 (1) as flow charts. As an example the design flow chart is included here as Figure 2.

The main durability objective during construction is to ensure the durability design is properly implemented within the contractor's overall construction procedures for the project. To achieve this it is recommended that the contract require the contractor to demonstrate the following in the tender:

- A construction team with appropriate experience to implement durability requirements will be used including the naming of key personnel.
- Training proposed for the construction team, including workshops, tool box talks, etc. training to ensure all staff have appropriate expertise to give required construction quality.
- Procedures to be used to develop and assess materials of acceptable durability performance.
- Understanding of how to develop, implement and achieve a suitable QA/QC program.
- How site trials will be developed to prove materials and construction methods.
- How method statements will be developed.
- How the contractor will deal with non-conformances.

Maintenance is an integral part of ensuring durability through the life cycle. It is recommended that the scope of works require that the contractor detail a maintenance plan that includes the following:

- Details of asset management inspection audits including life cycle program of tests to be undertaken, assessment criteria and actions to be taken related to the inspection and test results.
- Maintenance materials and methods to be adopted
- Maintenance and asset management planning based on materials deterioration expectations and costs to achieve acceptable asset owner performance predicted at appropriate intervals but not exceeding 10 years.
- Identify repairs during maintenance audits to prevent further deterioration that may result in major problems.
- Minor repairs completed within required time schedule.
- System for keeping records of defects and repairs throughout structure life, including repair materials used.

Notes:

1. Exposure of various elements, e.g. piles, bridge deck.
2. Durability Assessment Report (DAR)
3. Standards (e.g. AS 3600) durability coverage may be acceptable for small structures in non-aggressive environments. Consider engaging a durability consultant (recommended) for major structures.
4. After testing and/or avoidance measures, Standards may still be acceptable for design DAR.
5. Standards exposure classification example OK is AS 3600 A1, B1, or B2 and not OK is U or C.
6. Durability studies to include: penetration modelling, chemical attack, material selection, detailing, waterproofing, etc.
7. Tailor detail to level of technical competence of asset owner, and size of structure. Determine inspection monitoring details and any probes to be embedded in the structure.

Figure 2 : Durability Process During Design

## 6. Key Durability Performance Criteria

When developing key performance criteria for a particular concrete structure, dialogues need to be opened between the durability consultant and the asset owner as to what role the structure participates regarding the key public, social, and economic needs as well as the technical aspects of structure type/function/exposure/construction methodology/operation and maintenance. This can entail detailed dialogue with the asset owner's financier, operator, designer, and builder that all have key roles that contribute to performance of the built concrete structure.

Within concrete structures the range of deterioration includes mechanical attrition (e.g. abrasion), physical thermal exposures (e.g. fire), chemical attrition (e.g. reaction between the cementitious paste and/or aggregates with sulphates, pure water, acids, alkali-aggregate reactions, salt crystallisation, etc.), biological (fouling, biogenic attack), structural (overloading, settlement, cyclic loading), and reinforcement corrosion. Although some of these risks may occur simultaneously on a particular structure, the magnitude and frequency/risk of each needs to be characterised before addressing durability performance as well as assessing whether two or more mechanisms have a cumulative impact on durability.

The characterisation of the actions that deteriorate a concrete structure entail the measurement and assessment of the types, magnitude and frequencies of exposures, or "durability loading". Significant existing data may already be available from the asset owner, namely existing condition survey reports on adjacent structures. This may include visual, non-destructive test data, and core sampling accompanied by chemical and physical test data. If the structure is to be an industrial facility, the process engineers working on the design of the new structure may supply the likely chemical compositions and treatment conditions that could impose on future durability. Environmental data may also be available, including air temperatures/chemical composition/prevaling winds/acid rain, soil and ground water permeability and chemical compositions. On most projects, only a subset of this data will be available and it may be prudent to undertake site environmental testing. Geotechnical investigations are commonly undertaken and additional chemical testing for assessment of durability risk is unlikely to impact significantly on the drilling and sampling cost that is already being conducted. Surface concentration of chloride within concrete is attained within a relatively short period (1-3 years) and can be measured on adjacent structures, although care is required when assessing the concrete composition, geometry of the structural member, and environmental exposure.

Following the "durability loading" assessment, the macro- and micro- environments for each structural component of the concrete structure can then be classified. Together with the asset owner's team, the key "durability loads" can be placed within the contexts whether impairment of the durability of the concrete component will impact functionality of the built structure. The risks and containment actions can then be assessed

## 7. Durability Planning Concept Design

Current industry practice is at best ad hoc in the involvement of durability planning at the project concept design stage. If it does happen it is usually driven by an individual in the asset owner's or the design consultant's team who has an understanding of the risk mitigation and whole-of-life cost benefit value that durability planning can bring to a project if effectively implemented.

The intent of this section is to inform and inspire asset owners so they understand the benefits and insist that durability planning be a key function on any major project and that it is consistently applied to achieve the short term and long term business goals that the project is intended to deliver to their organisation. By defining key durability requirements at the project concept design stage the asset owner can achieve the greatest impact in terms of influencing risk and cost outcomes and sculpt the project terms of reference/deed/technical specification that will deliver the optimal whole-of-life solutions no matter what contract delivery form is used.

Durability is generally seen as a straightforward assessment of the performance of the structural materials that make up the asset in the environment in which it is to be located. The structure form and function of the assets being created influences the materials performance, environment and creates micro environments. Therefore, the asset owner is justified to obtain advice at the concept stage to identify if certain options have significant risk and potential costs compared to others.

Similarly, and particularly in the case of concrete structures, the construction options adopted can impact on the build quality that in turn change the durability performance and likely future maintenance profiles and operational costs.

Another key variable is the range in quality and types of concrete and construction quality available in different geographic locations, which impacts on the identification, implementation and cost of the optimum technical solution both in terms of durability and sustainability.

It is vital that the asset owner participates in developing an effective durability risk review process to be applied at the options selection and concept design stage. The form and methodology of this review should suit the size and complexity of the project, but it would be advisable to use existing corporate risk processes so that risk assessments and mitigation measures are consistent project to project and can be verified/audited internally.

Durability predictive models are commonly used to determine chloride penetration into concrete and carbonation of concrete, which provides input to reinforcement corrosion analysis. Other durability models may

be considered, however, concrete resistance to chemical attack is more typically assured by relating performance criteria to exposure estimates (e.g. sulphates attack, acid attack, etc.). Many more aspects of concrete durability, including alkali aggregate reaction, delayed ettringite formation, etc. are controlled through the concrete materials testing and specification. CIA Z7/05 will provide guidance on durability predictive modelling (see durability series outline at section 1).

The use and selection of predictive models for materials performance evaluation as a design tool is at the discretion of the durability consultant. However, the benefits and limitations of the models considered must be explained and justified to the asset owner and designer.

The benefit of using models is they provide a measurable, verifiable basis for materials selection and performance criteria that can be measured during construction and in-service. It is recommended that modelling used in the durability assessment report includes:

- Relevant details of the durability model.
- Assumptions made in the modelling, how these relate to normal values adopted in codes, standards or technical literature and the implications of the values used.
- Comparison of modelling outcomes with requirements in codes/standards together with an explanation of why the model values were adopted.
- How modelling outcomes will be used in technical specifications.

Design life prediction by durability modelling is based on achieving a prescribed level of reliability at the end of the design life, typically a 90-95% probability of failure. CIA Z7/01 (1) provides a definition of reliability and gives guidance on reliability values that might be used in durability modelling. Reliability is not currently a stated parameter in current Australian codes for durability design but may be included subjectively by having higher performance requirements for more critical structures.

Cracks in concrete are often inevitable. The impact of cracks on durability can be a contentious matter for all stakeholders during asset design, construction and operation. Therefore, all stakeholders should have design stage awareness of potential crack formation, location and size. The concrete crack risk is proactively evaluated during design, and any unexpected cracks evaluated reactively. The importance of concrete cracks has justified a specific CIA Z7/06 Recommended Practice (see durability series outline at section 1).

It is appropriate to define maximum allowable crack widths for durability impact. This needs to be linked to exposure classifications, structural forms, crack types and loading conditions so that there is clarity with regards to the degree of risk associated with the concrete mix and structural design and the minimisation of crack formation.

As construction techniques and sequencing can impact significantly on the quality of the materials installed and thereby their in-service performance, it is highly recommended that during the concept stage a constructability review workshop is held to review potential risks and determine how they will be ameliorated.

If this cannot be achieved then the technical specification should contain a requirement for the contractor to evaluate their construction solutions against the requirements of the durability assessment report. The contractor will need to confirm that the build quality they can achieve will support the design assumptions and meet the durability design and material criteria in the durability assessment report.

It is recommended that durability testing requirements be clearly specified for four stages:

- Mix trials to confirm the mix is suitable.
- Quality assurance tests as construction proceeds. Variability of durability tests must be taken into account by the durability consultant, with specification test criteria allowing for alternative solutions to achieve the required durability if the test results do not achieve the specified values. This can be achieved by conservative durability design and/or provision for use of additional measures such as protective coatings or special additives or other measures.
- Tests at end of defects liability period to create a list of items for repair.
- Tests during the design and service lives including monitoring.

The key durability design requirements, the methodology of how it is to be delivered during the project and transition into the operation phase of the asset life should be set out in a project specific durability assessment report at concept design.

The durability assessment report does not need to define all of the material solutions but should identify critical issues and propose the steps needed to be taken to ensure that they are handled effectively and any key milestones and/or dates by which actions/issues need to be resolved.

Roles and responsibilities for the implementation and delivery of the durability assessment report need to be clearly defined along with the key outputs, their format and who they need to be delivered to; again with key milestones so that the durability program is aligned with and tied to the overall project program.

## **8. Durability Planning Detailed Design**

The design stage durability strategy needs to minimise the risks of long term deterioration of the project assets and asset components. The durability risks need to be identified, the durability design solutions determined, critical construction processes identified, operational inspection and monitoring requirements outlined and maintenance recommendations provided.

Durability inputs into the design process includes review of exposure and materials test data, review of owner requirements, identification of deterioration mechanisms and critical durability issues, review of proposed construction methods and identification of durability issues, undertake modelling, prepare options for construction, recommend materials and outline inspection and monitoring requirements.

Outputs to the process include durability requirements in design packages, input into specifications and construction drawings and a durability assessment report: detailed design.

Durability design objectives contained in the durability assessment report are then used in the construction process. The outcomes of the durability recommendations and addenda during construction (durability assessment report: verification report) can then be incorporated into the maintenance manual for the assets and asset components. A continuous link in durability objectives is therefore maintained between design, construction and maintenance.

The design durability strategy to minimise the risks of long term deterioration of the structural assets and asset components within a project needs to be consolidated into a durability assessment report: detailed design. The durability risks are identified, the durability design solutions are determined, critical construction processes identified, operational inspection and monitoring requirements outlined and maintenance recommendations provided. The durability checklists are consolidated and incorporated into the durability assessment report: detailed design.

The main objectives of a durability assessment report: detailed design is to provide guidelines on the following (6):

- Identify the critical construction elements at risk of long term deterioration.
- Identify critical construction processes.
- Develop a detailed work plan/program for future materials durability input.

CIA Z7/01 (1) provides examples of the key deliverables and the durability process for water or wastewater retaining structures and a bridge. These examples assume a design and construct (D&C) and traditional design/tender construction contractual arrangements. However, the general approach can be applied with minor modifications for Alliance or other forms of contractual arrangement.

Design stage durability awareness and planning outcomes need to be incorporated into operations and maintenance (O&M) documentation for use during the asset service life. The O&M documentation that is prepared for a project needs to incorporate the outcomes of the durability assessment reports, durability checklists and addenda as well as suitably address inspection, monitoring and maintenance requirements.

Inspection and monitoring may just entail visual inspection but can also include monitoring probe measurements (e.g. in the case of inaccessible concrete elements) and monitoring points on structures (e.g. for future coring and testing).

## **9. Durability Planning Construction**

The construction phase involves execution of the works and presents a risk of failure to achieve the project's durability targets, many of which may be difficult for the asset owner to appreciate for a considerable length of time. Monitoring for conformance with the durability assessment report during construction is therefore essential.

The usual conventions of quality management apply, and entail measuring against the durability criteria set out for materials, methods and workmanship, which are contained in the project specifications.

At design stage the durability consultant is proactively engaged with the design and construction teams. However, during construction the durability consultant is typically involved on a "by-request" basis with quality assurance by the contractor, design and construct (D&C) contractor or alliance as per the respective contractual arrangements. This process has a potential quality weakness by not involving the durability consultant in random audits to complement regular quality assurance by for example a D&C contractor. Such audits by the durability consultant can be considered by the asset owner to provide improved assurance on the construction activities.

## **10. Durability Planning MAINTENANCE STAGE**

Once the operation and maintenance phase of a structure has commenced, cognizance of the following factors will influence the operations and maintenance plan:

- Desired operational service life.
- Durability assessment report.
- Maintenance plan/asset management plan.
- Birth certificate
- Proactive or reactive approach to future maintenance
- Whole-of-life cost analysis

The birth certificate created at the completion of construction provides all relevant design and construction information.

A reactive approach to on-going maintenance will be limited to visual inspections only and these may be performed on a regular basis or ad-hoc. This may be adequate provided no major defects are found and may be

sufficient to prevent minor defects from becoming major ones, if appropriate follow up repairs are performed as required. This approach may be suitable for minor structures and/or structures with a short design life.

Proactive maintenance will involve early intervention to prevent or delay the onset of corrosion initiation. This will require regular inspections in conjunction with additional activities such as structural monitoring and non-destructive testing, as required. Corrosion monitoring systems provide an early warning of corrosion risk. Probes and instrumentation are commonly installed at the time of construction in reinforced concrete civil infrastructure projects, where justified by aggressive environmental conditions, to provide operational maintenance feedback on materials condition.

Corrosion monitoring systems are particularly beneficial for tunnels, bridges and wharf structures, to supplement maintenance inspection for defects carried out by visual observation.

If significant repairs/strengthening have been carried out, then a post-intervention inspection should be carried out along similar lines to a new structure first inspection mentioned above.

A common feature in new structures such as bridges, buildings below ground level, jetties, tunnels, wharves, etc. is to make provision for cathodic protection installation in the future should it be required. The durability design for future cathodic protection includes:

- Reinforcement electrical continuity ensured (e.g. welded connections and/or additional reinforcement installed).
- Provision for negative returns from reinforcement.
- Positions are available for cathodic protection hardware.
- A corrosion monitoring system is implemented to determine if cathodic protection is justified (see details below).
- Cathodic protection concept design completed to prove that a system can be economically and practically installed in the future.

## **11. CONCLUSIONS**

In engineering terms, durability planning is cost-effective selection and usage of materials combined with design processes, construction methods and detailing to achieve the asset owner intended service life without premature unexpected operational maintenance. Asset deterioration also impacts on the community and this must be accounted for in the design process. A technical analysis determines the nature and rate of materials deterioration for given macro and micro environmental conditions, which is used to influence the design, construction and operational maintenance during the service life.

Durability knowledge is available for engineering analysis but formal durability processes in design, construction and operational maintenance are missing. Durability planning as outlined in this technical paper and CIA Z7/01 Durability Planning Recommended Practice (1) is the recommended change to formalise durability complementary with structural design.

A durability assessment report will explain the durability requirements and provide details to be included in the project design reports, specifications, design drawings, asset maintenance plans and/or operation and maintenance manuals. This report may be a page for simple structures or detailed for complex, critical or uncertain structures. Durability checklists in tabular form provide useful project guidelines complementary to the durability assessment report.

## **12. ACKNOWLEDGEMENTS**

The authors acknowledge the CIA Z7/01 task group was primarily responsible for developing the CIA Z7/01 Durability Planning Recommended Practice, plus many others who have contributed to reviews.

The authors would like to thank GHD Pty Ltd and BCRC for the support and permission in publishing this paper.

# Time-dependent stiffness of concrete members under cyclic loading

Angus Murray<sup>1</sup>, Raymond Ian Gilbert<sup>2</sup> and Arnaud Castel<sup>3</sup>  
<sup>1</sup>Ph.D. Candidate, <sup>2</sup>Emeritus Professor, <sup>3</sup>Associate Professor  
School of Civil and Environmental Engineering, UNSW

**Abstract:** In a cracked concrete flexural member, the difference between the stiffness observed at first loading to that observed after cycles of loading and unloading is measurable and significant. After cracking, concrete beams and slabs exhibit a permanent deflection in an unloaded state due to slip at the concrete-reinforcement interface. Existing models in the literature and in design codes for predicting the instantaneous stiffness provide reasonable estimates when the loads are increased monotonically, but these models underestimate stiffness even after a small number of load cycles. The instantaneous stiffness deteriorates still further when the beam is subjected to prolonged periods of sustained loading or after significant shrinkage has taken place, and this time-dependent loss of stiffness is accounted for with crude modifications to the existing models. The time-dependent decrease in stiffness after sustained loading and shrinkage is due to factors such as the formation of new cracks and the gradually diminishing effect of tension stiffening with time. In this paper, a tension chord model is described which accounts for the behaviour observed experimentally. Better estimates of the time-dependent stiffness of cracked RC members will enable designers to more reliably satisfy serviceability requirements of concrete structures.

**Keywords:** concrete, stiffness, cyclic loading, time-dependent, serviceability.

## 1. Introduction

Tension stiffening contributes significantly to the flexural stiffness of cracked RC members, particularly when they are subjected to typical service loads. In determining the short-term deflection of a cracked RC beam or slab, tension stiffening is usually accounted for by the application of one of a number of models commonly found in design codes. Both the Australian Standard for Concrete Structures (AS3600-2009) (1) and ACI 318-11 (2) make use of Branson's formula (3) to estimate the effective second moment of area of a cracked RC member. An alternative approach is that proposed by Bischoff (4) (based on the Eurocode 2 (5) approach for deflection calculations), which is known to be more reliable for lightly-reinforced members (6,7). Although both methods can predict short-term deflections with reasonable accuracy, they are not particularly accurate in assessing the stiffness of beams under cyclic loading.

When a RC flexural member is loaded beyond the point of cracking and is subsequently unloaded, it exhibits a permanent deflection. Fig. 1 illustrates the response of a RC beam subjected to two series of load cycles, separated by an extended period of sustained loading and drying (8). Immediately after the first cycle of load, the beam returns to a permanently-deflected state. The overall cyclic stiffness of the beam  $K_0$  (defined as the slope of the force-displacement curve) is greater than that which would be expected if this permanent deflection were ignored. The overall cyclic stiffness of the beam in the long term  $K(t)$  is again less than that in the short term (i.e.  $K(t) < K_0$ ).

The cause of the permanent deflection in cracked RC members is thought to be a combination of two main effects. Firstly, since the faces of a flexural crack are not perfectly imbricated, the crack is prevented from closing fully. This effect, cumulated over many cracks, results in a residual elongation of the tensile region of the member upon unloading (9,10). Secondly, a stiffer bond-slip response of reinforcement in a state of unloading compared to loading (11,12) means that upon removal of the load, a residual slip develops between the reinforcement and the concrete. It is beyond the scope of this paper to consider these two effects in any detail; rather, their combined effect on the cyclic response of RC members will be considered. The decay of the overall cyclic stiffness of RC members with time (as seen in Fig. 1) is also thought to be due to two main effects. Firstly, as the concrete shrinks and is restrained by the reinforcement, the tensile stresses that develop in it cause flexural cracks to form in regions where previously the applied bending moment was less than the cracking moment. As the extent of flexural cracking widens, the overall stiffness of the beam diminishes. Secondly, a time-dependent loss of tension stiffening occurs. The loss of tension stiffening is considered to be caused by the cumulative damage to the steel-concrete interface due to the propagation and formation of internal cracks in the region of the concrete surrounding the reinforcement (13,14). This process is also considered to be a result of shrinkage (4).

In this paper, a tension chord model is described that accounts for time-dependent effects in order to model the time-dependent stiffness of RC flexural members under cyclic loading.

## 2. Tension chord model

Consider the average stress-strain response of a symmetrically reinforced concrete tie subjected to axial loading, shown in Fig. 2. Prior to loading, the average strain of the tie at point A is zero, assuming that no significant shrinkage has taken place prior to loading. The straight line AB represents the linear-elastic behaviour of the tie before cracking and may be defined by an effective elastic modulus equal to:

$$E_{uncr} = E_s + E_c / \rho \quad (1)$$

where  $E_s$  and  $E_c$  are the elastic moduli of the reinforcement and the concrete, respectively; and  $\rho$  is the reinforcement ratio equal to  $A_s/A_c$ , where  $A_s$  and  $A_c$  are the cross-sectional areas of reinforcement and concrete, respectively. The curve BC represents the load-dependent loss of tension stiffening: as the applied load increases beyond the cracking load, the average response of the tie becomes increasingly similar to that of the bare reinforcement, whose stress-strain response is represented by the straight line AF, having an elastic modulus  $E_s$ . Suppose the tie were loaded beyond the cracking load to some point D and then subsequently unloaded. Due to the effects considered in Section 1, a permanent average tensile strain would remain (point E). The line DE would therefore represent the average axial stiffness of the tie under subsequent loading cycles. It is logical to assume that the effective elastic modulus of the tie subjected to loading cycles  $E_{cyc}$  is greater than that of the bare reinforcement, but less than that of the uncracked tie, thus:

$$E_{cyc} = E_s + k_{cyc}(E_c / \rho), \quad 0 \leq k_{cyc} \leq 1 \quad (2)$$

where  $k_{cyc}$  is a factor which represents the contribution of the concrete to axial stiffness during loading cycles. Over time, the value of  $k_{cyc}$  would be expected to decrease due to the time effects outlined in Section 1, resulting in an overall decay in axial stiffness of the tie. Despite the lack of experimental observations in the literature regarding the cyclic response of RC ties, a linear stress-strain response to loading cycles as depicted by the line DE in Fig. 2 may be assumed, based on the typical linear-elastic response of RC beams observed under loading cycles (8) (see Fig. 1).

Figure 1. Response of a RC beam to load cycles before and after sustained loading (8).

Figure 2. Typical average stress-strain response of RC tie to loading and unloading

### 2.1 General formulation

Consider a term  $\omega(x)$  (the *tension stiffening ratio*) defined as the ratio between the strain in a bare reinforcing bar  $\epsilon_{s,b}$  and the strain at some point in a concrete-embedded reinforcing bar  $\epsilon_{s,e}(x)$  subjected to the same tensile load. That is,  $\omega(x) = \epsilon_{s,b}/\epsilon_{s,e}(x)$ . Since the strain in a concrete-embedded bar is largely dependent on the distance from a crack face, it follows that the value of  $\omega(x)$  also depends on the position along the bar relative to a crack face. In this paper, a parabolic distribution of the concrete and steel strains between consecutive cracks is assumed. This assumption is made widely in the literature, including in (8), wherein the concrete strain distribution between cracks is assumed to take the form:

$$\epsilon_c(x) = g(x) \cdot \epsilon_{c,max}, \quad g(x) = 2(x/L_t) - (x/L_t)^2 \quad (3)$$

where  $g(x)$  is a parabolic distribution function;  $\varepsilon_{c,max}$  is the maximum concrete strain which occurs at a point  $x = L_t$ ; and  $L_t$  is the transmission length (i.e. the distance from the face of a crack over which slip occurs, and beyond which reinforcement and concrete strains are equal). At the point  $x = L_t$ , knowing that there is full interaction between the reinforcement and the concrete, it can be shown that the strain in the concrete  $\varepsilon_{c,max}$  is equal to:

$$\varepsilon_{c,max} = \frac{\sigma_s}{E_s + E_c/\rho} \quad (4)$$

where  $\sigma_s$  is the tensile stress in the reinforcement at a crack. Eq. (4) does not, however, take into account the diminished ability of concrete to develop tensile strain under increasing tensile load (i.e. the load-dependent loss of tension stiffening shown by the curve BC in Fig. 2). Therefore a term  $\lambda$  (the *bond damage parameter*) is introduced which accounts for the tendency of bond (and therefore tension stiffening) to decay under increasing load. Combining Eqs. (3) and (4) and the parameter  $\lambda$ , the concrete strain distribution between cracks may be expressed as:

$$\varepsilon_c(x) = g(x) \frac{\lambda \sigma_s}{E_s + E_c/\rho}, \quad 0 \leq \lambda \leq 1 \quad (5)$$

By equilibrium of forces, the strain in the reinforcement between cracks can be shown to be equal to:

$$\varepsilon_{s,c}(x) = \frac{\sigma_s}{E_s} \left( 1 - g(x) \frac{\lambda}{1+n\rho} \right), \quad 0 \leq \lambda \leq 1 \quad (6)$$

where  $n$  is the modular ratio  $E_s/E_c$ . Thus the tension stiffening ratio  $\omega(x)$  is found by dividing the strain in a bare reinforcement bar ( $\varepsilon_{s,b} = \sigma_s/E_s$ ) by the strain in a concrete-embedded bar given in Eq. (6), yielding:

$$\omega(x) = \frac{1+n\rho}{1+n\rho - g(x)\lambda} \quad \text{or} \quad \lambda = \left( 1 - \frac{1}{\omega(x)} \right) \left( \frac{1+n\rho}{g(x)} \right) \quad (7)$$

Consider now a RC tie that is subjected to both a sustained load (equivalent to a stress of  $\sigma_{s,sus}$  in the bare reinforcement) and a shrinkage strain  $\varepsilon_{sh}$ . Since the concrete is restrained by the reinforcement, a tensile stress will develop in the concrete with time. This time-dependent change in the concrete tensile stress, which may be found by applying the age-adjusted effective modulus method, can be thought of as the response to an equivalent tensile load (equal to a stress of  $\sigma_{s,eq}$  in the bare reinforcement), where  $\sigma_{s,eq}$  is:

$$\sigma_{s,eq} = \frac{1}{1+\bar{n}_e\rho} \left[ \sigma_{s,sus} - \frac{\lambda \sigma_{s,sus}}{1+n\rho} (1+n_e\rho) - \varepsilon_{sh} E_s \right], \quad \bar{n}_e = n(1+\chi\varphi), \quad n_e = n(1+\varphi) \quad (8)$$

where  $\varphi$  is the creep coefficient; and  $\chi$  is an ageing coefficient, which may be assumed to be a constant value (7). In Eq. (8), the value of  $\lambda$  is calculated for the maximum load experienced by the tie, which may be an initial loading of a greater magnitude than the sustained load. The application of an equivalent tensile load to account for time effects effectively induces further bond damage to the reinforcement-concrete interface. In this way, the influence of the time effects of sustained loading and shrinkage on the tension stiffening of the tie is accounted for.

## 2.2 Experimental analysis of RC ties

In order to calibrate the tension chord model, an analysis is undertaken of the average stress-strain behaviour of seventeen RC ties tested under monotonically increasing load in six different experimental programs (15-21). All ties were axially reinforced with deformed steel bars ranging in diameter from 11.3 to 32 mm. The dimensions of the concrete vary to give a range of covers between 1 and 3.67 times the bar diameter, and reinforcement ratios between 1.1 and 9.6 per cent. The compressive strength of the concrete ranged from 21.6 to 62 MPa. Specimens for which significant drying had occurred before loading were not considered in the analysis, since it was intended to study the tension stiffening effect in the absence of other effects. Considering the wide range of bar diameters, concrete covers, reinforcement ratios and concrete compressive strengths, the analysis should be useful in formulating a general model for RC structures.

In Section 2.1, the formula derived for the tension stiffening ratio  $\omega(x)$  given in Eq. (7) refers to a particular point relative to the face of a crack. However, in the analysis of RC ties, only the average stress-strain behaviour is known. Therefore, an *average* tension stiffening ratio  $\omega_{av}$  is introduced which is defined as the ratio between the strain in a bare reinforcing bar  $\varepsilon_{s,b}$  and the *average* strain in a concrete-embedded reinforcing bar  $\varepsilon_{s,e,av}$  subjected to the same tensile load. The average strain  $\varepsilon_{s,e,av}$  is found by integration of Eq. (6) between cracks. By symmetry, only one half of the crack spacing needs to be considered:

$$\varepsilon_{s,e,av} = \frac{2}{L_s} \int_0^{L_s/2} \frac{\sigma_s}{E_s} \left( 1 - g(x) \frac{\lambda}{1+n\rho} \right) dx = \frac{\sigma_s}{E_s} \frac{1+n\rho-0.744\lambda}{1+n\rho} \quad (9)$$

where  $L_s$  is the crack spacing and is taken to be equal to  $1.37L_t$ . In the literature, the ratio between the average crack spacing  $L_{s,av}$  and the transmission length  $L_t$  is taken to be either 1.33 (7,11,22) or 1.50 (8,23). The choice of 1.37 is for practical reasons only, since it yields a workable value of  $g(x) = 0.9$ . In any case, the value of  $g(x)$  is not particularly sensitive to the specific choice of this ratio. The average tension stiffening ratio  $\omega_{av}$  is then:

$$\omega_{av} = \frac{1+n\rho}{1+n\rho-0.528\lambda} \quad (10)$$

Alternatively, the bond damage parameter  $\lambda$  can be expressed in terms of  $\omega_{av}$ :

$$\lambda = (1.894 - 1.894/\omega_{av})(1+n\rho) \quad (11)$$

For each of the RC ties, the average tension stiffening ratio  $\omega_{av}$  was determined by considering the recorded average strain as a function of the normalised steel stress  $\sigma_s/\sigma_{s,cr}$ , where  $\sigma_{s,cr}$  is the stress in the reinforcement when cracking first occurs (i.e. at the cracking load). The bond damage parameter  $\lambda$  was then determined according to Eq. (11). The results of the analysis are presented in Fig. 3. The grey curves represent the relationship between  $\lambda$  and  $\sigma_s/\sigma_{s,cr}$  for each of the seventeen RC ties. It is immediately obvious that for levels of loading just in excess of the cracking load, the calculated values of the bond damage parameter  $\lambda$  are greater than 1.0, which is not permitted according to Eqs. (5) and (6). This is because the assumption that a stabilised crack pattern has been established is not justified at such low levels of loading and the relationship  $L_s = 1.37L_t$  is not accurate. For levels of loading greater than about  $\sigma_s/\sigma_{s,cr} = 1.3$ , the value of  $\lambda$  is generally less than 1.0 and at this level of loading a stabilised crack pattern has usually been established (24).

For each of these curves, a line of best fit in the form of a power function was determined, and the average of each of these lines of best fit is shown by the black curve, which is defined by the equation:

$$\lambda = 1.5 \left( \frac{\sigma_s}{\sigma_{s,cr}} \right)^{-2} \quad \text{when } \sigma_s/\sigma_{s,cr} > 1.3 \quad (12)$$

It is also important to note that in the analysis of the seventeen RC ties, none of the parameters considered (i.e. bar diameter, concrete cover, reinforcement ratio, and concrete compressive strength) appeared to have any apparent influence on the bond damage parameter  $\lambda$  as a function of the normalised steel stress  $\sigma_s/\sigma_{s,cr}$ . Although tension stiffening is known to be more pronounced in lightly-reinforced members (6), the formulation of  $\lambda$  in Eq. (11) tends to normalise this behaviour according to the reinforcement ratio. Therefore, the proposed model is expected to account for tension stiffening across a wide range of reinforcement ratios.

**Figure 3. Relationship between bond damage parameter  $\lambda$  and normalised load  $\sigma_s/\sigma_{s,cr}$ .**

### 3. Beam model (monotonic loading)

The tensile region of a RC beam or slab may be considered analogous to a RC tie, such as those analysed in Section 2.2. Fig. 4 depicts an uncracked cross-section of a typical RC beam as well as the cross-section of the same beam at some point between flexural cracks, where  $h$  is the overall depth of the member;  $b$  the width;  $d$  the effective section depth (measured from the extreme compressive concrete fibre to the centroid of the tensile reinforcement); and  $A_s$  the total cross-sectional area of tensile reinforcement. Between consecutive cracks, the cross-section may be considered to be composed of a compressive area of concrete located above an effective neutral axis depth  $d_{n,ef}(x)$  and a tensile zone comprising the tension chord model described in Section 2. The effective cross-sectional area of concrete within the tension chord is taken to be that given in the CEB-FIP Model Code 1990 (11):

$$A_{c,ef} = \min \{2.5(h-d)b, (h-d_{n,cr})b/3\} \quad (13)$$

where  $d_{n,cr}$  is the neutral axis depth of a fully-cracked section (i.e. at a point  $x = 0$ ) and may be evaluated using the modular ratio method. Previously, the tension stiffening ratio  $\omega(x)$  was introduced to represent the ratio between the strain in a bare reinforcement bar and the strain in a concrete-embedded bar subjected to the same tensile load. Therefore  $\omega(x)$  can be thought of as the ratio of the axial stiffness between the two cases. Consider, then, an *equivalent* cross-sectional area of tensile reinforcement  $A_{s,eq}(x) = \omega(x)A_s$  which represents the cross-sectional area of an equivalent bare reinforcement bar having the same axial stiffness of a concrete-embedded bar. In this way, the tension chord described in Section 2, comprising both reinforcement and concrete, can be replaced by this equivalent cross-sectional area of reinforcement alone. By applying the modular ratio method, it is possible to determine the effective neutral axis depth at any point between cracks:

$$d_{n,ef}(x) = \frac{-nA_{s,eq}(x) + \sqrt{(nA_{s,eq}(x))^2 + 2nA_{s,eq}(x)bd}}{b} \quad (14)$$

Considering the strain diagram in Fig. 4, the curvature between cracks is therefore equal to:

$$\kappa(x) = \frac{\varepsilon_{s,c}(x)}{d - d_{n,ef}(x)} = \frac{\varepsilon_{s,b}}{\omega(x)(d - d_{n,ef}(x))} \quad (15)$$

For a fully-cracked cross-section, the relationship between the applied bending moment  $M_s$  and the strain in the tensile reinforcement  $\varepsilon_{s,b}$  is given by:

$$M_s = \varepsilon_{s,b} E_s A_s (d - d_{n,cr}/3) \quad (16)$$

Finally, considering Eqs. (15) and (16), the second moment of area of the section at some point between cracks is derived as:

$$I(x) = \frac{M_s}{E_c \kappa(x)} = (d - d_{n,cr}/3) n A_{s,eq}(x) (d - d_{n,ef}(x)) \quad (17)$$

**Figure 4. Uncracked and cracked cross-sections of a typical RC beam**

Because the second moment of area formulation in Eq. (17) depends on the particular position under consideration between cracks, a simple alternative formulation is sought which, when applied uniformly between cracks, will yield the same overall flexural stiffness. Analysis of typical RC beams and slabs reveals that the second moment of area formulation in Eq. (17) is reasonably well approximated by a linear interpolation between the second moments of area calculated at a crack location and the mid-point between cracks. Thus:

$$I(x) \approx I_{cr} + \frac{2x}{L_s}(I_{mid} - I_{cr}), \quad 0 \leq x \leq \frac{L_s}{2} \quad (18)$$

where  $I_{cr}$  is the second moment of area at the location of a crack (i.e.  $x = 0$  in Eq. (17)); and  $I_{mid}$  is the second moment of area calculated at the mid-point between consecutive cracks (i.e. at  $x = 0.5L_s$  in Eq. (17)). For typical RC flexural members, considering the relatively small average crack spacing compared to the length of the member, it is reasonable to assume that the bending moment is more or less constant between consecutive cracks, regardless of the actual loading arrangement and bending moment distribution. Therefore, in order to determine an effective second moment of area to replace the linear approximation in Eq. (18), we enforce the criterion that the average curvature of a small beam segment between consecutive cracks having the linear second moment of area distribution in Eq. (18) and being subjected to a constant bending moment should be equal to the average curvature of a similar beam segment having a uniformly-applied *effective* second moment of area  $I_{ef}$ . By integration, this yields:

$$\frac{M}{E_c I_{ef}} = \frac{M(\ln(I_{mid}) - \ln(I_{cr}))}{E_c(I_{mid} - I_{cr})} \quad (19)$$

And therefore we derive the effective second moment of area to be:

$$I_{ef} = \frac{I_{mid} - I_{cr}}{\ln(I_{mid}/I_{cr})} \quad (20)$$

For a typical range of values for  $I_{mid}/I_{cr}$  in the order of 1-2, Eq. (20) becomes indistinguishable from a straight line and may be simplified to:

$$I_{ef} \approx 0.44I_{mid} + 0.56I_{cr} \quad (21)$$

Alternatively, substituting in a value of  $x = 0.22L_s$  into Eq. (18) achieves the same effective second moment of area. That is to say, the second moment of area determined at a point  $x = 0.22L_s$  may be considered to represent the effective second moment of area of the entire cracked region of the beam. At this point, there exists an *effective* tension stiffening ratio found by substituting  $x = 0.22L_s$  into Eq. (7):

$$\omega_{ef} = \frac{1 + n\rho}{1 + n\rho - 0.512\lambda} = \frac{1 + n\rho}{1 + n\rho - 0.768(M_s/M_{cr,t})^{-2}} \quad (22)$$

where  $\lambda = 1.5(M_s/M_{cr,t})^{-2} \leq 1.0$  (an equivalent expression to Eq. (12) for the case of flexure); and  $M_{cr,t}$  is the cracking load of the member at some point in time, taking into account the shrinkage that occurs.

### 3.1 Deflection calculations

The calculation of the mid-span deflection of a cracked RC flexural member is complicated by the fact that the flexural stiffness changes abruptly at the point where flexural cracking first occurs. In practice, the contribution to overall flexural stiffness of the uncracked parts of a RC member is often ignored. This approach would tend to overestimate deflections, particularly in cases where the RC member is loaded just in excess of its cracking load: for lightly-loaded members, the actual extent of flexural cracking might be restricted to a rather small region near the beam's mid-span. In this paper, the mid-span deflection is taken to be:

$$\Delta_{mid} = K_{ef} L^2 \kappa_{ef} \quad (23)$$

where  $K_{ef}$  is a parameter that accounts for the loading arrangement as well as the extent of flexural cracking;  $L$  is the length of the beam; and  $\kappa_{ef}$  is the effective curvature at the mid-span of the beam.

To illustrate the process of determining  $K_{ef}$ , a typically-encountered loading arrangement is considered. Fig. 5 depicts a cracked RC flexural member subjected to four point bending, with loads applied at the third span points. Point A is a simple support; point B represents the position along the beam at which the bending moment is equal to the cracking moment ( $x = M_{cr}/P$ ); point C is the third-point of the beam ( $x = L/3$ ) beyond which the bending moment remains constant; and point D is the mid-span. Within segment AB, the flexural stiffness is that of the uncracked section; within segments BC and CD, since cracking has occurred, the effective flexural stiffness in Eq. (17) is used, evaluated using the effective tension stiffening ratio  $\omega_{ef}$  in Eq. (22). By twice integrating the piecewise-defined curvature and applying the appropriate boundary conditions, an expression for the mid-span deflection is derived as:

$$\Delta_{mid} = \frac{1}{216} \frac{L^2 [8M_{cr,t}^3 (I_{ef} - I_{uncr}) + 23M_s^3 I_{uncr}]}{E_c M_s^2 I_{uncr} I_{ef}} \quad (24)$$

Equating the mid-span deflections in Eqs. (23) and (24) and noting that  $K_{ef} = M_s/(E_c I_{ef})$ , we get an expression for  $K_{ef}$ :

$$K_{ef} = \frac{1}{216} \frac{23a^3 b - 8b + 8}{a^3 b}, \quad a = \frac{M_s}{M_{cr,t}}, \quad b = \frac{I_{uncr}}{I_{ef}} \quad (25)$$

It is interesting to note that the formulation for  $K_{ef}$  in Eq. (25) is general and not restricted to the particular formulation of  $I_{ef}$  in this paper. A graphical representation of Eq. (25) is given in Fig. 6 for a typical range of values for  $\omega_{ef}$ , where  $\rho_{ef}$  is the effective reinforcement ratio for the tension chord equal to  $A_s/A_{c,ef}$ . For heavily-loaded members, for which the effective tension stiffening ratio  $\omega_{ef}$  is close to 1.0, the value of  $K_{ef}$  approaches the theoretical value of 0.107 for a uniformly-stiff beam. For lightly-loaded members, for which the value of  $\omega_{ef}$  is greater than 1.0, the value of  $K_{ef}$  decreases since the extent of flexural cracking is less. Similar results are observed in the derivation of  $K_{ef}$  for other load cases.

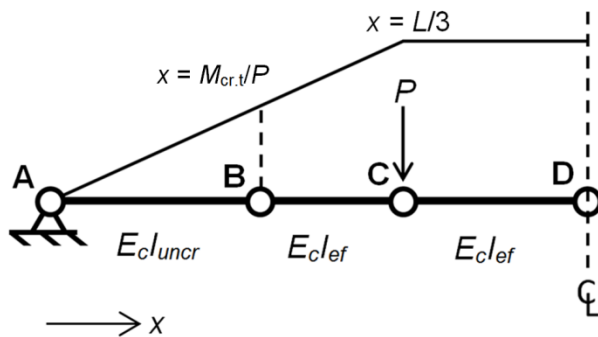

Figure 5. Beam model for the determination of  $K_{ef}$  (four point bending case)

Figure 6. Plot of  $K_{ef}$  for a range of  $\omega_{ef}$  and  $n\rho_{ef}$  values (four point bending case)

### 3.2 Validation of model

In order to evaluate the validity of the proposed tension chord model and its application to RC flexural members, an analysis is undertaken of a large number of cracked RC beams and slabs that have been tested in 26 individual experimental programs, the results of which have been collated by Espion (25). In total, 181 rectangular RC beams and slabs subjected to monotonically increasing load have been selected for analysis. The specimens represent a very wide range of concrete compressive strengths, cross-sectional dimensions, reinforcement ratios and reinforcement types (round or deformed). Load levels are in the range of 1.02 to 8.32 times the cracking load. Given the limited knowledge of reported material properties such as the concrete elastic modulus and tensile strength, these values have been estimated based on the material models in AS3600-2009 (1). The proposed model is compared to deflection calculations made using the AS3600-2009 method based on Branson's formula (3) and that by

Bischoff (4) based on the Eurocode 2 (5) approach. The results of this analysis are presented in Table 1, where the values represent the ratios of predicted short-term deflections to reported values.

**Table 1. Results of short-term deflection analysis**

		Method of Analysis		
		This Paper	AS3600-2009 (1)	Bischoff (4)
All specimens ( <i>n</i> = 181)	Mean	1.09	0.94	1.05
	<i>Standard Deviation</i>	0.36	0.31	0.35
Beams ( <i>n</i> = 132)	Mean	1.13	1.00	1.08
	<i>Standard Deviation</i>	0.36	0.30	0.34
Slabs ( <i>n</i> = 49)	Mean	0.98	0.77	0.95
	<i>Standard Deviation</i>	0.33	0.28	0.36

Despite limited knowledge of the material properties of the specimens, the model was able to predict short-term deflections of RC beams and slabs very well on average. In the estimation of beam deflections, the proposed model yielded very similar results to those obtained using Bischoff's method. Both of these methods predicted slightly greater beam deflections than the AS3600-2009 approach. In the estimation of slab deflections, the proposed model performed very similarly to Bischoff's method. Again, both of these methods predicted greater short-term deflections in slabs than the AS3600-2009 approach. The results of this analysis confirm that the proposed model is able to reliably predict the flexural response of RC beams and slabs for a wide variety of load levels and is therefore effective in modelling the tension stiffening of RC flexural members.

#### 4. Beam model (cyclic loading)

Having validated the tension chord and beam models for the case of monotonic loading, a beam model for the case of cyclic loading is now considered, for which (in the absence of appropriate RC tie experiments in the literature) the parameter  $k_{cyc}$  must be determined according to the experimental results of beams subjected to cyclic loads. Considering the effective elastic modulus  $E_{cyc}$  given in Eq. (2), it can be shown that the elastic portion of the mid-span deflection of a RC member under loading cycles (i.e. excluding permanent initial deflections and creep and shrinkage deflection components) is equal to:

$$\Delta_{cyc} = K_{ef} L^2 \kappa_{ef,cyc} = \frac{K_{ef} L^2 M_s}{A_s (E_s + k_{cyc} E_c / \rho_{ef}) (d - d_{n,ef}) (d - d_{n,cr} / 3)} \quad (26)$$

where  $\kappa_{ef,cyc}$  is the effective curvature under loading cycles at the mid-span of the beam; and  $d_{n,ef}$  is evaluated at the critical point  $x = 0.22L_s$ . The value of  $k_{cyc}$  may therefore be estimated according to:

$$k_{cyc} = \frac{K_{ef} L^2 M_s}{\Delta_{cyc} A_{c,ef} E_c (d - d_{n,ef}) (d - d_{n,cr} / 3)} - n \rho_{ef} \quad (27)$$

For the evaluation of  $k_{cyc}$  in the long term, adjustments should be made to account for the shrinkage-induced reduction in the cracking moment, and the consequent change to the value of  $K_{ef}$ . Furthermore, the concrete elastic modulus may be modelled to increase over time. Finally, the effects of sustained load and shrinkage on the tension stiffening effect must be taken into account. That is to say, the value of  $d_{n,ef}$  in the long term, evaluated at the critical point  $x = 0.22L_s$ , will depend on the effective tension stiffening ratio  $\omega_{ef}$  which is determined by considering the equivalent tensile load in addition to the applied load.

##### 4.1 Experimental derivation of $k_{cyc}$

The results of an experimental program by Castel et al. (8) as well as more recent tests by the same authors are used to determine the average stress-strain response of the tension chord under cycles of loading. The two experimental programs involved the application of several initial cycles of load to RC beams ranging from about 1.1 to 2.0 times the short-term cracking load followed by an extended period of

sustained loading during which the beams were free to shrink. The period of sustained loading was six months and twelve months for the two experimental programs. Following this, each RC beam was again subjected to several cycles of load having the same magnitude as the short-term cyclic load. In total, thirteen RC beams were tested. Using Eq. (27), the values of  $k_{cyc}$  for both the short-term and long-term responses to cyclic loading were determined. The results of this analysis are presented in Fig. 7.

For levels of loading just greater than the cracking load, the value of  $k_{cyc}$  is relatively high, suggesting that, like the bond damage parameter  $\lambda$ ,  $k_{cyc}$  is highly dependent on the magnitude of loading.

Similarly, the value of  $k_{cyc}$  decreases as the applied load increases. Due to the effects of sustained loading and shrinkage, the value of  $k_{cyc}$  decreases in every case. In Fig. 7, the values of  $k_{cyc}$  are plotted against the normalised load  $M_s/M_{cr,t}$  where  $M_{cr,t}$  has been adjusted in the long term to reflect the shrinkage-induced decrease in the cracking moment. Both the short-term and long-term results appear to obey the same trend. In general, the value of  $k_{cyc}$  may be modelled according to:

$$k_{cyc} = A(M_s/M_{cr,t})^B \approx A(\sigma_s/\sigma_{s,cr,t})^B \quad (28)$$

For the thirteen beams analysed here,  $A = 0.6$  and  $B = -3.5$ . Fig. 1 shows the response to short-term and long-term cyclic loading of one of the beams in the experimental programs considered. Considering the expression for the elastic portion of the mid-span deflection under cyclic loading in Eq. (26), it can be shown that, in the case of a beam subjected to four point bending (as is the case for the thirteen beams analysed here), the overall stiffness of a RC flexural member subjected to cycles of load is equal to:

$$K = \frac{F_{cyc}}{\Delta_{cyc}} = \frac{6A_s(E_s + k_{cyc}E_c/\rho_{ef})(d - d_{n,ef})(d - d_{n,cr}/3)}{K_{ef}L^3} \quad (29)$$

where  $K$  refers to either the short-term overall stiffness  $K_0$  or the long-term overall stiffness  $K(t)$ ;  $k_{cyc}$  is the corresponding short-term or long-term value; and  $F_{cyc}$  is the total cyclic load applied to the beam.

## 5. Conclusions

- In the analysis of the average stress-strain response of seventeen RC ties to monotonically increasing load, no clear influence on the bond damage parameter  $\lambda$  by any of the parameters considered was found. These parameters include bar diameter, concrete cover, reinforcement ratio, and concrete compressive strength. The bond damage parameter was shown to be governed by the level of applied loading in excess of the cracking load.
- A tension chord model based on the observations made in that analysis has been shown to reliably predict the post-cracking behaviour of RC flexural members. The proposed model is demonstrated to yield very similar results to those obtained using the widely-accepted method by Bischoff (4).
- The introduction of the  $K_{ef}$  factor in Section 3.1 is thought to have improved deflection estimates significantly, particularly in lightly-reinforced members and members subjected to loads just greater than the cracking load.
- In the analysis of thirteen RC beams, it was found that the overall stiffness under cycles of load is closely related to both the magnitude of load cycles in excess of the cracking load as well as the degree of restrained shrinkage that occurs over time.
- A distinct lack of experimental observations reported in the literature regarding the average stress-strain response of RC ties subjected to cyclic loads warrants further experimental investigations.

# Role of Ettringite in Expansion and Cracking Potential in Steam Cured Precast Concrete Elements

Johnson Mak, Paul Thomas, Kirk Vessalas, Daksh Baweja  
Centre for Built Infrastructure Research, University of Technology Sydney.

**Abstract:** The susceptibility of precast concrete elements to failure due to DEF is a significant issue to the construction industry in Australia although little work has been carried out on the potential susceptibility of precast concrete elements to DEF in an Australian context. In order to address this issue, a research program investigating the development of hydration phases in the presence of elevated sulfate and alkali contents over a range of curing temperatures has been carried out and related to expansion in the mortar specimens containing 25% fly ash as a partial Portland cement replacement. This paper reports on the relationship between the development of these phases and the expansion over a period of 400 days after the initial precuring and assesses the potential of these mortars to undergo expansion associated with DEF.

**Keywords:** Delayed ettringite formation (DEF), steam cure concrete elements, Portland cement, fly ash.

## 1. Introduction

In recent years cracking and potential failure of some concrete elements particularly in high sulfate environments or when manufactured by precast steam curing processes, has been linked to the expansive formation of ettringite at times long after the hardening process has been completed; a process commonly termed delayed ettringite formation (DEF). Crystalline ettringite has been observed in cracks (Lawrence et al, 1999) and laboratory experiments have demonstrated expansion in cured mortar prism specimens due to the hydrostatic pressure produced through the formation of the higher specific volume ettringite phase (Taylor et al, 2001; Tousin and Baradan, 2010). Laboratory experiments have identified a number of factors which increases the susceptibility of concretes to DEF formation such as elevated sulfate and alkali ion concentrations and at curing temperatures of greater than 70°C (Glasser, 1996; Odler and Chen, 1996), however, there has also been discussion associated with the presence of DEF and alkali-silica reaction (ASR) (Diamond, 2000) and that the formation of DEF occurs in conjunction with ASR as a secondary mineralisation process (Shanyan and Ivanusec, 1996).

The susceptibility of precast concrete elements to failure due to DEF is a significant issue to the construction industry although little work has been carried out on the potential susceptibility of precast concrete elements to DEF in an Australian context. In order to address this issue, a research program investigating the development of hydration phases in the presence of elevated sulfate and alkali contents over a range of curing temperatures has been carried out and related to expansion in the mortar specimens containing 25% fly ash as a partial Portland cement replacement. This paper reports on the relationship between the development of these phases and the expansion over a period of 400 days after the initial elevated temperature pre-curing and assesses the potential of these mortars to undergo expansion associated with DEF.

## 2. Materials and Methods

General purpose Portland cement (PC) manufactured in Gladstone, QLD, a Gladstone Class F fly ash (FA) (AS 3582.1-1998), Pink Lily course aggregate sand and Kinka Beach fine aggregate sand, whose compositions are listed in Table 1, were used in the preparation of 150 x 40 x 40 mm mortar shrinkage prisms which were prepared following the method outlined in AS2350.13 (2006). To control the flow properties of the mortars, ADVA Cast 620, a polycarboxylic high range water reducing type admixture was used in accordance with (AS 1478.1 – 2000). All materials required for preparation of mortar prisms were supplied through Humes Australia. Paste specimens, prepared for phase analysis, were also prepared based on AS2350.13 (2006) with the main alteration being that no aggregate sand was added. The mix design for both mortar and paste specimens are listed in Table 2.

Table 1. Composition of mortar components in oxide wt% determined using XRF.

Oxide	Portland Cement	Fly Ash	Pink Lily Course Sand	Kinka Beach Fine Sand

Table 2. Mortar and paste mix designs.

Material	Mortar Specimen	Paste Specimen
Portland cement	337.5g	337.5g
Class F Fly ash	112.5g	112.5g
Total binder content	450.0g	450.0g
Water	135.0g	135.0g
Water:binder ratio	0.3	0.3
Superplasticiser	2.0mL	0.5mL
Coarse sand	1147.5g	N/A
Fine sand	202.5g	N/A
Total sand content	1350.0g	N/A

Control of the sulfate and sodium composition of the mortar and paste specimens was achieved by adding calcined (at 100°C for 24 hours) gypsum (CaSO<sub>4</sub>) and sodium hydroxide, both technical grade, obtained from Chemsupply, SA, Australia. Sulfate and sodium composition was altered to achieve addition based on equivalent oxide composition; SO<sub>3</sub> additions of 1, 2, 3 and 4% and Na<sub>2</sub>O additions of 0.5 and 1% in addition to the PC content to give a range of 2.3 to 6.3% SO<sub>3</sub> and 0.78 to 1.78% Na<sub>2</sub>O. The alkalis contained in the FA are considered to be bound by the presence of tetrahedral aluminium and, hence, not considered to be available to influence the reaction directly.

Mortar specimens were prepared in triplicate and transferred to a commercial sterilising autoclave set at 60, 70, 80, 90 or 100°C for 8 hours. At the termination of the eight hour curing period the autoclave was turned off and allowed to cool naturally to room temperature over a 16 hour period whereupon the mortar specimens were stripped from their moulds and transferred to enclosed vessels and submerged in distilled water. Room temperature (23°C) cured specimens were also prepared, however, these specimens were sealed in polypropylene bags and allowed to cure for 24 hours prior transfer to the enclosed vessels.

For each set of mortar specimens and equivalent set of paste specimens were prepared and cured in conjunction with the mortar specimens. The paste was transferred in 20g batches to small polystyrene cups and cured concurrently with the mortar specimens.

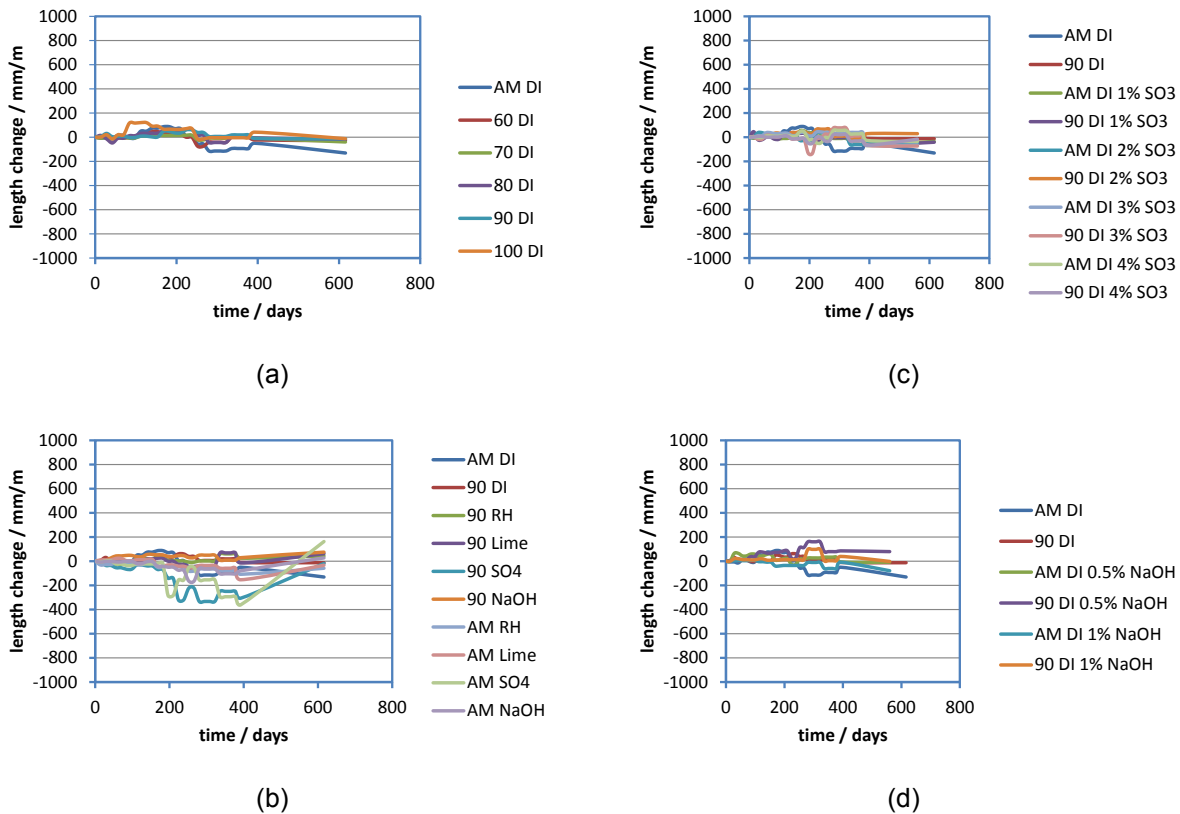

Figure 1. Expansion measurements carried out on mortars according to the procedures described in AS2350.13 (2006). Expansion has been plotted as length change in  $\mu\text{m/m}$  and has been plotted on a full scale of 2000  $\mu\text{m/m}$ , which represents a 0.2% expansion full scale. Data is plotted in series groups: (a) represents curing temperature, (b) environment in which the samples are submerged (DI – deionised water; RH – supported in saturated atmosphere above DI; NaOH – 1 M NaOH solution; Lime – saturated lime solution), (c) effect of increasing sulfate content showing  $\text{SO}_3$  equivalent % addition, (d) effect of increasing sodium concentration showing  $\text{Na}_2\text{O}$  equivalent % addition.

Dimension analysis was carried out on mortar specimens in accordance with the procedure laid out in AS2350.13 (2006). Dimension analysis was performed on specimens at 28 day intervals. The mortar specimens were removed from their submerged environments patted dry with paper towel and placed in a digital length comparator. Prior to returning specimens to their environment, the environmental liquid was replaced.

A paste specimen was also removed from the environment dried in a vacuum oven at RT and subsequently crushed and ground in a ring mill prior to characterisation by XRD using a Siemens D5000 diffractometer with an angular scan of  $3^\circ - 65^\circ 2\theta$  with a step size of 0.08 at 4 sec/step scanning time. Thermal analysis was carried out on a TA Instruments Simultaneous TG-DTA (SDT) Q600 instrument in  $\text{N}_2$  atmosphere with a flow rate of 120mL/min on  $30.0 \pm 0.1\text{mg}$  of binder paste powder using a  $10^\circ\text{C}/\text{min}$  heating rate over the temperature range of 30 to  $1200^\circ\text{C}$ .

## 2. Results

Mortar bars and cement paste specimens were prepared at a range of curing temperatures and stored in a range of environments. Mortar expansion (shrinkage) data were collected with a 4 week periodicity and are shown in Figure 1. Paste specimens were also collected at the same aging time and were dried ground and phase analysis was carried out using thermogravimetric analysis and x-ray diffraction (XRD). Only XRD data is presented in this paper and the data are shown in Figure 2.

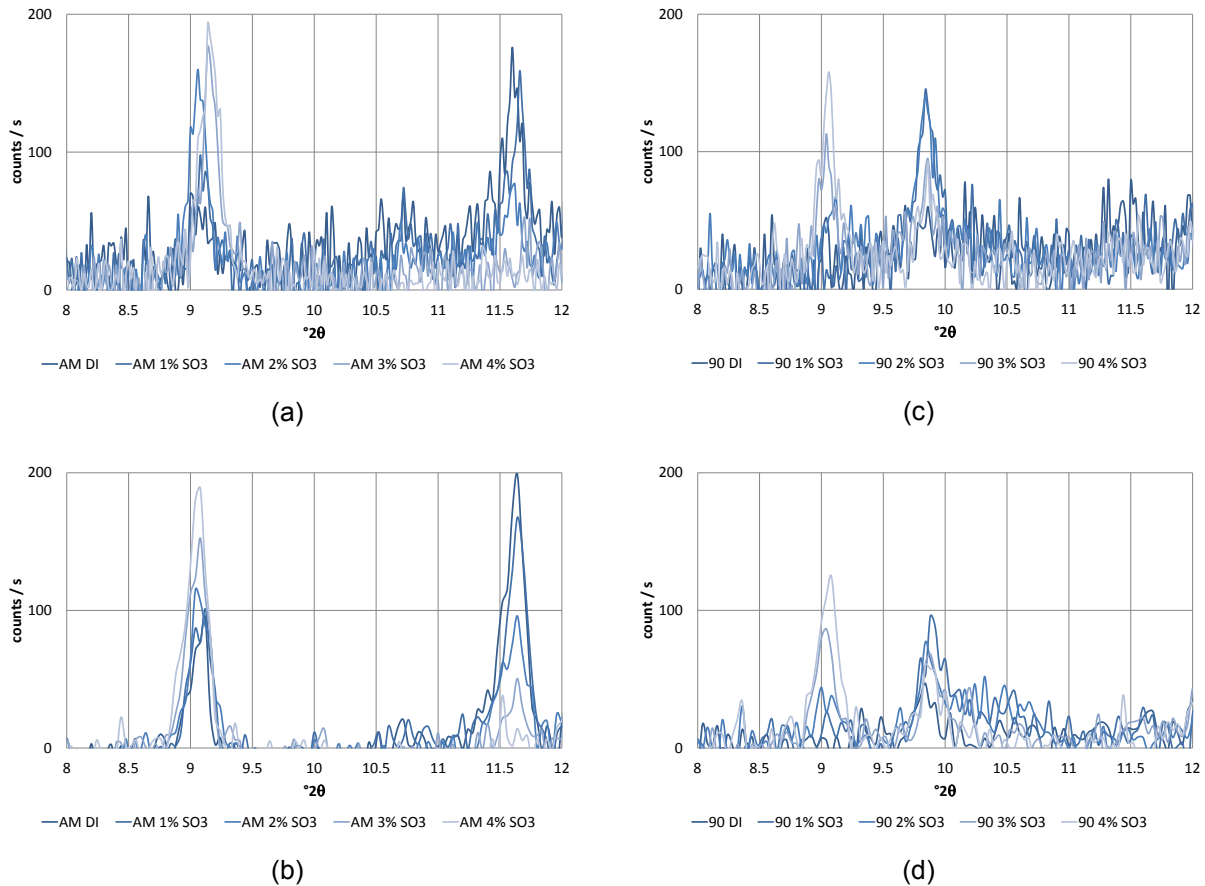

Figure 2. XRD data in the AFt, AFm region of the diffraction pattern: (a) ambient temperature (AM) cure, 28 days storage in deionised water (DI), (b) ambient temperature cure, 396 days storage in deionised water, (c) 90°C cure, 28 days storage in deionised water, (d) 90°C cure, 392 days storage in deionised water. Phases present:  $2\theta = 9.1^\circ$  - ettringite (AFt);  $2\theta = 9.8^\circ$  - monosulphate (AFm);  $2\theta = 11.6^\circ$  - monocarbonate.

## 2.1 Mortar Expansion Tests

The expansion (shrinkage) data is shown in Figure 1. The scales have been drawn so that full scale represents a 0.2% expansion. Expansion observed in laboratory experiments has been typically reported to be in the range 0.5 to 1% within a 400 days of curing (Yand, 1999, Ekolu 2007) which is significantly greater than the expansion observed in this study where no systematic expansion has been observed up to 600 days and length changes of less than 0.02% have been observed. Generally, laboratory experiments are carried out in the absence of mineral additions such as SCMs although reactive aggregates have been added to induce ASR (Ekolu 2007). In this study, all cement mortars contained 25% Class F fly ash.

## 2.2 XRD Phase Analysis

Figure 2 shows the XRD patterns for paste specimens collected at 28 and 392 days aging for ambient (AM) and 90°C curing for a series of cement pastes which have been modified with the addition of calcined (at 100°C for 24 hours) gypsum so that the  $\text{SO}_3$  equivalent is increased by 1, 2, 3 and 4%. Inspecting the ambient cured systems (Figure 2(a) and (b)), two peaks are observed in the range 8 to  $12^\circ 2\theta$  at 9.1 and  $11.6^\circ$ . The peak at  $9.1^\circ$  corresponds to ettringite. This peak increases in intensity with increasing proportion of sulfate addition suggesting that the proportion ettringite formed is linked to the sulfate present. A peak is also observed at  $11.6^\circ$  which indicates the presence of a (calcium aluminate)

monocarbonate phase (Matschei et al, 2007). The origins of this phase are uncertain, however, the Gladstone cement supplied by Humes Australia did contain an interground mineral addition of 7.5% limestone which could be a source of carbonate ions. Ettringite and monocarbonate are present in the ambient cured specimens at both 28 days and 392 days and, although these measurements are not truly quantitative, the relative peaks sizes appear consistent indicating that there is little change in the phase development with time.

Figure 2 (c) and (d) show the XRD patterns in this region for specimens cured at 90°C for 8 hours. In this case the monocarbonate peak at 11.6° is absent. Two peaks are still apparent at 9.1° and 9.8° indicating the presence of ettringite and (calcium aluminate) monosulfate. The monosulfate is more significant in the lower sulfate content cements while the ettringite peak is more significant in the higher sulfate content cements. This relationship of shift from monosulfate to ettringite with increasing sulfate content is consistent with increased sulfate concentration driving the equilibrium between these two phases toward ettringite. These data are also consistent with the reduced stability of ettringite at elevated temperature (Glasser, 1996). Again the relative size of the diffraction peaks suggests that there is little change in the phase composition from 28 days to 392 days.

### **3. Discussion**

Mortar and paste specimens were prepared and cured at ambient temperatures and at elevated temperature with varying sulfate composition in order to promote ettringite formation and in particular delayed ettringite formation resulting in expansion. A wide range of formulations have been prepared. The expansion measurements for many of these samples are shown in Figure 1. Within experimental error no expansion is observed in the timeframe of the study. This is surprising as a wide range of sulfate and alkali equivalent compositions have been incorporated and a range of curing temperatures has been applied. A compositional range from 2.4 to 6.4% sulfate in the presence of alkali ions should provide a pessimum composition. XRD phase analysis suggests that this compositional range is indeed enough as for an initial curing temperature of 90°C ettringite is absent in lower sulfate content pastes and present in the higher sulfate content pastes. This situation is mirrored in the ambient cured specimens although, qualitatively, it appears that there is a greater ettringite content for the higher sulfate content cements. Additionally, the observation of the presence of monosulfate in the 90°C cured specimens indicates that ettringite is depleted at elevated temperature in favour of monosulfate and as the sulfate content is increased, an equilibrium between ettringite and monosulfate is produced.

One significant difference between this study and other studies is that the cement used contained 25% fly ash in order to mimic field conditions in which this cement was used in the preparation of precast concrete element by Humes Australia. It is possible that the fly ash has a significant influence on the formation nucleation and precipitation of sulfo-aluminate phases. This study cannot draw any specific conclusions as only systems containing fly ash have been investigated.

### **4. Conclusions**

Mortar and paste specimens containing a range of sulfate and alkali contents and cured at a range of temperatures were investigated. Although ettringite has been produced, and elevated temperatures have aided the partial decomposition of ettringite in these systems, no expansion has been observed in mortar prisms containing elevated sulfate and alkali contents. A significant difference in the mortars and pastes studied was the presence of Gladstone fly ash which could influence the formation and stability of sulfo-aluminate phases that may be involved in DEF. In this study to date, although proportion of ettringite has been altered by changing the composition of the cements, no change in the ettringite content has been observed with time for a particular paste composition / curing temperature system. The role of the fly ash may be significant in mitigating DEF expansion, however, further work is required to demonstrate a relationship between fly ash and expansion mitigation in DEF susceptible systems.

## 5. Acknowledgement

The Authors would like to thank Humes Australia for financial support for this project and the supply of materials.

# Improved Sustainability by Design for Concrete Durability

R. Doug Hooton<sup>1</sup>

<sup>1</sup>Professor of Civil Engineering, University of Toronto

**Abstract:** While many new types of concrete binder materials have been proposed and they can help in production of lower-carbon footprint concrete, far bigger contributions to sustainability over the whole life-cycle of concrete structures and infrastructure can be made through design and construction to ensure that sufficient durability is attained to extend their useful service life. To do this requires more than selection of limits on such things as maximum w/cm and minimum strength to meet durability requirements as required in national specifications. Influencing factors on attained durability include the materials, the concrete mix designs, volume stability, crack control (influenced by size, shape and restraint of structural elements, as well as structural detailing), as well as placing, protection and curing during construction. Prequalification testing of concrete placed in mock-up units, evaluation of the adequacy of the contractor's construction processes, as well as on-site inspection are required to ensure that in-place durability is obtained. Globally, the most severe environment that has resulted in premature deterioration of concrete structures is from corrosion of reinforcement in chloride exposures, from both marine and de-icing salts. Obtaining durability for a known service life in chloride exposures requires knowledge of the concrete properties, relevant transport processes, depths of cover as well as minimization of cracking and construction defects. For example, imperfect curing can result in depth-dependent effects on resistance to chloride ingress.

Several service life models with various levels of sophistication exist for prediction of time-to-corrosion of concrete structures exposed to chlorides. However, very few models deal with the influence of cracks or the fact that concrete in the cover zone will almost certainly have a higher diffusion coefficient than the bulk concrete as the result of imperfect curing or compaction. While many models account for variability in input properties, they will never be able to account for extremes in construction defects.

Therefore, to ensure the reliability of service life predictions and to attain a concrete structure that achieves its predicted potential, designers, contractors and suppliers need to work together to ensure proper detailing, minimize defects, and adopt adequate, yet achievable, curing procedures. As well, concrete structures are often also exposed to other destructive elements in addition to chlorides (eg. frost, ASR) and this adds another level of complexity since regardless of cause, cracks will accelerate the ingress of chlorides. These issues are discussed along with the need to use performance-based specifications together with predictive models.

**Keywords:** chloride ingress, diffusion, construction defects, cracks, performance specifications, durability.

## 1. Introduction

Concrete is a durable material and the most widely used construction material. Reinforced concrete structures can be designed to be resilient to severe storms, fire and earthquakes as well as to be durable in severe environmental exposures. Whether from marine or de-icing salts, chloride corrosion of steel reinforcement is the biggest challenge for both builders and owners of concrete structures. In addition to using materials and mix designs that will resist chloride ingress, construction detailing and practices have a large impact on durability. Achievement of concrete durability in-place is more likely with the use of appropriate performance specifications since temperature control, adequate compaction, protection of fresh concrete, and curing need to be detailed in specifications as well as requirements for sufficient inspection and testing to ensure that the specifications are being met.

In order to quantify the service life in severe environments, numerous predictive models have been developed over the last 25 years, especially related to the time-to-corrosion of reinforced concrete exposed to marine or de-icer salts. While early chloride ingress models, based on Fick's second law of diffusion were overly simplistic, newer models account for time-dependent changes in diffusion, the time to build up of surface chloride concentration, chloride binding and, in some cases, depth-dependent diffusion. However, diffusion is only one mechanism of ingress of fluids including aggressive ions such as chlorides. Other mechanisms including capillary absorption, permeability, and wick action can greatly accelerate ingress of chlorides, and some models have added terms to account for their effects. Taking a

different approach, more fundamental multi-species models have been developed such as Stadium (1, 2) that use effective diffusion values for different ions and account for their interactions and the nature of the pore structure and transport processes. In addition, deterministic models only provide average predictions which are not realistic given the level of uncertainty in concrete composition, rebar placement, and transport properties. However some models, such as DuraCrete (3) and LIFE-365 Version 2 (4) are at least semi-probabilistic and typically standard deviations as well as average values for each input value are used. The *fib* 2010 model code has incorporated some aspects of the Duracrete model (5). Unfortunately, space does not allow for more discussion.

## **2. Durability Design**

### **2.1 Design of Durable Concrete Mixtures**

Concrete mixtures that will be durable in aggressive exposures need to have low water/binder ratio, low unit water content, and contain appropriate levels of supplementary cementing materials. Typically, in order to minimize concrete permeability, a w/b of no higher than 0.40 is required. Using optimized total aggregate gradations and water-reducing admixtures, the unit water content can often be reduced to 135-140 L/m<sup>3</sup>, minimizing the paste volume fraction, thus reducing permeability while reducing thermal and drying shrinkage. Appropriate levels of supplementary cementing materials have many benefits in reducing paste permeability, reducing the porosity of the interfacial transition zones surrounding aggregates. Slag and fly ash will improve permeability at later ages, and silica fume improves properties at early ages, so ternary mixtures will work synergistically to improve initial properties and provide long-term benefits. In addition, SCMs improve the chloride binding capacity of the matrix, due to the lower Ca/Si ratio of the C-S-H and the incorporation of alumina into the hydrates, forming C-A-S-H (6, 7, 8).

Binder contents should be minimized, consistent with obtaining workable concrete, in order to minimize volume changes due to hydration temperatures and due to shrinkage. This will help minimize early-age cracking potential.

### **2.2 Types of performance testing**

Tests are or can be performed at various stages in construction.

- Pre-qualification Tests: Used by producers to demonstrate that a concrete mixture, when placed and cured under defined conditions, can meet the specification requirements and, if needed, provide input data for service life prediction. These tests often require significant lead time to complete and may include tests needed as inputs to service life models.
- Identity Tests: Performed when the concrete arrives on-site but before concrete is placed to demonstrate that the concrete being supplied is equivalent to the mixture that was pre-qualified (Similar to a DNA test). Unfortunately the range of identity tests that can be performed prior to acceptance of the truck load of concrete are quite limited. Typically, slump or slump flow is measured, and air content is determined. Useful information on concrete uniformity and air content can also be obtained from measuring the fresh density of the concrete, and some owners, such as the New York/New Jersey Port Authority have adopted the AASHTO microwave test to determine the water content of the delivered concrete (9) (as a partial check on w/cm (assuming that the cementitious materials are typically batched accurately) related to unintentional or deliberately added water).
- Quality Control: To document that the concrete supplied meets strength and other specification limits (a) at the change of ownership (the point of discharge from the truck) and (b) at the point of placement to demonstrate that pre-qualified placing practices are being followed.
- In-Place Testing: Using NDT and/or tests on cores extracted from the structure to ensure that the combination of the concrete supplied and the placement and curing methods used resulted in achieving the owner-defined performance levels. This is required in the End Result Specifications (ERS) used by several highway agencies.

Traditionally, concrete producers and contractors are often just interested in prequalification and quality control testing. However, owners are interested in performance of the hardened concrete in the structure, a number of highway agencies in North America have adopted or are currently considering the use of ERS where contractors are paid based on consistently meeting specified performance requirements using in-place testing of concrete in the structure. A number of these agencies have developed ERS with defined financial bonuses for consistently meeting performance, and penalties for failure to meet the in-place requirements. If performance is lower than a certain threshold, removal can be required. Regardless, of the type of performance specification adopted, the acceptance criteria and the responsibilities of the various parties in cases of failure need to be clearly defined.

While there are many types of aggressive exposures which could potentially require a multitude of durability tests, for resistance in all aggressive exposures the “permeability” or fluid penetration resistance of concrete needs to be minimized. Therefore, adoption of one or more tests for measuring fluid penetration resistance is fundamental to ensuring durable concrete.

Most deterioration processes involve two stages. Initially, aggressive fluids (water, ionic solutions with dissolved salts, gases) need to penetrate or be transported through the capillary pore structure of the concrete to reaction sites (e.g., chlorides penetrating to reinforcement, or sulfates penetrating to reactive aluminates) prior to the actual chemical or physical deterioration reactions. Therefore, a standard acceptance test or tests to measure rates of ingress of aggressive fluids, or a related rapid index test, is fundamental to the development of performance-based durability specifications. However, before tests are adopted in specifications, they must not only be shown to be useful and reliable, they must also be standardized and should include precision data based on interlaboratory evaluations (as is required for ASTM test methods), in order to set realistic specification limits that take account of test variability. Many tests have been proposed by researchers, but only a few have been found to be sufficiently robust to be adopted in recognised standards. Some interlaboratory data on non-destructive tests of concrete cover quality have been published (10, 11).

However, to be effective, the relevant mechanisms of fluid ingress for the environmental exposure of the structure or of specific structural elements need to be determined and appropriate test methods need to be adopted. Potential transport mechanisms include capillary absorption, diffusion, permeability and wick action, all of which are time-dependent. Many service life models only account for diffusion, but that is only one mechanism of chloride ingress. Capillary absorption into unsaturated near-surface zones can allow rapid ingress of dissolved ions in the so-called convection zone of the concrete cover. In some cases, pressure heads are also involved so permeability will also accelerate ingress. In the cases of tunnel liners, pipes, and slabs-on-grade, wick action from the air boundary can evaporate water from the near-surface capillary pores, leaving behind a buildup of precipitated chloride salts (12, 13, 14).

Test methods related to measurement of various durability properties exist in various North American standards (e.g. CSA, ASTM, AASHTO, US Corps of Engineers (CRD), and individual Departments of Transportation (DOT) in North America). Limits based on some of these test methods are specified in ACI, CSA and individual DOT specifications, amongst many others. Currently, standard test methods and/or limits do not exist for all of the relevant durability or performance concerns. As well, existing test methods are not always sufficiently rapid, accurate, or repeatable, nor do they necessarily adequately represent any or all of the in-situ exposure conditions. The lack of adequate performance-related test methods for concrete is one of the main factors that inhibit the move from prescriptive to performance specifications.

Limits on specific penetration resistance properties such as bulk chloride diffusion (ASTM C1556 (15), Nordtest NT Build 443 (16)), and water sorptivity (ASTM C1585 (17)) may be suitable for adoption in HPC specifications during pre-qualification and as inputs into predictive service life models, they are too time consuming to be used for acceptance purposes. For acceptance testing, a rapid permeability-index test should also be tested during prequalification and limits set that relate to the desired limits in the diffusion and sorptivity tests. Such rapid index tests include the ASTM C1202 (18) that was adopted in the CSA A23.1 concrete specification (19), the Rapid Chloride Migration Test (Nordtest NT492 (20) or AASHTO TP-64 (21)), a resistivity test (22, 23), or a chloride conductivity test (24). Because it is relatively simple, rapid and due to familiarity with its use, the ASTM C1202 test has become widely used for this purpose in North America. However, there is current activity at ASTM to adopt much simpler surface and bulk resistivity tests that may eventually replace the C1202 test. Many of these test methods are discussed by Lane et al (25).

In 2004, the Canadian CSA A23.1 concrete standard (19) introduced limits for the ASTM C1202 rapid chloride penetration test for prequalification of concrete mixtures to meet (a) C-1 exposure conditions (concrete exposed to freezing in a saturated condition with de-icer salts, 35 MPa, air-entrained, 0.40 w/cm max.) of 1500 coulombs at 56 days, and (b) C-XL exposure (similar exposure as the C-1 but where extended service life is required, 50MPa, air-entrained, 0.37 w/cm max.) of 1000 coulombs at 56 days. These limits effectively mandated the use of either blended cements or SCM's in all such concretes since 100% Portland cement concretes would be unable to meet these limits. The limits were originally set at 56 days of age to allow concretes containing slag or fly ash, that develop their properties more slowly, to be able to meet them, and have recently been revised to allow up to 91 days.

CSA A23.1 [19] includes statistical limits for acceptance purposes. The CSA coulomb limits were originally intended for prequalification, so notes were added that the 1500 coulomb requirement for Exposure Class C-1 an average value with no single result to be greater than 1750 coulombs. Similar wording was added for the high-performance C-XL Exposure Class concrete, except with different coulomb values (average of 1000, with no single value to exceed 1250). The 2014 revision of CSA A23.1 has moved these notes into the body of the specification. It is expected that the next revision will include a much simpler and less costly bulk resistivity test method and limits that will likely replace the C1202 test.

### **2.3. Identity tests and the monolith approach**

A challenging issue in implementation of performance specifications is the establishment of identity tests to confirm, at the start of a contract, that the concrete mixture being delivered is the correct one. Of necessity, these tests need to be done at the point of discharge from the truck and provide immediate confirmation that the mixture is essentially the same as the pre-qualified one. So how can it be determined that the measured slump, density, and air content, even if they are in the approved range, actually represent the concrete pre-qualified by the supplier to meet the specified strength and durability criteria? In connection with pre-qualification and constructability tests made by the authors for a proposed nuclear power station, casting of a pre-concreting monolith test procedure has been used (26). A similar performance approach was also developed for a series of underground transit stations). In these trials an insulated one cubic meter cube, suitably instrumented with thermocouples, was used as a pre-construction approval process. Specified performance criteria based on data and cores extracted from the monolith, were compressive strength, impermeability, freeze-thaw resistance, maximum temperatures, and temperature gradients. There are no instant tests for most of these properties so the monolith approach allows the Owner's design professional to check all the specified properties of the mixture that the contractor proposes to use. The sketch in Figure 1 shows a cross section of the monolith with locations of thermocouples. If needed to better determine thermal gradients, additional thermocouples can be added. The form is insulated so that curing is similar to the internal conditions in the mass concrete base slab. For this project compression tests up to 120 days were required, plus testing of in-place entrained air void systems, in-place rapid chloride permeability, and temperature gradients and maxima at all locations. The in-place tests were made on cores drilled from the monolith at different ages. On behalf of the owner the fabrication, concrete placing, compaction and curing can be witnessed. The owner can then make the tests on the concrete listed above and confirm that the concrete meets all strength and durability requirements. From then on the total responsibility for the quality of concrete delivered placed and cured rests with the contractor and the concrete supplier. This approach requires significant lead time, typically in excess of 3 months, but on most infrastructure contracts this is typically not a problem.

**Figure 1. Sketch of insulated one cubic metre monolith used for pre-qualification of concrete mixtures, showing locations of thermocouples (TC) (26)**

#### **2.4. Roles and Responsibilities in Performance Specifications**

Adoption of true performance-based specifications presupposes that we have a clear understanding of all the performance issues that can affect concrete. It also assumes that there are appropriate performance test methods in place to evaluate all of the performance issues for: concrete materials, fresh concrete, hardened concrete, and durability. It also assumes that performance can either be measured in time to affect the outcome, and/or can be used to pre-qualify concrete mixtures. Most parties to construction are familiar with testing for fresh properties and strength of concrete, but the biggest challenges in this regard relate to requirements for durability (27, 28, 29).

While there are many types of aggressive exposures which might require a multitude of durability tests, the common element is that most aggressive exposures require that the permeability or fluid penetration resistance of concrete be minimized. Therefore adoption of one or more tests for penetration resistance is fundamental to ensuring durable concrete.

The Canadian concrete standard CSA A23.1 (19) outlines the requirements and responsibilities for use in performance-based concrete specifications. The responsibilities of the various parties need to be clearly defined with a performance specification. This has been documented in CSA A23.1, as shown in Table 1. In addition, an Annex J to that standard explains each of the table items in more detail.

#### **2.5. Implementation of Performance Specifications**

The onus for meeting performance clearly rests with the producer up to point of placement. Since in-place performance is also affected by the contractor's placement methods, the producer must work with the contractor to ensure the owner's performance requirements are achieved: for example, the contractor (not the owner/specifier) should set the target slump to allow for proper placement and compaction for the situation, and the producer needs to design and provide this without reducing the intended performance of the hardened concrete.

Even if performance requirements are clearly stated in a specification, experience suggests that the successful implementation of a contract depends significantly on a dialogue between the contractors bidding for a contract and the Owner's design professional. Recent experience on a major HPC project suggests that where this requirement is established as an absolute and where there is constant and open communication across the construction team, all members will come to recognize the benefits of this approach.

A few important points are as follows:

- Require all contract bidders to attend a pre-bid meeting to hear about special requirements—so they cannot complain afterwards that they missed some of the performance requirements.

- Make contractors, including subcontractors, detail in their bid how they intend to meet the special requirements part of the bid submittal. eg. Concrete placement methods, protection, curing, hot/cold weather provisions.
- Do not accept low-price bids that are not responsive to the special requirements.
- Once work has commenced, require pre-pour meetings for important placements: The contractors, the suppliers, the subcontractors, including the finishers need to be aware of what needs to be done to ensure that the concrete can be delivered, placed, compacted, protected, finished, and cured to achieve the performance objectives. Even the person who will be fog misting, or applying other protective measures needs to be there to understand why it is important.
- During construction, the owner must be notified of any errors or problems without delay together with documentation and communication of the action being taken to rectify the problem.

Achieving the owner's performance requirements requires more cooperation between the concrete suppliers, the contractors, and concrete finishers than often exists in typical practice. As stated earlier, this type of information is detailed in Annex J of CSA A23.1(19).

## **2.6. Minimizing Construction Defects**

Construction detailing and practices as well as defects can significantly affect actual penetration rates of aggressive ions and fluids, but are rarely quantified or modeled. Almost no current service life prediction models can deal with the influence of cracks or the fact that concrete in the cover zone will almost certainly have a higher diffusion coefficient than the bulk concrete as the result of imperfect curing or compaction. An example of the variation in properties of similar bridge structures is given by Tikalsky et al (30).

It is the unpredictable areas of poorly compacted, poorly cured, or cracked concrete with less than the design depth of cover which will severely shorten the predicted the time to corrosion, regardless of what model is used. Therefore, one of the most effective ways to obtain the model-predicted service life of a structure is to address these site issues prior to and during construction. Pre-construction and pre-pour meetings mentioned previously are effective in ensuring that the contractor and sub-contractors understand the issues and have the required labor, materials and equipment on site to ensure best practices are followed.

As well, inspection of formwork placement and reinforcement cover depths prior to each placement of concrete can be used to correct areas of low cover deficiencies. In probability-based models, a common approach is to assume an average and range of properties such as concrete cover depth. But by correcting cover deficiencies prior to concrete placement, the variability in predicted service life can be significantly reduced. For example at the newest parking garage at Toronto's Pearson airport, this process of inspection prior to placement led to a standard deviation in cover depth of only 3 mm over a huge deck area (Figure 2) (the specified cover was 40 mm), significantly below the CSA A23.1 (19) allowable variation of 10 mm (31).

The ability to adequately place, vibrate and compact concrete in areas of congested reinforcement also needs to be established, preferably with test of mock ups but also by letting the contractor select the required workability required for the situation given the available equipment and labour. The concrete supplier can then design appropriate mixtures for the contractor's required workability. To address compaction and curing, cores extracted from the in-place concrete can be tested to assess the in-place performance of the final structural element (to avoid drilling cores from precast elements, extra elements for coring can be cast with the structural elements).

Early-age cracking can results from inadequate protection of plastic concrete, restrained drying shrinkage and from thermal gradients. Cracks wider than 0.05 to 0.10 mm have been shown to accelerate chloride ingress (36, 37). Therefore, in design detailing, mix proportions and construction practice, emphasis must be placed on minimizing cracking as well as the widths of cracks.

**Table 1. Prescriptive vs Performance Specification Responsibilities (adapted from CSA A23.1) (19).**

Alternative	The owner shall specify	The contractor shall	The supplier shall
<p><b>Performance:</b></p> <p>When the owner requires the concrete supplier to assume responsibility for performance of the concrete as delivered and the contractor to assume responsibility for the concrete in place.</p>	<p>(a) required structural criteria including strength at age;</p> <p>(b) required durability criteria including class of exposure;</p> <p>(c) additional criteria for durability, volume stability, architectural requirements, sustainability, and any additional owner performance, pre-qualification or verification criteria;</p> <p>(d) quality management requirements (Annex J)</p> <p>(e) whether the concrete supplier shall meet certification requirements of concrete industry certification programs; and</p> <p>(f) any other properties they may be required to meet the owner's performance requirements.</p>	<p>(a) work with the supplier to establish the concrete mix properties to meet performance criteria for plastic and hardened concrete, considering the contractor's criteria for construction and placement and the owner's performance criteria;</p> <p>(b) submit documentation demonstrating the owner's pre performance requirements have been met; and</p> <p>(c) prepare and implement a quality control plan to ensure that the owner's performance criteria will be met and submit documentation demonstrating the owner's performance requirements have been met.</p>	<p>(a) certify that the plant, equipment, and all materials to be used in the concrete comply with the requirements of this Standard;</p> <p>(b) certify that the mix design satisfies the requirements of this Standard;</p> <p>(c) certify that production and delivery of concrete will meet the requirements of this Standard;</p> <p>(d) certify that the concrete complies with the performance criteria specified;</p> <p>(e) prepare and implement a quality control plan to ensure that the owner's and contractor's performance requirements will be met if required;</p> <p>(f) provide documentation verifying that the concrete supplier meets industry certification requirements, if specified; and</p> <p>(g) at the request of the owner, submit documentation to the satisfaction of the owner demonstrating that the proposed mix design will achieve the required strength, durability, and performance requirements.</p>

#### 4. Conclusions

Achieving durability requires more than selecting an appropriate concrete mixture, construction practices and details also impact durability. In addition, performance specifications, making use of appropriate durability tests and limits, can help in the achievement of durable structures. While far from perfect, use of performance approaches in durability design is a step forward. Such approaches are being used successfully in large infrastructure projects and serve to focus attention on the whole construction process and not just on the concrete mixture being supplied. To achieve durability in the completed structure, designers, contractors and suppliers need to effectively communicate and work together to resolve problems quickly, to minimize defects, and to adopt adequate, yet achievable, curing procedures.

To quantify durability in chloride exposures, there have been impressive achievements in the development of predictive service-life models in the last 25 years. This is especially true in the area of time to onset of reinforcement corrosion where models have developed far beyond application of very simplistic Fick's 2<sup>nd</sup> Law methods to much more sophisticated multi-mechanistic, time-dependent, probabilistic transport models. Test methods have been developed to provide input values for these models, but often these tests are time-consuming, making them unsuitable beyond prequalification purposes. Some of these tests also suffer from high levels of variability. Faster, more reliable test methods will provide better predictions and will be better suited for quality assurance purposes during construction. In the meantime, rapid index tests for resistance to chloride ingress can be used for that purpose.

#### 4. Acknowledgements

The author would like to thank Dr. John A. Bickley, retired consultant, for ideas and useful discussions. As well, the support for the Author's Natural Sciences and Engineering Research Council of Canada / Cement Association of Canada, Industrial Research Chair in Concrete Durability and Sustainability, is greatly appreciated.

# Exp-Ref: A Simple, Realistic and Robust Method to Assess Service Life of Reinforced Concrete Structures

Roberto Torrent

Technical Director, Materials Advanced Services Ltd.

**Abstract:** The hereby proposed “Exp-Ref” method of Service Life Assessment presents two characteristic features. First, it is “Experimental”, because the prediction is based on the “in situ” ND determination of the cover depth  $d$  and of the coefficient of air-permeability  $kT$ . Second, the assessment is not based on a prediction starting from  $t=0$  as most other methods, but from a “Reference” condition corresponding to 50 years. This is the service life expected if the prescriptions of concrete quality (EN206-1 and EN 13670) and cover depth (Eurocode 2) are observed. By comparing the actual values of  $d$  and  $kT$  measured on site with those corresponding to the reference condition, it is possible to estimate the service life (SL) with the simple formula  $SL = \alpha \cdot d^2 / kT^{1/3}$ , with  $\alpha = f(\text{chloride exposure condition})$ . The proposed method is simple and realistic (is based on real data obtained on the end-product, referred to values for 50 years of SL) and is robust (neither ambiguities nor subjectivity by selective choice of model parameters as for other methods). It provides also a probabilistic representation of SL as a single value is assigned to each measurement point. A couple of application cases are presented.

**Keywords:** Service life, assessment, chlorides, cover, permeability.

## 1. Introduction: the Need for Service Life Assessment

Traditionally, Concrete Codes and Standards have applied the “Deemed-to-satisfy” approach [1] to specify durability requirements. Based on the accumulated experience in many countries, a set of primarily prescriptive rules has been established which, when rigorously observed, should result in a service life typically of 50 years (e.g. [2,3]). This applies also to codes that have adopted a more performance oriented approach, such as Australian and Swiss Standards [4-6].

Important structures, such as the Panama Canal and the Chacao Bridge (Chile) present a design Service Life of 100 years, reaching 120 years for the Hong Kong-Zhuhai-Macao Bridge (China), 150 years for the Port of Miami Tunnel (USA) and even 300 years for the 2<sup>nd</sup> Gateway Bridge in Brisbane (Australia).

All the above listed structures have something in common: the design should contemplate sufficient resistance against one of the most insidious deterioration problems of reinforced concrete structures, namely chloride-induced steel corrosion, for an extended service life well beyond 50 years.

These service lives clearly exceed the reach of existing experience with reinforced concrete and, therefore, some extrapolation via modeling is required for their design.

## 2. Modeling Chloride Ingress with Diffusion Fick’s 2<sup>nd</sup> Law

Most Service Life (SL) prediction models for chloride-induced steel corrosion assume that the penetration of chlorides into the exposed concrete follows a purely diffusive mechanism, governed by 2<sup>nd</sup> Fick’s Law which, for uniaxial flow is given by Eq. 1.

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} \left( D \frac{\partial C}{\partial x} \right) \quad (1)$$

Where  $C = C(x,t)$  is the concentration of chlorides in concrete at depth  $x$  and time  $t$  and  $D$  is the coefficient of diffusion to chlorides, expressed in  $[L^2]/[t]$  units, typically  $m^2/s$ .

Assuming that  $D$  is constant, i.e. independent of  $x$ ,  $C$  and  $t$ , and that the initial concentration of chlorides in the concrete mix is 0, an explicit solution, given by Eq. 2 can be derived.

$$C(x, t) = C_s \left[ 1 - \operatorname{erf}\left(\frac{x}{\sqrt{D \cdot t}}\right) \right] \quad (2)$$

$C_s$  = concentration of chlorides at the surface of concrete (assumed constant with time)

$\operatorname{erf}$  = error function

Eq. 2 is at the root of the most widespread models to predict service life.

From Eq. 2, the corrosion Initiation Time  $t = T_i$ , at which the concentration of chlorides  $C$  reaches a certain critical threshold value  $C_{cr}$  at the depth  $x$  equal to the rebar cover depth  $d$ , can be calculated. This Initiation Time  $T_i$  is commonly assumed as the limit state for the Service Life Design.

By making  $C(x, t) = C_{cr}$  at  $x = d$ , the initiation time  $T_i$  can be computed from Eq. 2, as:

$$T_i = \frac{d^2}{4 \cdot D} \cdot A^2, \quad \text{with} \quad (3)$$

$$A = \frac{1}{\operatorname{erf}^{-1}\left(1 - \frac{C_{cr}}{C_s}\right)} \quad (4)$$

where  $\operatorname{erf}^{-1}$  is the inverse error function.

Despite the fact that Eqs. 2 to 4 were derived assuming that  $D$  is constant, many models assume that the coefficient of diffusion of chlorides in concrete decreases with time (a fact that has been observed experimentally). The main justification for this phenomenon is the densification of concrete due to the hydration of cement at ages beyond that considered for the tests to measure  $D$  (typically 28 days). This is expressed as:

$$D = D_0 \left(\frac{t_0}{t}\right)^m \quad \text{for } t \leq t_h \quad (5)$$

where:

$D$  = coefficient of diffusion of chlorides at age  $t$

$D_0$  = coefficient of diffusion of chlorides measured at age  $t_0$

$m$  = exponent indicating the intensity of the "ageing" effect; if  $m = 0$ ,  $D$  is constant and not affected by age (only mathematically correct case)

$t_h$  = duration of the effect of hydration on the reduction of  $D$

The set of Eqs. 3 to 5 constitutes the core of the more widely used models to predict Service Life against chloride-induced corrosion: Life-365 [7], Duracrete [8], Duracon [9] and EHE-08 [10].

### 3. Limitations of Current Models

#### 3.1 Uncertainty of key parameters

Models based on the application of Eqs. 3 to 5 find application during the design stage, to make a preliminary SL assessment. As a result of their application, the durability design leads to the selection of the associated design variables  $d$  and  $D$  (or  $D_0$ ). The mix design should propose mixes that achieve the required  $D_0$  value used in the design and a binder compatible with the  $m$  and  $t_h$  values used in Eq. 5.

One of the limitations of the current models is the difficulties associated with the definition of key parameters  $C_s$ ,  $C_{cr}$ ,  $m$  and  $t_h$ , for the structure under design.

The validity of the power decay function (Eq. 5) and of the exponent  $m$  values proposed is a subject of much uncertainty and controversy [11,12]. In particular, the effect of  $m$  on  $T_i$  is "dramatic" [13]. The duration of the effect  $t_h$  is also controversial; Life-365 [7] proposes a maximum duration of 25 years, other models [8-10] extend the duration to the entire initiation time  $T_i$  of the structure. The experimental determination of  $m$  is difficult, due to the long-term nature of the exponent. Therefore it is not possible to count with representative values of  $m$  and  $t_h$  at the time of the SL design.

The factor  $A^2$  has also an important influence on  $T_i$  as shown in Fig. 1, where its relation to the ratio  $C_s/C_{cr}$  is presented. As shown in the figure, different models propose widely different values of  $C_s$  and  $C_{cr}$  (for Tidal and Spray exposure) and of their ratio, which have a strong effect on the SL designed.

**Figure 1. Effect of  $C_s/C_{cr}$  ratio on factor  $A^2$  (for Tidal and Splash Exposure)**

Hence, the rather arbitrary and sometimes subjective choice of key parameters  $C_s$ ,  $C_{cr}$ ,  $m$  and  $t_h$ , when applied to Eqs. 3 to 5, may lead to huge differences in the predicted service life, even to absurd results, such as  $1.5 \cdot 10^{29}$  years, which makes the Models non robust and extremely user-dependent.

### 3.2 Design and Real values of $d$ and $D_0$

As mentioned above, the SL design results in a selection of  $d$  and  $D_0$  values that satisfy the design Initiation Time  $T_i$  required by the project.

The cover depth  $d$  is usually specified in the project documents, as a minimum or nominal value and  $D_0$  is associated to the coefficient of diffusion measured by long-term tests (e.g. [14]), or by short-term migration tests (typically [15]), on laboratory-cast specimens, after 28 or 56 days of moist curing.

It is well known that the real values of  $d$  and  $D_0$  in the “as-built” structure are usually quite different to the ones assumed for the design or measured on laboratory specimens.

Neville [16], among others, has pointed out the differences (often on the unsafe side) between the specified and the real values of cover depth. From Eq. 2, we see that 10% less cover means 20% less service life.

The loss of quality, in terms of resistance to chloride penetration, of the real concrete (“Realcrete”) compared with that measured on laboratory specimens (“Labcrete”) has been well documented. Several laboratory and site investigations have shown that the transport parameters of the Realcrete may be significantly worse than those obtained on the Labcrete [17], due to segregation, lack of curing and the inevitable scale differences between treating a small specimen and a large structure.

Even when considered by coefficients (e.g. curing factor in Duracrete), the modeling will hardly consider the different and extremely variable quality of Realcrete.

## 4. The “Exp-Ref” Method

The proposed “Exp-Ref” Method for SL assessment aims at solving some of the limitations of the current methods, discussed in Section 3. As suggested by its name, it has two components:

Exp: It is based on the non-destructive “Experimental” assessment of  $d$  and  $D_0$  (indirectly through the measurement of the coefficient of air-permeability  $kT$ ), to get realistic values of the “Realcrete” quality

Ref: The method defines a “Reference” situation, established as a “deem to satisfy” condition, on which the SL prediction for different conditions is based.

A full description of the hypotheses and derivation of the formulae used to predict  $T_i$  from measured values of  $kT$  and  $d$ , can be found in [18]. In what follows, just the the fundamental concepts are presented.

#### 4.1 The Experimental Component of “Exp-Ref”

The principle consists in sampling the exposed surface of a concrete structure and, at the selected points, to measure non-destructively (using Standardized methods), both the cover depth  $d$  (e.g. [19]) and the coefficient of air-permeability  $kT$  [20], preferably at an age between 28 and 90 days. An experimental relationship (see Eq. 8) is used to transform the  $kT$  values into equivalent  $D_0$  values. Fig. 2 shows a possible arrangement of the readings, including the measurement of the moisture content of the concrete ( $m\%$ ) which, according to [20] shall not exceed 5.5% when measured by the electrical impedance method.

Figure 2. Arrangement of ND measurement of  $kT$  and  $d$ , after the Exp-Ref Method

#### 4.2 The Referential Component of “Exp-Ref”

In order to avoid the need to define the elusive key parameters  $C_s$ ,  $C_{cr}$ ,  $m$  and  $t_h$  for the prediction, a reference situation is assumed, for the exposure situation under consideration.

The concept is outlined in Fig. 3, based on the EN Codes and Standards.

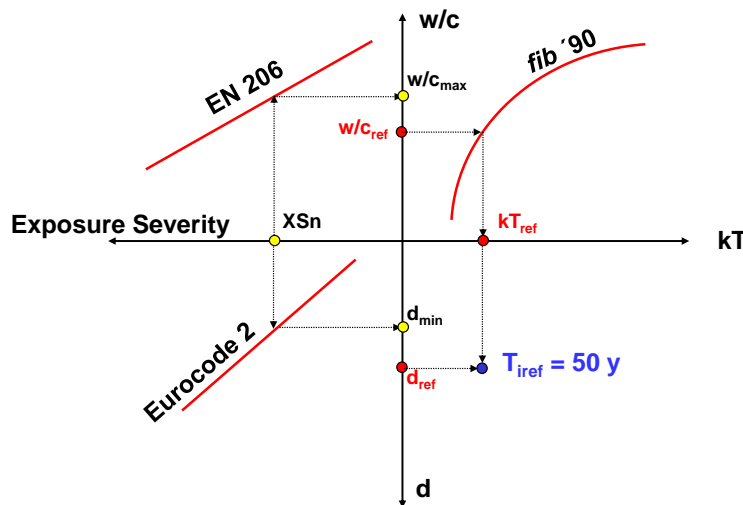

Figure 3. Concept of the Reference Condition in “Exp-Ref” Method

For the Exposure Severity of the Structure (e.g. XS3), the maximum  $w/c$  ratio and minimum cover depth  $d$  are obtained from EN 206-1 and Eurocode 2 (for 50 years SL), respectively. The reference values of  $w/c$  and  $d$  are the target values aimed at to satisfy these limiting values:  $w/c_{ref} = w/c_{max} - 0.02$  and  $d_{ref} = d_{min} + 10 \text{ mm}$ .

The relation between gas permeability and  $w/c$  ratio proposed in the CEB-FIP Model Code 1990 [21], applicable to air-permeability  $kT$ , is used to convert the  $w/c_{ref}$  value into a  $kT_{ref}$  value (Eq. 6):

$$\log kT_{ref} (\text{m}^2) = -19 + 5 \cdot w/c_{ref} \quad (\text{Eq. 2.1-107 of [21]}) \quad (6)$$

A point of the concrete structure, on which the values  $kT_{ref}$  and  $d_{ref}$  have been measured, is expected to have 50 years of service life. If the  $kT$  value measured is lower than  $kT_{ref}$  and/or the  $d$  value measured is higher than  $d_{ref}$ , the SL life estimated at the point will be longer than 50 years.

### 4.3 Relation between $kT$ and $D_0$

Any attempt to use values of air-permeability measured on site to predict service life of concrete exposed to chlorides requires a relation between  $kT$  and the coefficient of chloride diffusion  $D_0$ .

Results of  $kT$  and  $D_0$  (measured under  $\text{Cl}^-$  ponding/immersion long-term tests) are plotted with black symbols in Fig. 4. The empty circles in Fig. 4 correspond to  $kT$  and Coulomb ASTM C1202 [22] values available in the literature [23]. The Coulomb values were converted into  $D_0$  applying the following formula, established at Purdue University [24]:

$$D_0 (10^{-12} \text{ m}^2/\text{s}) = 0.4 + 0.002 \cdot \text{Coulomb} \quad (7)$$

Figure 4. Relation between  $D_0$  and  $kT$

A relation between  $kT$  and  $D_0$  has been fitted to the values in Fig. 4, of the form:

$$D_0 = 10 \cdot kT^{1/3} \quad \text{with } D_0 \text{ in } (10^{-12} \text{ m}^2/\text{s}) \text{ and } kT \text{ in } (10^{-16} \text{ m}^2) \quad (8)$$

### 4.4 Calculation of Service Life with “Exp-Ref” Method

Combining Eqs. 3, 5 and 8 we have:

$$Ti = \frac{d^2}{4.10 kT^{1/3} (t/t_0)^m} A^2 \quad (9)$$

Applying Eq. 9 to the reference condition:

$$Ti_{ref} = \frac{d_{ref}^2}{4.10 kT_{ref}^{1/3} (t/t_0)^m} A^2 \quad (10)$$

Now, we can assume that  $C_s$ ,  $C_{cr}$  (and therefore  $A$ ),  $m$  and  $t_h$  are the same for the reference (50 y) and the Service Life condition (e.g. 100 y). So, dividing Eqs. 9 and 10 and rearranging:

$$Ti = Ti_{ref} \cdot \frac{d^2}{d_{ref}^2} \cdot \frac{kT_{ref}^{1/3}}{kT^{1/3}} \quad (11)$$

and making

$$\alpha = Ti_{ref} \cdot \frac{kT_{ref}^{1/3}}{d_{ref}^2} \quad (12)$$

The calculation of Service Life with the Exp-Ref Method is done through the simple formula:

$$Ti = \alpha \cdot \frac{d^2}{kT^{1/3}} \quad (13)$$

Where:

$Ti$  = Corrosion Initiation Time (years), usually assumed as the Service Life

$d$  = cover depth (mm)

$kT$  = coefficient of air-permeability ( $10^{-16} \text{ m}^2$ )

$\alpha$  = factor depending on the Exposure condition of the structure (see Table 1)

**Table 1. Values of factor  $\alpha$  for different Exposures and intermediate variables:  $Ti_{ref} = 50$  years**

Indicator	Environmental Aggressivity (Exposure Classes X)					
	Marine Chlorides			Other Chlorides		
	XS1	XS2	XS3	XD1	XD2	XD3
$w/c_{max}$	0.50	0.45	0.45	0.55	0.55	0.45
$d_{min}$ (mm)	35	40	45	35	40	45
$w/c_{ref}$	0.48	0.43	0.43	0.53	0.53	0.43
$kT_{ref}$ ( $10^{-16} \text{ m}^2$ )	0.25	0.14	0.14	0.45	0.45	0.14
$d_{ref}$ (mm)	45	50	55	45	50	55
<b><math>\alpha</math></b>	<b>0.0156</b>	<b>0.0104</b>	<b>0.0086</b>	<b>0.0189</b>	<b>0.0153</b>	<b>0.0086</b>

#### 4.5 “Exp-Ref” Method Application Examples

Two examples will be described, to show how the Exp-Ref Method can be applied.

##### Data from RILEM TC 230-PSC Application Test

Within the working program of Rilem TC 230-PSC [25], a series of reinforced concrete test panels were built with two different cements (OPC and Fly-Ash Cement) and two different w/c ratios, with one face of each panel having a nominal cover of 30 mm and the opposite face of 50 mm. All willing participants were asked to conduct ND measurements on the panels in order to predict their service life assuming them exposed to a XD3 environment (direct contact with chloride solution from deicing salts).

Two of the researchers worked on the panels at 3 months of age, measuring  $kT$  on at least 6 points randomly distributed across both panel surfaces. One of them also conducted measurements of  $d$  on the same locations, using an electromagnetic covermeter, as sketched in Fig. 1.

The values of  $d$  and  $kT$  obtained were used to compute the Initiation Time of corrosion for each location, applying Eq. 13, with  $\alpha = 0.0086$  (for XD3 exposure).

Fig. 5 presents the minimum, maximum and mean Initiation Time, estimated from the 6 pairs of data ( $d$  and  $kT$ ) obtained on each panel and nominal cover side. The cement type and w/c are indicated for each case.

The positive effect of a low w/c ratio and a higher cover depth are demonstrated by the corresponding longer Initiation Times.

Please, notice the large scatter of  $T_i$  obtained in some of the panels, which reflects the variability in permeability and cover depths within the panels.

Figure 5. Estimated Initiation Time for panels made with different cements, w/c and covers

## Data from Hong Kong-Zhuhai-Macao Bridge

Statistical data for the HK-ZH-MA Bridge, measured on precast sections of submerged elements, have been reported [26], including values of  $kT$  of  $d$ , as shown in Table 2.

**Table 2. Statistical distributions and parameters assumed for  $d$  and  $kT$  [26]**

Variable	Extrados Cover Depth $d$ (mm)	Air-Permeability $kT$ @ 56 days ( $10^{-16}$ m <sup>2</sup> )
Distribution	Normal	Log-Normal
Mean	Arithmetic: 73.4	Geometric: 0.069
Standard Deviation	3.9 mm	of $\log_{10}$ of $kT$ = 0.179

A Monte Carlo simulation was made calculating the  $T_i$  values, applying Eq. 13, assuming  $d$  and  $kT$  as independent variables, with the results shown in Fig. 6 for Exposures XS1 (atmospheric), XS2 (submerged) and XS3 (tidal/splash zone), using the corresponding  $\alpha$  values given in Table 1.

Fig. 6 shows the predicted  $T_i$  probability distributions for a structure showing the values of  $kT$  and  $d$  reported in Table 2, under different exposure conditions. It can be seen that the results are compatible with the 120 years design service life expected for the structure (XS2 submerged condition).

**Figure 6. Calculated Probability Distributions of  $T_i$  for different Exposures**

## 5. Conclusions

A review of the more widely used SL prediction approaches has been made, pointing out two weaknesses:

- The difficulties in establishing the values of key and elusive parameters used in the calculations, namely: Surface chloride concentration  $C_s$ , Critical chloride concentration  $C_{cr}$ , ageing exponent  $m$  and duration of the Chloride diffusion decay effect  $t_h$

- The fact that the design values  $d$  and  $D_0$  are theoretical, or obtained from test on laboratory specimens that are not representative of the “as-built” quality of the real structure

The proposed “Exp-Ref” method, based on “Experimental” ND site measurements of cover depth  $d$  and air-permeability  $kT$  solves the second weakness. By taking a “Reference” situation, corresponding to a SL of 50 years, the method avoids the need of defining the above mentioned elusive parameters, thus solving the first weakness. It is simple (Eq. 13), realistic (based on hard data measured experimentally on the as-built product) and robust (no subjective influence of users).

Obviously, same as for other prediction methods, it is not possible to claim that the corrosion initiation times will be exactly the ones calculated by the proposed method. However, the Exp-Ref method will pinpoint areas of dubious quality, where to place especial attention during monitoring/maintenance of the structure. It is a useful tool for documenting the “Birth Certificate” of a structure.

**Abstract:** The concrete immersed tube tunnel in the Hong Kong-Zhuhai-Macau (HZM) sea link project was designed for a service life of 120 years. The concrete tunnel is exposed externally to the sea water and internally to traffic and marine air. This paper reviews the durability design of this concrete sea tunnel and the key durability parameters retained for the structural concrete. During the construction, the concrete properties were tested in the laboratory and nondestructive tests were performed on the prefabricated segments of concrete tube. The quality of structural concrete is evaluated on the basis of these in-situ data and their statistical properties. Further the achieved durability of the immersed tube tunnel is assessed through Fick's law for chloride ingress via a fully probabilistic approach. The safety margin for structural durability is represented in terms of failure probability and reliability index. Based on the durability assessment in construction phase, a preliminary maintenance planning is given taking into account the accidental working case of sea water infiltration.

**Keywords:** HZM project, immersed tube tunnel, durability design, chloride ingress.

## 1. Introduction

The Hong Kong-Zhuhai-Macau sea link project includes sea bridges of 28.8 km (three navigable spans), two artificial islands and an immersed tube tunnel of 5.6 km, with a total investment more than 12 billion US dollars. One of the main technical requirements is to achieve the service life of 120 years for the concrete structures in an aggressive marine environment. The hydrology data show the chloride (Cl<sup>-</sup>) concentration is within 10700-17020 mg/L, the sulfate (SO<sub>4</sub><sup>2-</sup>) concentration is within 1140-2260 mg/L, and the total salinity is between 25.4-32.9 (sea bottom).

**Figure 1. Segment of concrete tube tunnel in prefabrication of HZM project.**

The immersed tube tunnel is made of four cast-in-place segments of 112.5m long and 27 prefabricated segments of 180m long, and these segments are connected by water-proof connections. Each prefabricated segment itself is composed of 8 sub-segments of 22.5m long and these sub-segments are made in the prefabrication factory near the HZM project site, cf. Figure 1. Once these sub-segments are cast and cured to predetermined age, they are linked together to form one tunnel segment by prestress tendons. The cross section of tunnel amounts to 11.4m high and 38m wide, and the thickness of the external wall is 1.5m. No special protection measures are designed for the external wall of tunnel tube, and the structural concrete in external wall is the only barrier to ensure the durability of the tunnel exposed directly to the sea water environment. This paper is to review the durability design of the immersed tube

tunnel, analyze the construction quality from the in-situ test data and evaluate the achieved durability of these tunnel tube segments. On the basis of the durability assessment, a preliminary maintenance planning is proposed for the tube tunnel for the 120 years of service life.

## 2. Durability model and requirements

### 2.1 Model for chloride ingress

The durability related processes of this tunnel include the concrete carbonation from internal surface, sulfate attack from sea water as well as the reinforcement steel corrosion by sea water infiltration. In the preliminary study phase these deterioration processes were investigated for their criticality and the chloride-induced corrosion of steel reinforcement was identified as the control process for durability design. The relevant durability design was performed through a model-based approach (1,2). The model for chloride induced corrosion is adapted from the widely used analytical model of Fick's second law (3,4). The durability limit state (DLS) is specified as the corrosion initiation of the reinforcement steel, and the design equation is written as,

$$G = (C_{cr} - C_0) - (C_s - C_0) \left[ 1 - \operatorname{erf} \left( \frac{x_d}{2\sqrt{D_{Cl}t}} \right) \right] \geq 0 \quad (1)$$

where  $C_{cr,s,0}$  stand for the threshold chloride concentration for steel corrosion, the concrete surface chloride concentration and the initial chloride concentration in concrete (in mass percentage of binders) respectively;  $x_d$  is the concrete cover thickness (m);  $D_{Cl}$  is the chloride diffusion coefficient of concrete ( $m^2/s$ );  $t$  is the exposure age of structural elements; and  $\operatorname{erf}$  is the mathematical error function. The chloride diffusion coefficient,  $D_{Cl}$ , is assumed to decrease with the concrete exposure age  $t$ ,

$$D_{Cl}(t) = D_{Cl}^0 \left( \frac{t_0}{t} \right)^n = D_{Cl}^0 \eta(t_0, t) \quad (2)$$

with  $n$  as the exponential coefficient for  $D_{Cl}$  decrease law and  $D_{Cl}^0$  the diffusion coefficient at concrete age  $t_0$ . The term  $\eta(t_0, t)$  is the ageing coefficient of diffusion coefficient. Physically, the decrease of  $D_{Cl}$  with time is attributed to the microstructure evolution due to long-term hydration of binders after concrete hardening (5). Since the densification process of concrete cannot last infinitely with exposure age the decrease law of  $D_{Cl}$  is truncated at  $t=30$  years to obtain conservative results. Thus this models contains six parameters totally:  $C_{cr}$ ,  $C_s$ ,  $C_0$ ,  $x_d$ ,  $D_{Cl}^0$  and  $n$ (or  $\eta$ ). Note that the  $D_{Cl}^0$  in this model corresponds to the long-term exposure condition and the design values for this coefficient are converted to rapid migration test values  $D_{Cl}^{NSSM}$  through correlation analysis, see (1).

### 2.2 Durability requirements for tube tunnel

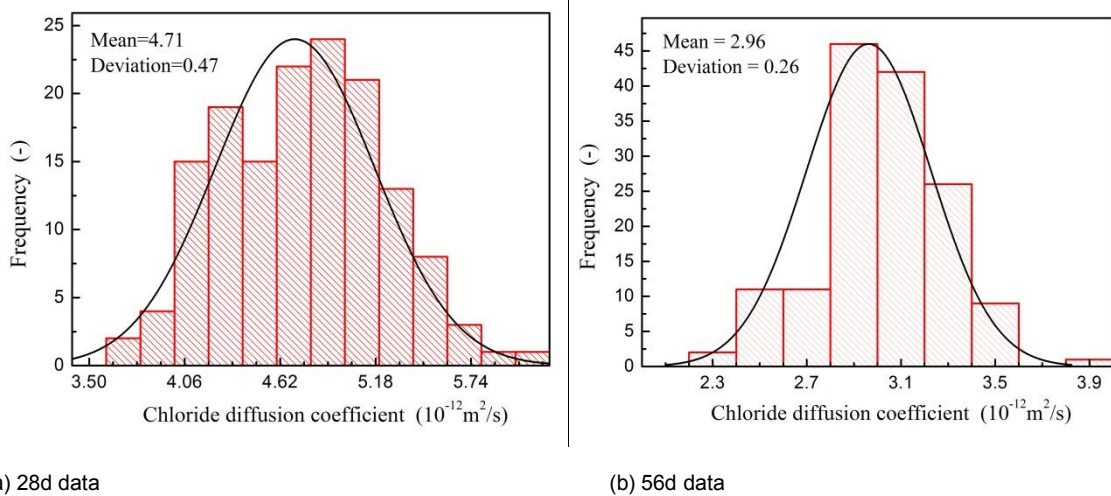

**Table 1. Durability requirements for structural concrete in tube tunnel segments.**

Condition and requirements	Tunnel intrados	Tunnel extrados
Exposure	Marine air (salty air)	Splashing
Design service life (year)	120	120
Durability limit state (DLS)	Steel corrosion initiation	Steel corrosion initiation
Concrete cover $x_d^{\min}$ (mm)	50	70
Concrete grade	C45	C45
Chloride diffusion coefficients ( $10^{-12} m^2/s$ )/28d	6.5	6.5
Chloride diffusion coefficients ( $10^{-12} m^2/s$ )/56d	4.5	4.5

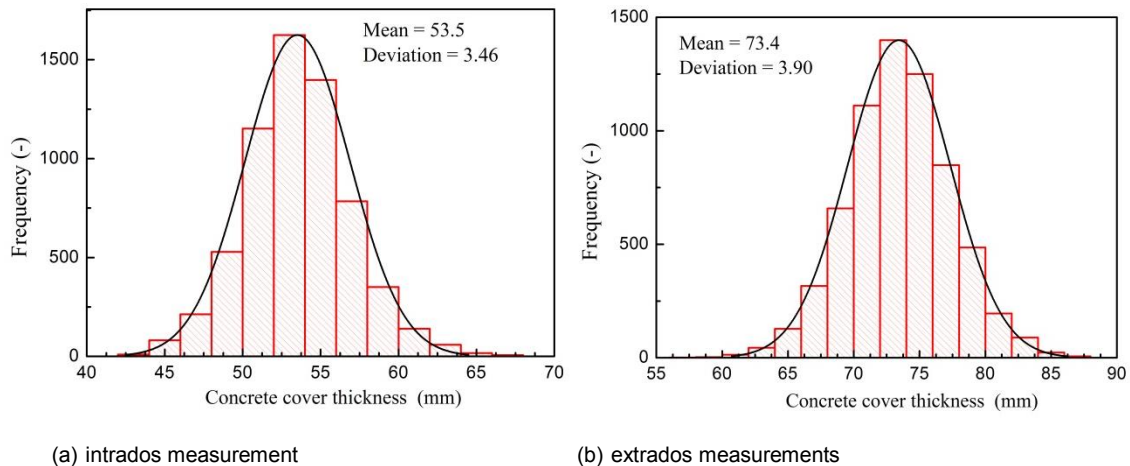

In the design phase, the model was used to specify the durability requirements for the tunnel tube segments through a fully probabilistic approach. The performance function was taken as Eq.(1) and the target reliability index was chosen as  $\beta=1.3$  for a service life of 120 years. Through Monte-Carlo simulations, the durability requirements were given in terms of the thickness of concrete cover and the chloride diffusion coefficient. The intrados of tunnel is exposed to traffic and a marine atmospheric

exposure condition is considered. For the extrados of tunnel, a splashing condition is considered since both the chloride in sea water and the oxygen in air can possibly be available to the reinforcement steel near the extrados, and the critical chloride concentration for corrosion initiation would be similar to the splashing condition. The detailed analysis can be found in the relevant publications (1,2). In Table 1 are summarized the retained durability requirements for the intrados and extrados of the tunnel segments. The tunnel concrete (C45) has a water to binder ratio  $w/b=0.36$ , and the binder materials contain ordinary Portland cement (50%), slag (30%) and fly ash (20%).

**Figure 3. Statistical analysis on the thickness of concrete cover for tunnel tube segments.**

### 3. Quality control for durability in construction

#### 3.1 Chloride diffusion coefficients

The in-situ data of chloride diffusion coefficient of structural concretes were collected from the on-site laboratory for the prefabricated tunnel segments. The chloride diffusion coefficients were measured on concrete specimens under standard curing conditions ( $20^{\circ}\text{C}$  and  $\text{RH} > 95\%$ ) at given ages, 28d and 56d, by rapid migration method (RCM) (6). The data are presented in Figure 1(a) and 1(b) for 28d and 56d measurements. A total of 296 sets of data are collected for 28d and 56d with 148 sets of data for each age. The target mean values for  $D_{\text{Cl}}^{\text{NSSM}}$  are respectively  $6.5 \times 10^{-12} \text{m}^2/\text{s}$  and  $4.5 \times 10^{-12} \text{m}^2/\text{s}$  for 28d and 56d according to the durability requirements in Table 1. One can see that the mean values of measured  $D_{\text{Cl}}^{\text{NSSM}}$  are  $4.68 \times 10^{-12} \text{m}^2/\text{s}$  (28d) and  $2.95 \times 10^{-12} \text{m}^2/\text{s}$  (56d), much lower than the required values. The dispersion, variation coefficient in statistical terms, of this  $D_{\text{Cl}}^{\text{NSSM}}$  is 9.9% (28d) and 8.7% (56d), smaller

than the expected level of 20% in design phase, especially for 56d age. This decrease of dispersion will help to reduce the uncertainty associated with the chloride diffusion coefficients.

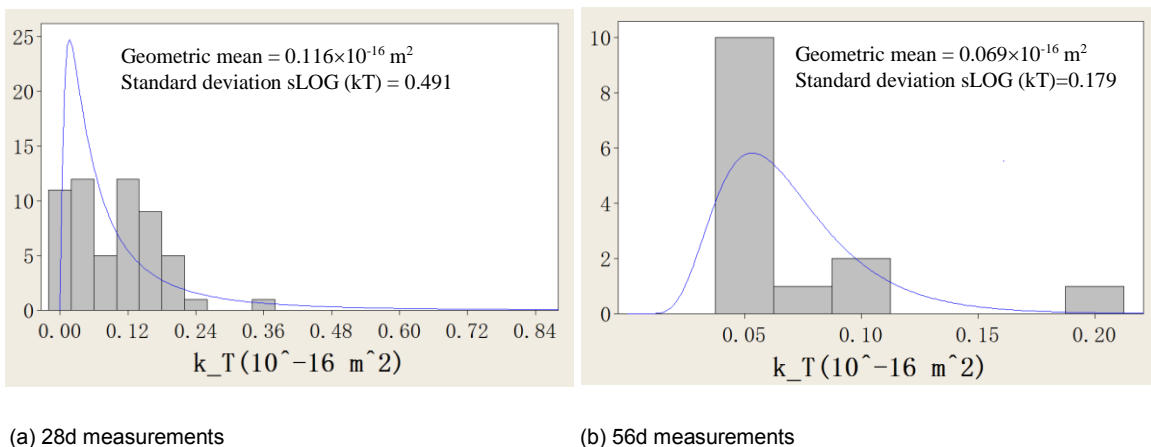

### 3.2 Concrete cover thickness

The measurements of concrete cover thickness are presented in Figure 3 for tunnel segments. The concrete cover was measured through the common midpoint (CMP) method and the principle of CMP method is to detect the depth of reinforcement bars through transmitting an electromagnetic wave pulse and receive the reflected waves from the steel bars by two adjacent antennas (7). The measurement error of the device used in HZM project is evaluated as around 3mm through the comparison with the measurement on extracted cores from test segments of tunnel in preliminary study.

Figure 3 illustrates the statistical analysis on the concrete cover thickness on the intrados and extrados of the tunnel segments. The data sets are 6,368 and 6,571 for intrados and extrados measurements respectively, thus sufficient to support a reliable statistical analysis. The required values for thickness are respectively 50mm (intrados) and 70mm (extrados). The analysis shows that the mean values are 53.5mm (intrados) and 73.4mm (extrados) and the construction error, corresponding to the distance between 5% percentile value and mean value, is 5.8mm (intrados) and 6.4mm (extrados), slightly larger than the expected construction tolerance, 5.0mm, for prefabricated elements.

### 3.3 Non-destructive tests: Air permeability

The NDT device of air permeability measurement used for prefabricated tunnel segments is the "Torrent Permeability Tester (TPT)", and its principle is to create a vacuum above the concrete surface and measure the steady flow of air coming through the concrete surface (8). The Torrent air permeability has been adopted by Swiss standard as the recommended method for in-situ concrete quality control (9). However, it should be noted that several factors can have important influence on  $k_T$  values, including the water content, hardening age and temperature of concrete surface. The results in literature show that extreme temperatures can also greatly affect  $k_T$  values (10) and the measurement temperature above 10°C was recommended (9). For these reasons, the air permeability measurements on the prefabricated segments were performed at 26d/56d ages with surface water content lower than 5.5% (measured by Tramex water content meter), as prescribed in (9).

**Figure 4. Lognormal statistics of air permeability measured at extrados of tunnel segments.**

From the in-situ measurement, a total of 56 data were obtained for 28d age and 14 data obtained for 56d age. The log-normal statistics of these two sets of air permeability data are given in Figure 4 with statistic parameters. The first observation on these data is that the  $k_T$  values are relatively low for the structural concrete, *i.e.* of the order of  $10^{-18} \text{ m}^2$ . Also, the 56d values are systematically lower than the 28d values. The dispersion of  $k_T$  values for 56d measurements is also quite low (sLOG below 0.2), according to Swiss experience [11]. It is interesting to note that both the geometric mean  $k_{Tgm}$  and sLOG compare well with results obtained on segments of the Port of Miami Tunnel ( $k_{Tgm}=0.57 \times 10^{-16} \text{ m}^2$  and sLOG=0.24 at 120d age), made with high-quality concrete [12], particularly when considering the two different brands of

instrument used in the investigations [13]. The correlation between the  $k_T$  values and the temperature, water content and hardening age of structural concrete is given in Figure 5. An analysis of the data shows that the changes in temperature (always above the critical 10°C) and water content (always below the critical limit of 5.5%), see Figure 5, do not influence significantly  $k_T$ . The dispersion is, therefore, the result of the inherent heterogeneity of structural concrete in different segments and sub-segments.

Figure 5. Correlation between  $k_T$  and temperature, water content and hardening age.

### 3.4 Non-destructive tests: Electrical resistivity

The principle of electrical resistivity measurement on concrete is to read the electrical current under a certain electrical potential. The resulted electrical resistivity reflects the pore space and its connectivity in concrete materials since the solid phases in concrete have very low electrical conductivity [14]. This measurement can be performed on both concrete specimens in the laboratory and concrete surfaces in project site. As air permeability, the electrical resistivity has also been regarded as a durability indicator for structural concrete. The device of electrical resistivity used is the Wenner probe that comes as accessory to the TPT instrument.

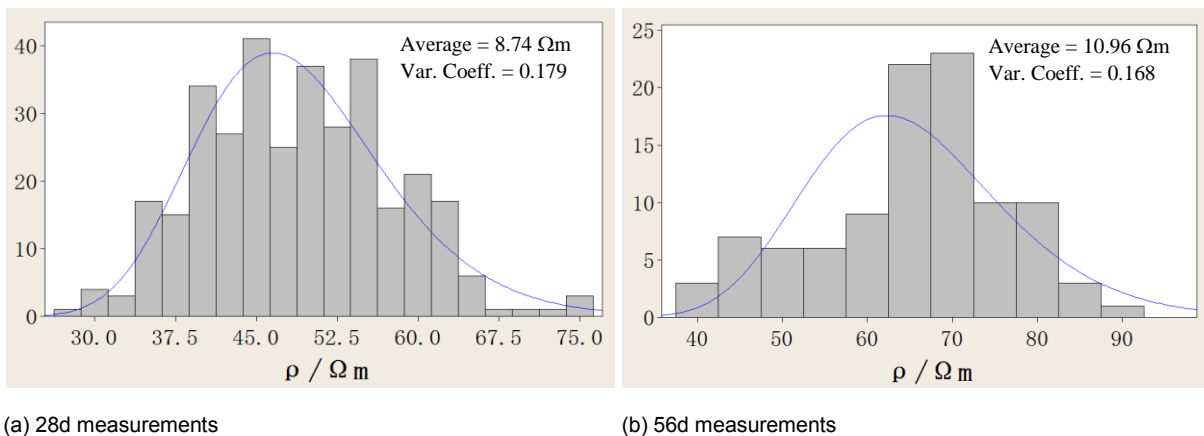

Figure 6. Statistics of electrical resistivity at 28d and 56d.

A total of 686 data were obtained for Wenner electrical resistivity on four tunnel segments for hardening ages from 3d to 56d. The log-normal distribution statistics of these data for hardening ages, 28d and 56d, are illustrated in Figure 6 with the corresponding statistical parameters. The first observation is that these values increase constantly with hardening age, which is related to both the densification of pore structure of concrete during hardening and the moisture drying on the concrete surface. Then, the values of

electrical resistivity values are relatively stable and show low variability with variation coefficient around 15% since age of 7d.

From the above figure, the resistivity values show a log-normal distribution. Certainly, the temperature, hardening age and water content all have impact on the resistivity measurement values, and their correlation is illustrated in Figure 7. It can be seen that the values are more correlated to hardening age, and less to other factors. The increase of electrical resistivity  $\rho$  with age is due to two mechanisms: the more compact microstructure of concrete achieved by further hydration with age, and the reduced water content resulting from evaporation.

Figure 7. Correlation between  $\rho$  and temperature, water content and hardening age.

#### 4. Durability assessment of tube tunnel

##### 4.1 Probabilistic assessment of durability

The model in Eqs.(1) and (2) is used to evaluate the durability performance with respect to the chloride ingress process through a fully probabilistic approach. To this purpose, the statistical properties of the model parameters, chloride diffusion coefficients  $D_{Cl}^0$  and concrete cover thickness  $x_d$ , obtained in the previous section are taken into account. Other model parameters, surface chloride concentration  $C_s$ , critical concentration  $C_{cr}$ , exponent coefficient  $n$ , adopt the same distributions as in the preliminary study phase, cf. Table 2.

Table 2. Statistical properties of durability parameters for probabilistic durability assessment.

Parameter (distribution)	Statistical properties	Extrados (splashing)	Intrados (Atmopsheric)
Initial chloride content $C_0$ (Rectangle)	Lower limit (%)	0.02	0.02
	Upper limit (%)	0.04	0.04
Surface concentration $C_s$ (Lognormal)	Average (%)	5.76	2.10
	Deviation (%)	0.86	0.32
Critical concentration $C_{cr}$ (beta)	Lower bound $L$ (%)	0.45	-
	Upper bound $U$ (%)	1.25	-
	Coefficient $\alpha$ (-)	0.22	-
	Coefficient $\beta$ (-)	0.36	-
Critical concentration $C_{cr}$ (Lognormal)	Average (%)	-	0.85
	Deviation (%)	-	0.13
Diffusion coefficient $D_{Cl}^0$ (Lognormal)	Average ( $10^{-12}$ m <sup>2</sup> /s)	4.71 (28d)	4.71 (28d)
	Coefficient of variance	9.8%	9.8%
Exponent coefficient $n$ (Normal)	Average (-)	0.47	0.53
	Deviation (-)	0.029	0.079
Concrete cover $x_d$ (Normal)	Average (mm)	73.4	53.5
	Deviation (mm)	3.90	3.46

The fully probabilistic analysis for the durability assessment is realized through Monte-Carlo simulations. A computer-based program is developed especially to perform the probabilistic assessment. In the simulation, six parameters are considered as joint occurrence random variables:  $C_{cr}$ ,  $C_s$ ,  $C_0$ ,  $x_d$ ,  $D_{Cl}^0$  and  $n$ . The statistical properties are presented in Table 2. For a given exposure age  $t$ , the Monte-Carlo simulations are performed to calculate the failure probability of Eq.(1), and 1,000,000 samplings are used to ensure the solution of “real” probability. Accordingly, the failure probability is solved with time from  $t=0$  to  $t=120$  years. The assessment results are presented in Figure 8 in terms of the failure probability with respect to corrosion initiation, for the intrados and extrados of tube segments. The assessment gives  $p_f=1.7\%$  and  $\beta=2.13$  for extrados and  $p_f=0.25\%$  and  $\beta=2.81$  for intrados at 120 years.

**Figure 8. Failure probability (corrosion initiation) of tube tunnel for extrados, intrados exposed to salt fog and intrados exposed to salt water infiltration (accidental scenario).**

In Figure 8 an accidental working case of sea water infiltration is also analyzed for the intrados. If sea water leakage occurs due to segment joint failure or local concrete permeability failure, the intrados will contact with liquid sea water and the splashing action should be considered. In Figure 8, the intrados is evaluated under splashing condition and the failure probability rises to 27% ( $\beta=0.59$ ) at 120 years. Accordingly, this accidental scenario should be monitored and the corresponding special maintenance actions should be planned.

#### 4.2 Preliminary maintenance planning

Following the analysis in Figure 8, this section investigates the maintenance planning for the accidental scenario of sea water infiltration. The only maintenance technique against the sea water infiltration is the installed cathodic protection in the tube segments. The following analysis is dedicated to the planning of the activation time of the cathodic protection in terms of the sea water infiltration intensity. The analysis is carried out in a rather engineering way and no physical model for the sea water leakage rate is included. Suppose the intensity of the sea water leakage can be represented by a ratio,  $\delta$  (-), between the area of intrados exposed to sea water infiltration and the whole intrados surface. In a straightforward way, the whole failure probability,  $p_t$ , of intrados is the addition of the two parts,

$$p_t(t) = \delta p_{sp}(t) + (1 - \delta) p_{air}(t) \quad (3)$$

where  $p_{sp,air}$  are respectively the time-dependent failure probabilities of intrados exposed to splashing action and to marine salty air. This global probability can be calculated from the results in Figure 7 for different infiltration area ratios. The analysis shows that a ratio of 10% intrados leakage will increase the failure probability to  $p_f= 3.0\%$  at 120 years and a ratio of 70% intrados leakage gives  $p_f=19.5\%$  at 120 years.

According to the state-of-the-art of the maintenance planning (15), different maintenance strategies can be adopted following different  $p_f$  values: The intervention at  $p_f=2\%$  corresponds to a preventive maintenance,  $p_f=5\%$  corresponds to a necessary strategy and  $p_f=20\%$  corresponds to a mandatory

maintenance. Early intervention of maintenance at low failure probability is considered cost-effective. The activation time of the cathodic protection corresponding to different  $p_f$  levels, from 1% to 20%, at intervention is illustrated in Figure 9. The activation times are around 65 years for preventive maintenance ( $p_f=2\%$ ) and 80 years for necessary maintenance ( $p_f=5\%$ ) for 100% infiltration area ratio.

**Figure 9. Maintenance planning for the activation time of cathodic protection in terms of intervention levels.**

## 5. Concluding remarks

(1) The concrete immersed tube tunnel in HZM project was designed for its durability of 120 years exposed to sea water and traffic/marine air. The durability requirements were specified from a model-based approach and involved mainly the cover thickness and the chloride diffusion coefficients of the structural concrete. The target reliability of the durability requirements was fixed to 1.3 at 120 years.

(2) The collected data included the measurements of chloride diffusion coefficients on concrete specimens, concrete cover thickness of prefabricated segments as well as the non-destructive test results of air permeability and electrical resistivity on the extrados of segments. The chloride diffusion coefficients showed less dispersed distribution than expected with the variation coefficient within 10%, and the statistics on concrete cover thickness gives a construction tolerance very near to the assumed value of 5mm. The air permeability results confirm that high compactness of the structural concrete in the segments. Both the air permeability and the electrical resistivity depend much on the hardening age and less related to the ambient temperature or the surface water content.

(3) The achieved durability of tube segments is evaluated on the basis of the collected data and their statistical properties in construction phase. A fully probabilistic approach is adopted and the Monte-Carlo simulations are used to calculate the failure probability with respect to the corrosion initiation DLS. The analysis gives  $p_f=1.7\%$  for extrados and  $p_f=0.25\%$  for intrados of segments, and the corresponding reliability index is much higher than the presumed reliability level ( $\beta=1.3$ ). The safety margin comes mainly from the lower and less dispersed chloride diffusion coefficients measured in the construction phase.

(4) An accidental scenario of sea water infiltration into the intrados of tube tunnel is considered in the analysis and the corresponding failure probability is as high as 27% at 120 years for the intrados. Thus this accidental working case should be monitored during service life. Following the analysis results, a preliminary maintenance planning is performed for this accidental case, and the cathodic protection activation times are calculated in terms of the infiltration intensity and the intervention  $p_f$  levels. In the most severe infiltration and most strict preventive planning, the activation time is estimated to around 60 years. By precaution, a minimum protection would be recommended once the tunnel is open to traffic.

**Abstract:** The precursors typically used for producing alkali-activated binders can be described within the CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub> system; however, depending on the source of the precursor, contents of different elements such as magnesium and iron can vary. In the case of alkali-activated slag binders, magnesium plays a significant role in formation and evolution of secondary reaction products, including layered double hydroxide (LDH) type phases, and consequently in the development of structural and physical properties of these materials. The formation of LDH can strongly affect the durability of alkali-activated slag binders, as it has the potential to chemically interact with aggressive agents such as CO<sub>2</sub> and chlorides. The inability to control key compositional parameters, due to the varying composition and mineralogy of commercial slags has made it difficult to isolate the effect of Mg on the structure and physical properties of alkali-activated materials.

In this study, stoichiometrically controlled alkali-activated binders containing both C-(A)-S-H and N-A-S-H gels with varying Mg content are produced by chemical reaction of a sodium silicate solution with magnesium-calcium-aluminosilicate nanopowders. These synthetic precursors were synthesised via a novel solution-polymerisation method utilising polyethylene glycol to sterically inhibit movement of precursor cations. The effect of the content of Mg, Ca, Si and Al on the chemistry, reaction kinetics and microstructure of the geopolymer is assessed using X-ray diffraction and scanning electron microscopy.

**Keywords:** Geopolymer, alkali-activated binder, layered double hydroxides, aluminosilicate powder synthesis.

## 1. Introduction

Alkali-activated binders offer a viable low-CO<sub>2</sub> alternative to Portland cement and exhibit desirable technical properties, as well as a potential reduction in CO<sub>2</sub> emissions by over 80% [1-3]. The main reaction product of an alkali-activated slag is an aluminium- and sodium-substituted calcium silicate hydrate gel (C-(N)-(A)-S-H), and the study of the microstructure and phase assemblage of this phase within alkali-activated slags has received significant attention in recent years [4-12]. Microstructural development of C-(N)-(A)-S-H is strongly dependent on the chemistry of the precursor slag, and most studies have focused on investigating reaction products within the quaternary CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>-Na<sub>2</sub>O system. Magnesium plays a significant role in formation and evolution of layered double hydroxides, which have been identified as the main secondary reaction products in these binders, when a sufficient content of MgO is present in the slag, used. Its formation modifies the phase assemblage of alkali-activated slags and consequently its performance [13]. The content of magnesium varies significantly between commercial slags, and despite the vast number of studies investigating the chemistry of alkali-activated slags few have investigated the role of magnesium in microstructural development in these materials [4, 13, 14]. Further to this, the literature is often conflicting and the experimental analysis involves a large number of unrestrained parameters. It is then necessary to develop a method to study alkali-activated binders which enables strict control of the stoichiometry in these systems, to gain a more complete understanding of the relationships between thermodynamics, reaction kinetics and the initial compositions of the precursors used to produce these materials.

The sol-gel procedure [15] has been used to synthesise and investigate the effect of composition on C-(A)-S-H and N-A-S-H phase assemblages [16-20], as well as compatibility studies of C-S-H and N-A-S-H

gels [18, 20], however these studies mostly investigate the effect of addition of alkali cations, alkaline earth cations or aluminium on C-S-H or N-A-S-H gels after formation of the gel. In order to accurately represent the physical and chemical interactions occurring during alkali-activation, all of the ionic species of interest must be present in a precursor powder prior to alkali-activation. This study examines the effect of the content of Mg Ca, Si and Al on the chemistry, microstructure and phase assemblage of C-(N)-(A)-S-H by synthesising mixed oxide powders within the quaternary CaO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>-MgO system via an organic polymeric steric entrapment solution-polymerisation route [21]. This method utilises polyethylene glycol (PEG) to sterically inhibit the movement of the metal cations during solution-polymerisation, forming a homogeneous mixed oxide powder upon drying. The stoichiometrically controlled reactive precursor powders are subsequently activated with an alkaline solution to form an alkali-activated binder.

## 2. Experimental

### 2.1 Precursor powder synthesis

A 5 wt.% polyethylene glycol (PEG) solution was produced by adding polyethylene glycol powder (Sigma Aldrich, MW=20,000 g/mol) to distilled water and stirring at 60°C. Aluminium nitrate nonahydrate, Al(NO<sub>3</sub>)<sub>3</sub>·9H<sub>2</sub>O (Sigma Aldrich, 98.5 wt.%), calcium nitrate tetrahydrate, Ca(NO<sub>3</sub>)<sub>2</sub>·4H<sub>2</sub>O (BDH Prolabo, VRW International, 99.0 wt.%), and magnesium nitrate hexahydrate, Mg(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O (Sigma Aldrich, 98.0 wt.%) were added to distilled water to produce 40 wt.% solutions of each, which were then added to the 5 wt. % solution of polyethylene glycol and stirred at 60°C. Colloidal silica, SiO<sub>2</sub> (Sigma Aldrich, 40 wt.% in water), was added to the 5 wt.% solution of polyethylene glycol containing aqueous aluminium nitrate, calcium nitrate and magnesium nitrate, and water was evaporated by stirring over heat at 80°C to form a viscous aerated gel. The stoichiometry of the metal cation-polyethylene glycol solution was designed so that the ratio of positive valences from the metal cations to negative valences from the polymer was 2. The viscous aerated gel was then placed in a drying oven at 100°C overnight. The dry polymer matrix was then calcined at 900°C to produce a fine white powder which was subsequently ground by hand using a mortar and pestle in preparation for characterisation and alkali-activated binder synthesis.

### 2.2 Alkali-activated binder synthesis

The activating solution was prepared by dissolution of sodium hydroxide powder (AnalaR, 99 wt.%) in sodium silicate solution (N grade, 37.5 wt.%, PQ Australia) and distilled water. The reaction mixtures had an activating solution modulus of SiO<sub>2</sub>/Na<sub>2</sub>O = 1 and a water/solids ratio and cation ratios as outlined in Table 1. The activating solution was mixed with the precursor powder to form a homogeneous paste, which was subsequently cast in sealed containers and cured at ambient temperature for 3 days. Previous work has shown the precursor powders to be sufficiently reactive such that any difference in w/b ratios is unlikely to affect the degree of saturation of each cation reached during alkali-activation.

**Table 1.** Molar ratios of the reaction mix for each sample.

Sample	Mg/(Al+Si)	Ca/(Al+Si)	Al/Si	Na/Al	Water/solids
A	0.05	0.67	0.15	0.5	0.75
B	0.25	0.67	0.15	0.5	0.75
C	0.05	1.00	0.15	0.5	0.83
D	0.25	1.00	0.15	0.5	1.13

### 2.3 Characterisation

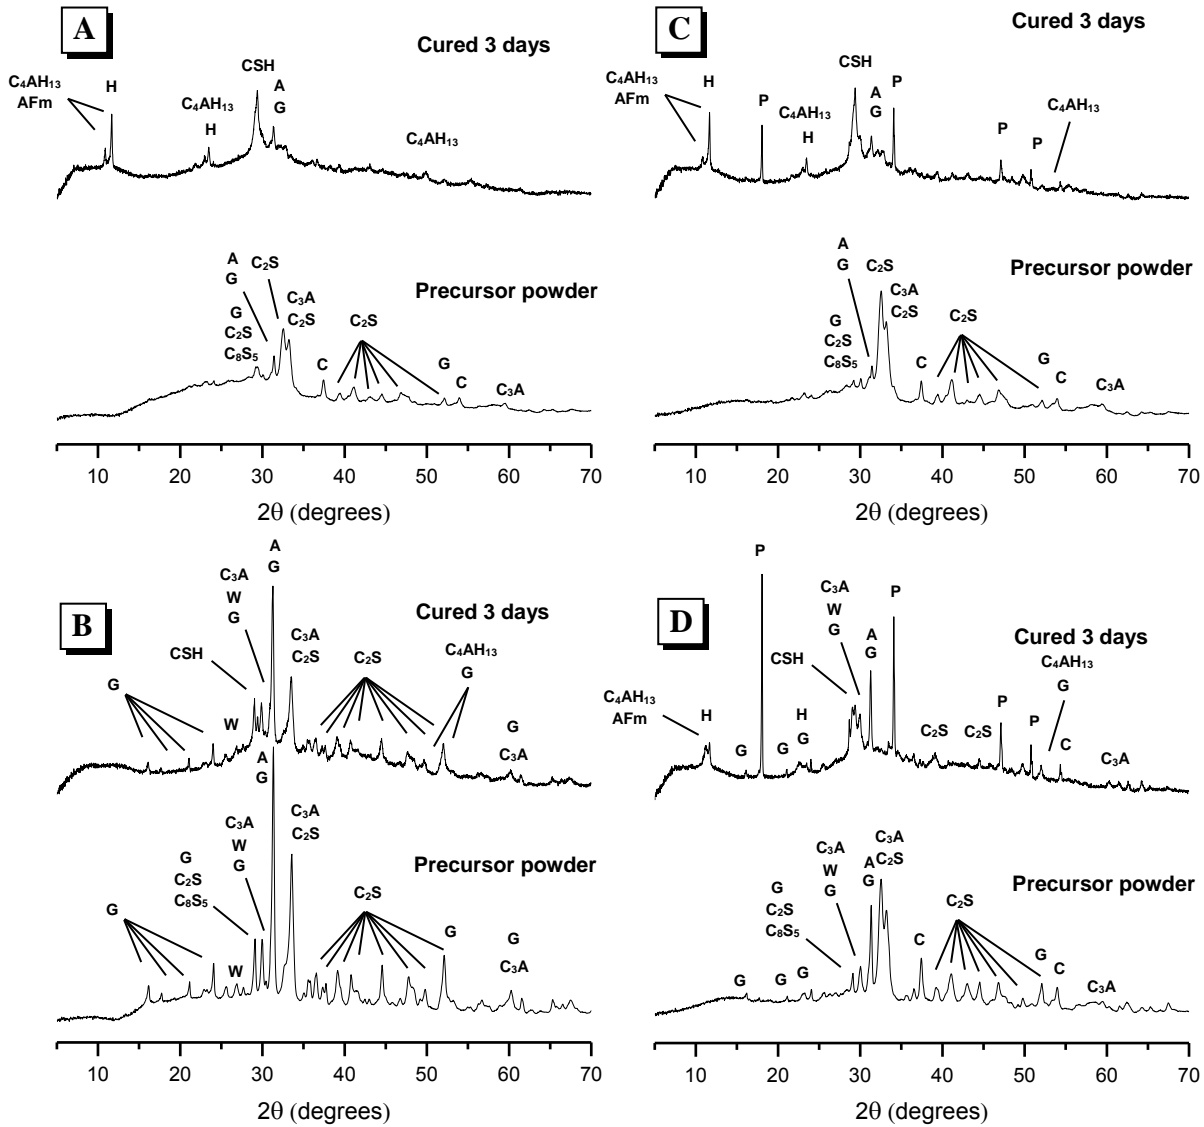

X-ray diffraction (XRD) data were collected using a Bruker D8 Advance instrument with Cu K $\alpha$  radiation, a nickel filter, a step size of 0.020°, and 3 s/step. Environmental scanning electron microscopy (ESEM) was conducted using an FEI Quanta instrument with a 15 kV accelerating voltage, a working distance of 10.0 mm and a Link-Isis (Oxford) X-ray energy dispersive (EDX) detector.

## 3. Results and Discussion

### 3.1 X-Ray diffraction

X-ray diffractograms of the calcined precursor powder and alkali-activated binders are presented in Fig. 1. The X-ray diffractograms of the precursor powders for each sample display a broad hump centred ~29°

CSH – calcium silicate hydrate C<sub>2</sub>S – dicalcium silicate C<sub>3</sub>A – tricalcium aluminate  
 C<sub>8</sub>S<sub>5</sub> – tricalcium silicate C – calcium oxide AFm – silica-substituted AFm H – hydroxalcite  
 A – åkermanite W – wollastonite G – gehlenite C<sub>4</sub>AH<sub>13</sub> – hydroxyl-AFm P – portlandite

**Figure 1.** X-ray diffractograms of the calcined precursor powder and alkali-activated binder cured for 3 days for samples A, B, C and D.

2θ, indicating a predominantly poorly crystalline nature of these powders, as is observed in granulated blast furnace slags (GBFS) [8, 9]. Small amounts of C<sub>3</sub>A (Ca<sub>3</sub>Al<sub>2</sub>O<sub>6</sub>) (PDF # 33-0251), calcium oxide (PDF# 48-1467), gehlenite (Ca<sub>2</sub>Al(AlSiO<sub>7</sub>)) (PDF # 35-0755), åkermanite (Ca<sub>2</sub>Mg(Si<sub>2</sub>O<sub>7</sub>)) (PDF # 98-000-0030), C<sub>8</sub>S<sub>5</sub> (Ca<sub>8</sub>Si<sub>5</sub>O<sub>18</sub>) (PDF # 29-0368) and two polymorphs of C<sub>2</sub>S (Ca<sub>2</sub>SiO<sub>4</sub>) (PDF # 33-0302 and 36-0642) are identified in all the precursor powders produced. Trace amounts of wollastonite (CaSiO<sub>3</sub>) (PDF # 27-0088) are also found in samples B and D. Calcination of the precursor powder to 900°C is necessary to remove any calcium carbonate present in the sample (converting it to free lime), however it is evident from the X-ray diffractograms in Fig. 1 that the calcination process has resulted in the formation of a small amount of crystalline phases. The lower calcium content of the precursor for samples A and B (Ca/(Al+Si) = 0.67) has resulted in greater formation of gehlenite and åkermanite when compared to samples C and D (Ca/(Al+Si) = 1.00). Alkali-activation of the synthetic precursors promoted the formation of a broad amorphous hump centred at approximately 29° 2θ, characteristic of alkali-activated slag cements [8, 9].

In sample A the crystalline phases present in the calcined precursor powder, with the exception of åkermanite and gehlenite, appear to be completely consumed upon alkali activation, leading to the formation of a poorly crystalline aluminium-substituted calcium silicate hydrate (C-(A)-S-H) phase with structural similarity to aluminium-containing tobermorite (PDF # 19-0052) as the main reaction product. Secondary reaction products crystalline  $C_4AH_{13}$  (PDF # 02-0077) and hydrotalcite ( $Mg_6Al_2CO_3(OH)_{16}\cdot 4(H_2O)$ ) (PDF # 41-1428) are also formed. Åkermanite and gehlenite do not appear to participate in the reaction, as the intensity of the reflection assigned to this phase remains unchanged upon activation. The diffractograms of the alkali-activated sample A also shows the formation of a partially silicate-substituted AFm phase type phase  $[(Ca_2(Al)(OH)_6] \cdot X \cdot xH_2O$  where X is a doubly charged carbonate or aluminosilicate anion), indicated by the peak at  $10.7^\circ 2\theta$  [22, 23]. In sample B the crystalline phases present in the calcined precursor powder, including gehlenite, appear to be only partially consumed upon alkali activation, and consequently small amounts of these phases are present in the alkali-activated sample B. The main reaction product in sample B appears to be a poorly crystalline C-(A)-S-H phase, as indicated by the broad amorphous hump centred at approximately  $29^\circ 2\theta$ .

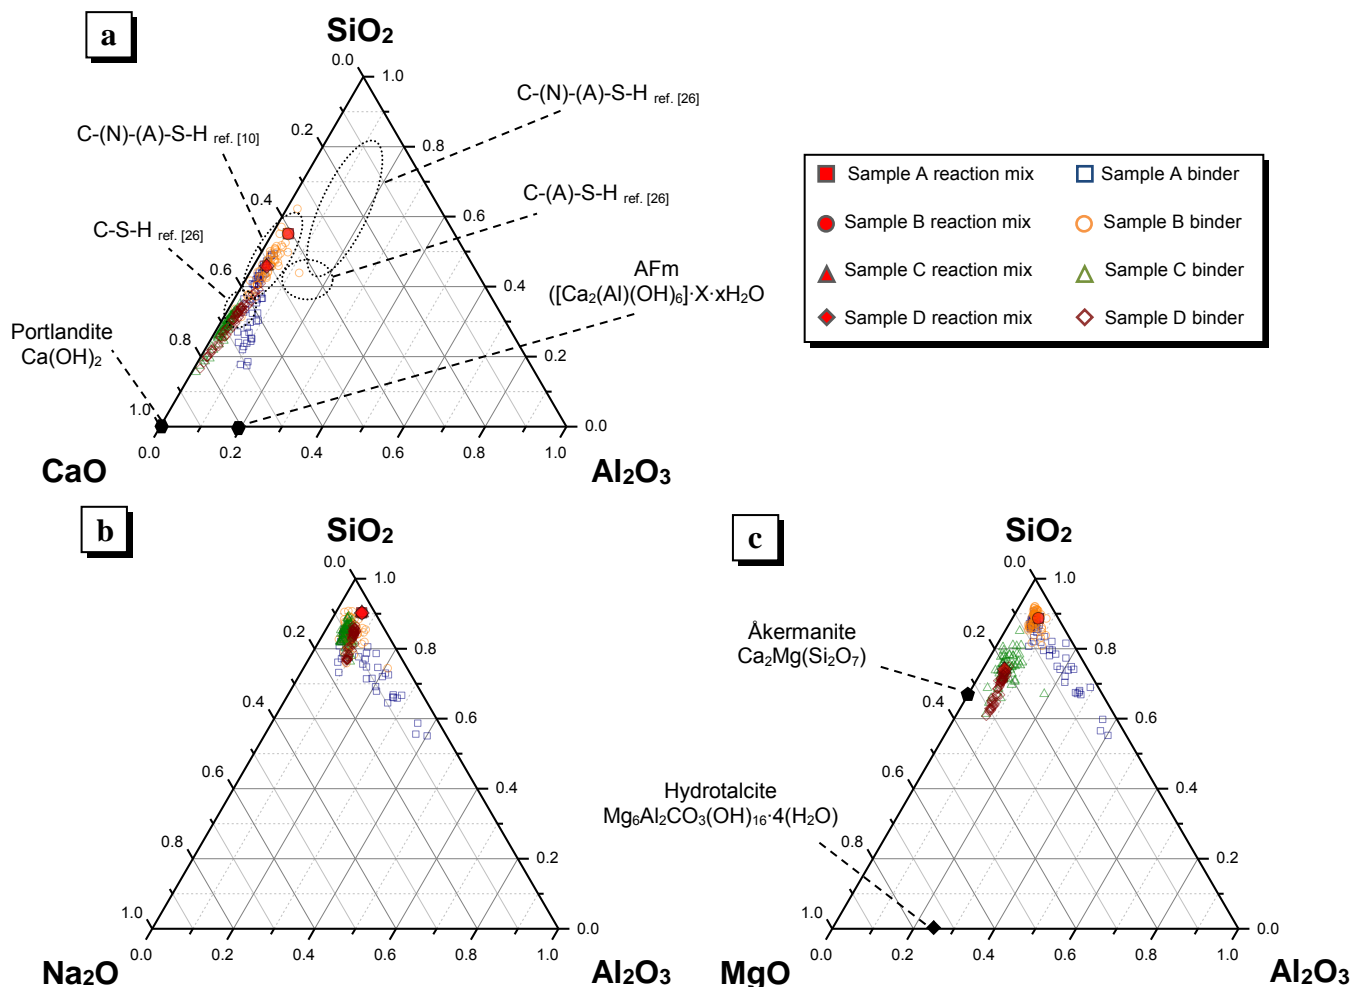

The crystalline phases in samples C and D, with the exception of åkermanite and gehlenite, appear to be completely consumed upon alkali-activation, leading to the formation of a poorly crystalline C-(A)-S-H phase as the main reaction product as well as secondary reaction products crystalline  $C_4AH_{13}$ , hydrotalcite, silicate-substituted AFm and portlandite ( $Ca(OH)_2$ ) (PDF # 44-1481). Again, åkermanite and gehlenite, and in sample D, wollastonite, do not appear to participate in the reaction.

The diffractograms for the alkali-activated samples A and B display each display a reflection attributed to poorly ordered C-(A)-S-H, but with significantly different intensities. The peak assigned to hydrotalcite (present at approximately  $11.5 2\theta$ ), identified in the diffractogram for the alkali-activated binder of sample A, is absent from the diffractogram of alkali-activated sample B, while the peak assigned to gehlenite and åkermanite (present at approximately  $30.7 2\theta$ ) in the alkali-activated binder for sample A has significantly less intensity than in sample B. Hydrotalcite is a common reaction product in alkali-activated slag where magnesium is present in the precursor, and as such is expected to be forming in the binders synthesised here [8, 9, 12, 24, 25]. These results suggest that, when the calcium and aluminium content in the precursor powder are held constant, a lower content of magnesium in the precursor powder ( $Mg/(Al+Si) = 0.05$ ) promotes greater formation of hydrotalcite during alkali-activation, while a higher content of magnesium in the precursor powder ( $Mg/(Al+Si) = 0.25$ ) results in no formation of hydrotalcite. This is contrary to what is observed during alkali-activation of ground granulated blast furnace slag (GGBFS), where increased magnesium content promotes formation of increased amounts of hydrotalcite [9]. In the samples here, increased magnesium content has resulted in increased formation of gehlenite and åkermanite during synthesis and calcination of the precursor powder. Consequently the amount of aluminium and magnesium available to participate in the reactions during alkali-activation at early age is significantly reduced, causing a reduction in the amount of hydrotalcite observed. Differences in the crystallinity of the hydrotalcite phases between samples may also be significant here.

This trend is also observed when comparing the diffractograms of samples C and D. As mentioned above, the formation of gehlenite and åkermanite during precursor synthesis is much less for these high-calcium containing samples. Consequently these samples will contain more freely available magnesium than samples A and B. Despite this, a higher content of magnesium in the precursor powder appears to have resulted in reduced formation of hydrotalcite and C-S-H and increased formation of portlandite, consistent with the trends observed for samples A and B. In samples with higher calcium content ( $Ca/(Al+Si)=1.00$ ), a higher magnesium content of the precursor powder also induces greater formation of portlandite, suggesting that magnesium also plays an important role in the formation of magnesium-free secondary reaction products.

### **3.2 Scanning electron microscopy**

The chemistry of each sample as determined by ESEM – EDX is reported in Fig. 2. Alkali-activated sample A binder exhibits a range of  $Ca/(Al+Si)$  ratios which lie along an imaginary line drawn between the  $Ca/(Al+Si)$  ratios of an aluminium- and sodium-substituted calcium silicate hydrate (C-(N)-(A)-S-H) phase and a partially silicate-substituted AFm phase (Fig. 2a). This is consistent with the XRD results of this sample (Fig. 1a). The main binding phase forming in the alkali-activated samples B exhibits a range of  $Ca/(Al+Si)$  ratios which lie within the region typically observed for C-(N)-(A)-S-H gels and C-S-H gels (Fig. 2a). This is consistent with that identified in the X-ray diffractograms where traces of a silicate-substituted

**Figure 2.** Projection of alkali-activated binder chemistry onto the a) ternary CaO – Al<sub>2</sub>O<sub>3</sub> – SiO<sub>2</sub> system, b) ternary Na<sub>2</sub>O – Al<sub>2</sub>O<sub>3</sub> – SiO<sub>2</sub> system and c) ternary MgO – Al<sub>2</sub>O<sub>3</sub> – SiO<sub>2</sub> system showing elemental is composition of alkali-activated binders cured for 3 days for samples A, B, C and D as determined by ESEM-EDX analysis. Approximate compositional regions in C-(N)-(A)-S-H, C-(A)-S-H and C-S-H have been determined from [26] and [10].

AFm phase were observed in sample A, while this phase is not identified in sample B. Given that the bulk calcium, silicon, aluminium and sodium content of the precursors were the same for each sample, it is clear that the magnesium content of the precursor plays a significant role in determining phase development. Increased magnesium content in the precursor powder appears to promote formation of C-(N)-(A)-S-H and less formation of C-S-H and silicate-substituted AFm phases. This is consistent with the relative intensities of the peaks assigned to C-S-H and silicate-substituted AFm in the X-ray diffractograms.

The chemistry of the alkali-activated binders for each of samples C and D ( $\text{Ca}/(\text{Al}+\text{Si}) = 1.00$ ) (Fig 2. b) exhibit a similar range of  $\text{Ca}/(\text{Al}+\text{Si})$  ratios which lie along an imaginary line drawn between the  $\text{Ca}/(\text{Al}+\text{Si})$  ratios of the reaction mix, C-S-H and portlandite, consistent with the phases observed by XRD. Alkali-activated binders for all samples exhibit  $\text{Na}/\text{Al}$  ratios clustered around that of the precursor powder ( $\text{Na}/\text{Al} = 0.5$ ) (Fig 2b). This suggests that despite formation of greater amounts of C-S-H and portlandite in binders where the precursor powder contained higher calcium content, sodium incorporation into the binder has occurred to approximately the same extent.

Each of the alkali-activated binders exhibits  $\text{Mg}/(\text{Al}+\text{Si})$  ratios similar to that of the precursor powders. Alkali-activated sample A exhibits an  $\text{Al}/\text{Si}$  ratio of approximately 0.35, while alkali-activated sample B

exhibits an Al/Si ratio which is similar to that of the precursor powder (approximately 0.16) (Fig. 2c). The higher Al/Si ratio in sample A is consistent with the observation by XRD of greater amounts of hydrotalcite compared to sample B. This is consistent with the mechanism discussed above (Section 3.1) where an increased content of magnesium in the precursor powder appears to have promoted the formation of greater amounts of åkermanite during the precursor synthesis and calcination, consequently decreasing the amount of freely available magnesium and hence inhibiting the formation of hydrotalcite upon alkali-activation. Consequently a greater amount of Al is freely available and greater substitution of Al into the calcium silicate hydrate (C-S-H) phase occurs, promoting the formation of a C-(N)-(A)-S-H gel. This is in contrast to observations for alkali-activated commercial slags [4, 9] and highlights the importance of consideration of freely available magnesium content rather than bulk magnesium content within the precursor.

The alkali-activated binders for each sample display a range of values for the ratios Ca/Si, Mg/Si and Al/Si which are very similar to those observed for alkali silicate-activated GGBFS slags where the precursor slag contained 1.17, 5.21 wt % and 7.44 wt % MgO, respectively [9]. This suggests that the chemistry of these binders produced from synthetic slags is representative of that of alkali silicate-activated commercial slags with varying magnesium content.

#### 4. Conclusions

Stoichiometrically controlled alkali-activated materials within the system CaO-MgO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>, with varying Mg content, were synthesised via alkali-activation of precursor powders which were in turn synthesised from aqueous precursor solutions via an organic steric entrapment solution-polymerisation route. The main reaction product in all samples was a C-(N)-A-S-H gel, and the secondary reaction products hydrotalcite, crystalline C<sub>4</sub>AH<sub>13</sub> and a partially silicate-substituted AFm phase were also formed. Samples where the precursor powder contained higher amounts of calcium (Ca/(Al+Si)=1.00) also formed portlandite upon alkali-activation. Lower Mg content within the precursor appears to promote less formation of gehlenite and åkermanite during the precursor synthesis. More magnesium is then freely available during alkali-activation, and subsequently alkali activation promotes greater formation of C-(N)-(A)-S-H and less formation of hydrotalcite. Increased magnesium content promotes greater formation of gehlenite and åkermanite during the precursor synthesis. Less magnesium is then available to participate in the reaction, and subsequent alkali-activation promotes reduced formation of C-(N)-A-S-H and greater formation of hydrotalcite. This highlights the importance of considering freely available magnesium content rather than bulk chemistry when investigating the effect of network modifying cations on phase assemblage. Consequently, the availability of network modifying cations such as magnesium, among other factors, is expected to dictate microstructural changes occurring within alkali-activated materials induced by environmental factors (such as acidic attack, carbonation and other aggressive environments). The availability of magnesium during alkali-activation is then expected to be a significant factor controlling the physical properties and durability of alkali-activated materials.

**Abstract:** Geopolymer Concrete has been extensively studied in the past and recognised as a greener substitute for Ordinary Portland Cement (OPC) concrete. Geopolymer concrete is proven to have good engineering properties with a reduced carbon footprint. Geopolymers not only reduce the greenhouse gas emission but also use a large amount of industrial wastes such as fly ash and slag. This environmentally friendly material is being embraced by the construction industry after its use in the Global Change Institute at University of Queensland. However, research into the use of geopolymer concrete in structural applications is very limited.

This research paper aims at investigating the applicability of a constitutive relationship that authors developed for OPC concrete in predicting the constitutive relationship of geopolymer concrete. This model has the capacity to predict the lateral dilation of concrete which in turn will be used to establish the confinement provided by the lateral reinforcement in column applications. Load deformation behaviour of twelve geopolymer concrete slender columns reported in the literature is used to validate the proposed model. Since geopolymer concrete exhibits higher brittleness than OPC concrete, careful consideration should be given in the structural design of geopolymer concrete. Predicted behavior for slender geopolymer concrete columns using the proposed stress-strain relationship for confined geopolymer concrete is in good agreement with the experimental results. The outcomes of this paper will be useful in the structural analysis of geopolymer concrete columns.

**Keywords:** geopolymer concrete, stress-strain relationship, confinement, slender column.

## 1. Introduction

Emission of greenhouse gases such as carbon dioxide and nitrous oxide is a major contributing factor for global warming while the production of cement contributes about 5-7% of CO<sub>2</sub> emissions globally. Although the production of one ton of Ordinary Portland Cement (OPC) releases approximately one ton of CO<sub>2</sub> into the atmosphere [1, 2], it is widely used as a construction material around the world. As a result of few decades of research activities, geopolymer concrete (GPC) has become a potential candidate to replace the OPC concrete. It is reported that mechanical properties of GPC depend mainly on the source material, mix design and curing method [3]. However Reed et al. [4] proposed that fly ash based GPC is suitable for in-situ applications. The changes in the mortar with OPC and geopolymer are compatible with the changes in the OPC and GPC [5]. Some mechanical properties of GPC (tensile strength) are higher than those of OPC concrete [3, 5, 6], while some properties such as elastic modulus [5, 6] and flexural strength [6] are comparatively lower. Although design guidelines for geopolymer concrete are not very well documented, equations for some properties such as tensile strength, flexural strength and modulus of elasticity can be found in the literature [3, 7]. Commercial use of geopolymer concrete has taken place in the recent past for small scale applications. However the use of geopolymer concrete by Wagners, Australia in the Global Change Institute at University of Queensland and in the Wellcamp airport in Toowoomba are reported as its first structural application on large scale construction projects.

Geopolymer concrete has highly desirable structural engineering properties, which can lead to significant environmental and economical benefits. Its use is, however, limited by concerns regarding its increased brittleness compared with OPC concrete [5] and a lack of understanding of the behaviour under complex multi-axial loading conditions. The ductility of geopolymer concrete has not been investigated by many researchers in the past. The traditional method of improving ductility of columns is by using lateral confinement with steel reinforcement. However, effective methods of lateral confinement have not been reported for geopolymer concrete. The above concerns have led to very few research projects around the world [8], [9, 10]. In these studies the experimental/ analytical studies covered the behaviour of small-scale

square columns with a limited configuration of steel reinforcements, tested under laboratory conditions. In most studies, the confining pressure is assumed to be that corresponding to the yield stress of the confining steel. However the confining pressure exerted by the lateral steel is corresponding to the lateral dilation of concrete in that instance. Currently, with very limited research on the structural performance of geopolymer concrete, there is no agreement among researchers about the amount of lateral steel required in geopolymer concrete columns to provide a required level of ductility.

Based on experimental results, various stress-strain models for unconfined/confined normal or high strength concrete have been proposed in the literature [11-16]. These models can be divided into three broad categories. One group of researchers used a form of equation proposed by Sargin et al. [15]. The second group of researchers proposed a second order parabola for the ascending branch and a straight line for the descending branch and their studies were based on equations proposed by Kent and Park [14]. The third group developed stress strain relationships based on equations suggested by Popovics [16]. There are many developments to all the three preliminary equations. In these models, selected parameters were included in the stress-strain curves and then they were calibrated using the test results. There are very limited knowledge about the stress-strain relationship for unconfined/confined geopolymer concrete although it is the basis of any structural application of this new green construction material.

## 2. Existing stress-strain models for geopolymer concrete

There are two categories of constitutive models that have been discussed in the literature, one for geopolymer concrete [9, 17] and the other for geopolymer paste [18]. Haider et al. [18] developed a stress-strain model for geopolymer paste based on the experimental results with active confinement. The model proposed by the Concrete Institute of Australia is a modified version of Popovics [16] which gives a single curve for both the ascending and descending branches of the stress-strain curve for unconfined geopolymer concrete. Sarker [9] also proposed a modified version of Popovics [16] and applied this model for confined geopolymer concrete in column applications. Ganesan et al [17] used another version of Mander et al. [19] which was originally proposed by Popovics [16]. Ganesan et al [17] used the stress-strain relationship for geopolymer concrete to predict the behaviour of geopolymer concrete short columns confined by spiral reinforcement. These constitutive models are capable of predicting only the axial stress versus axial strain relationships. However, the confinement provided by lateral steel reinforcement depends on the lateral dilation of concrete. Therefore it is a timely concern to develop or investigate a complete deformational behaviour including both axial and lateral strains of laterally confined geopolymer concrete with axial compression. With the increased popularity in geopolymer concrete due to environmental and economic benefits, the greener material will be used in high-load-carrying structural members all over the world in the near future. Therefore a thorough knowledge of the material behaviour of the constituents (such as geopolymer concrete and steel) subjected to monotonically increasing loading is of great importance.

## 3. Methodology

Proposed stress-strain models for confined geopolymer concrete, steel and the procedure used in obtaining the load deformation curves are described in the following sub sections.

### 3.1 Proposed stress strain model for confined geopolymer concrete

The model proposed in this paper was originally developed by the authors for normal and high strength concrete. It is described in detail in Lokuige et al. [20]. Only one material parameter in the original model was changed to suit geopolymer concrete. Two different exponential curves form the complete stress-strain relationships for confined geopolymer concrete. The terms described in this model are illustrated in Figure 1.

Figure 1. Typical stress-strain relationship for confined and un-confined concrete.

### 3.1.1 Relationship between axial strain and lateral strain

Relationship between axial strain  $\varepsilon_1$  and lateral strain  $\varepsilon_2$  is described below:

$$\frac{\varepsilon_2}{\varepsilon'_{cc}} = \begin{cases} \nu_i^a \left( \frac{\varepsilon_1}{\varepsilon_{cc}} \right) & \text{if } \varepsilon_1 \leq \varepsilon' \\ \left( \frac{\varepsilon_1}{\varepsilon_{cc}} \right)^a & \text{if } \varepsilon_1 > \varepsilon' \end{cases} \quad (1)$$

$\varepsilon_{cc}$  and  $\varepsilon'_{cc}$  are axial strain and lateral strain corresponding to peak axial stress.  $a$  is a material parameter which depends on the characteristic compressive strength of concrete ( $f_c$ ) and can be approximated by:

$$\mathbf{a} = 0.0177f_c + 1.2818 \quad (2)$$

$\varepsilon'$  can be obtained by equating the right hand side of Equation 1.  $\nu_i^a$ , the initial Poisson's ratio is defined as follows:

$$\nu_i^a = 8 \times 10^{-6}(f_c)^2 + 0.0002f_c + 0.138 \quad (3)$$

Equation 1 completely defines the relationship between axial strain and lateral strain if axial strain ( $\varepsilon_{cc}$ ) and lateral strain ( $\varepsilon'_{cc}$ ) corresponding to peak axial stress are known. Axial strain corresponding to peak axial stress  $\varepsilon_{cc}$  can be expressed as follows.

$$\frac{\varepsilon_{cc}}{\varepsilon_{co}} = 1 + (17 - 0.06f_c) \left( \frac{f_l}{f_c} \right) \quad (4)$$

$f_l$  is the confining pressure and  $\varepsilon_{co}$  is the axial strain corresponding to the peak uniaxial compressive strength. Peak axial stress for confined concrete  $f_{cc}$  is defined as:

$$\frac{f_{cc}}{f_c} = \left( \frac{f_l}{f_t} + 1 \right)^k \quad (5)$$

where  $k$  is a constant given by:

$$k = 1.25 \left( 1 + 0.062 \frac{f_l}{f_c} \right) (f_c)^{-0.21} \quad (6)$$

$f_t$  is the tensile strength. Tensile strength of geopolymer concrete is given by:

$$f_t = 0.9 \times 0.32(f_c)^{0.67} \quad (7)$$

Equations 1-7 can predict the lateral strain for a given axial strain if the unconfined concrete strength and lateral strain corresponding to peak axial stress are known.

### 3.1.2 Lateral strain at peak axial stress

Similar to the observations for normal and high strength concrete [20] and for geopolymer paste [18] it is assumed that geopolymer concrete samples will return to the original volume when the axial strain is corresponding to the peak axial stress. Therefore at peak stress:

$$\bar{\varepsilon}_v = \frac{\varepsilon_1 + 2\varepsilon_2}{\varepsilon_{v,\max}} = 0 \quad (8)$$

$$\varepsilon_{cc} = 2\varepsilon'_{cc} \quad (9)$$

By introducing Poisson's ratio, Equation 9 can be written as:

$$\nu_f^a = 0.5 \quad (10)$$

where  $\nu_f^a$  is the secant value of Poisson's ratio at peak stress.

### 3.1.3 Relationship between axial stress, axial strain and lateral strain

Based on shear stress factors and shear strain factors, axial stress ( $\sigma_1$ ), axial strain ( $\varepsilon_1$ ) and lateral strain ( $\varepsilon_2$ ) constitutive behaviour of geopolymers concrete can be expressed as:

$$\sigma_1 = \begin{cases} 2\tau_{mp} \left( 1 - e^{-c \left( \frac{\varepsilon_1 + \varepsilon_2}{2\gamma_{mp}} \right)} \right) + f_l & \text{before peak} \\ 2\tau_{mp} \left( 1 - e^{d \left( \frac{\varepsilon_1 + \varepsilon_2}{2\gamma_{mp}} \right)^2} - d \right) + f_l & \text{after peak} \end{cases} \quad (11)$$

$c$  and  $d$  are material parameters defined as follows:

$$\begin{aligned} c &= -0.0427f_c + 3.15 \quad \text{and} \\ d &= -0.0003f_c - 0.0057 \end{aligned} \quad (12)$$

$c$  is the only material parameter that was modified to suit geopolymers concrete better.

$\tau_{mp}$  is the maximum shear stress at peak and  $\gamma_{mp}$  is the maximum shear strain at peak. They are defined as:

$$\tau_{mp} = \frac{f_{cc} - f_l}{2} \quad \text{and} \quad \gamma_{mp} = \frac{\varepsilon_{cc} + \varepsilon'_{cc}}{2} \quad (13)$$

Therefore complete deformational behaviour of concrete can now be generated.

### 3.2 Stress-strain model for steel

A simple idealised elasto-plastic stress-strain model was used in this investigation.

$$f_s = \begin{cases} E_{st} \varepsilon_s & \text{if } 0 \leq \varepsilon_s \leq \varepsilon_y \\ f_{sy} & \text{if } \varepsilon_s > \varepsilon_y \end{cases} \quad (14)$$

Where  $f_s$  and  $\varepsilon_s$  are steel stress and strain,  $E_{st}$  is the modulus of elasticity and  $f_{sy}$  and  $\varepsilon_y$  are the yield strength and corresponding strain of steel.

### 3.3 Load-deformation relationships

The analysis was performed by assuming plane sections remain plane after bending, perfect bond between the longitudinal steel and the concrete and only tension steel resists the tensile forces. The stress-strain relationships for concrete and steel are assumed to be as described in the previous section.

A standard pin-ended column is used in analysing the slender columns used in the experimental results reported in the literature. The procedure used in obtaining the mid height deflection is the one suggested by Rangan [21]. The deflected shape,  $v(x)$  is assumed to be represented by a sine wave as follow:

$$v(x) = \delta \sin\left(\frac{x\pi}{L_e}\right) \quad (15)$$

$L_e$  is the effective length of the column. At mid height, when  $x = L_e/2$ , the relationship between the curvature and the deflection can be obtained by:

$$\varphi\left(\frac{L_e}{2}\right) = \frac{\pi^2}{L_e^2} \delta \quad (16)$$

The section is divided into a number of strips. For an assumed strain distribution (using curvature,  $\varphi$  and strain at extreme compression side,  $\varepsilon_t$ ), stresses in core, cover and reinforcement are calculated using the corresponding stress-strain relationships. Mid height deflection calculated using Equation 14 can be used to obtain the calculated eccentricity. For a given curvature,  $\varphi$  and eccentricity,  $e^*$ , strain at extreme compression side,  $\varepsilon_t$  is iterated until the calculated eccentricity is equal to the actual eccentricity within a given tolerance level. The procedure used in getting the load-deflection curve is shown in Figure 2.

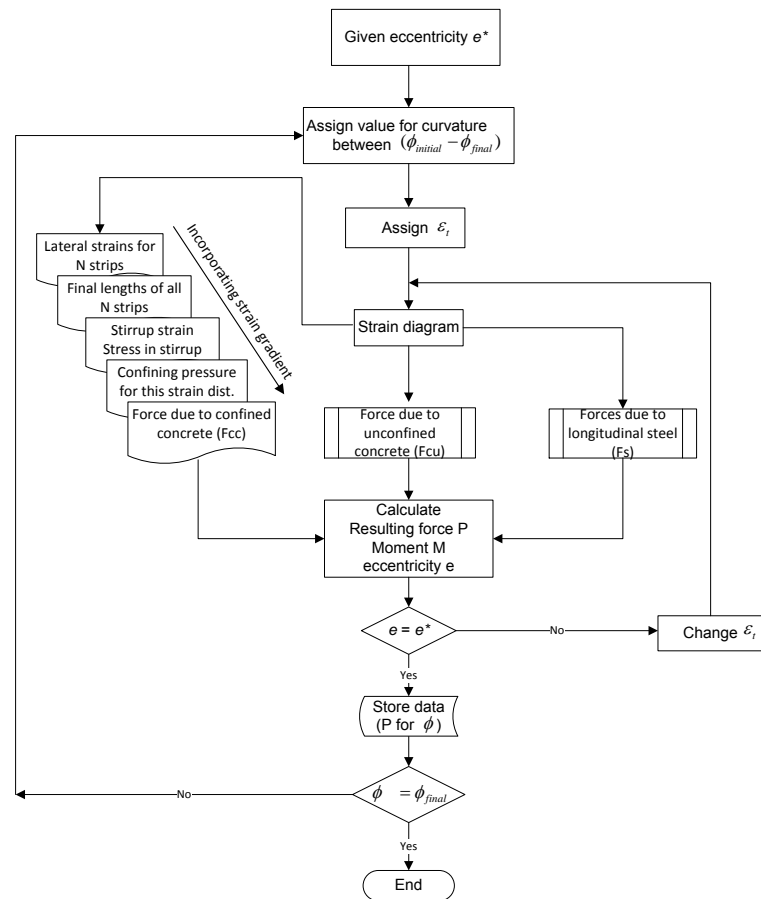

Figure 2. Flow chart used to draw load-deflection curves

#### 4. Experimental results used to compare model predictions

Twelve reinforced geopolymer concrete slender columns tested by Sumajouw et al.[8] are selected in this research to compare with model predictions. These columns were eccentrically loaded and two test series were utilized. Compressive strength of geopolymer concrete, reinforcement configuration and level of eccentricity were the test variables in their experimental program. Compressive strengths were in the range of 42-66 MPa and three level of eccentricities 15, 35 and 50 mm were used. Longitudinal reinforcement used in these columns are of type N12 deformed bars with cross sectional area of 110 mm<sup>2</sup> and yield strength of 519 MPa from tensile strength tests. Two different reinforcement configurations were used with 4N12 and 8N12. Lateral reinforcement used were 6 mm diameter hard drawn wires (W6) with 100 mm spacing for all the columns. Details of column specimens are shown in Figure 3 and Table 1. Length of all the columns was 1500 mm and the effective length was found to be 1684 mm.

### 5. Results and discussion

Twelve slender column results reported in the literature [8] were used to validate the theoretical analysis described before. Figure 4(a) and Figure 4(b) show the experimental and theoretical load versus deflection curves for GCI and GCII series respectively.

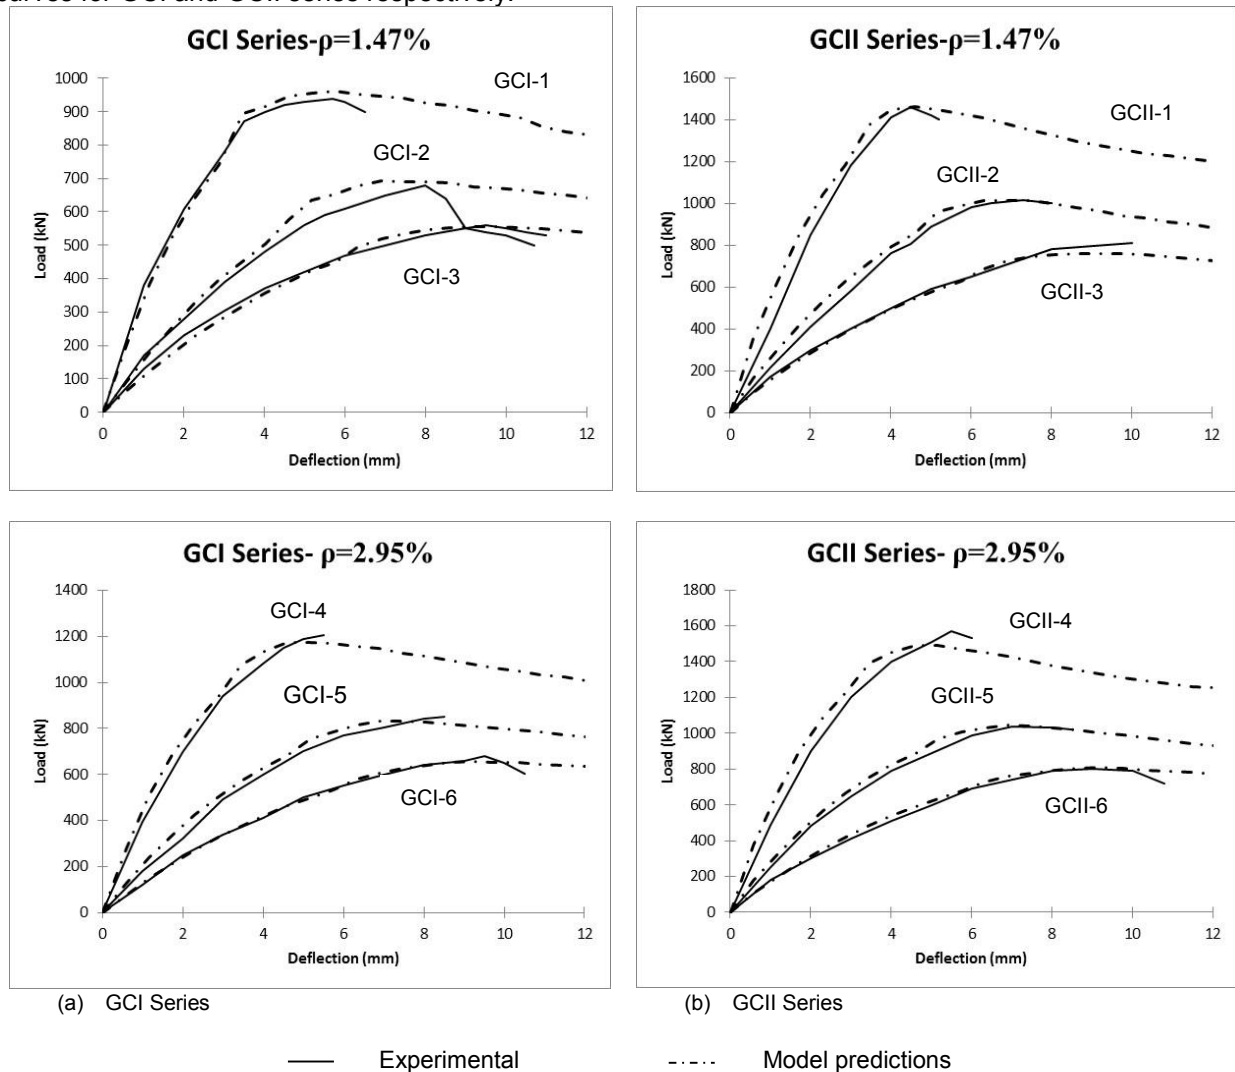

Figure 4. Load versus deflection curves for GPC slender columns

The analytical procedure was capable of predicting the ascending branch as well as the descending branch for all the twelve curves while a short post peak behavior is observed in majority of the experimental curves. Model predictions are in reasonable agreement especially for GCI series (low compressive strength) and for higher eccentricity values irrespective of the compressive strength. The load capacity of slender geopolymer concrete columns considerably decreases with increasing eccentricity for both experimental and model predictions. The predicted peak load and the corresponding deflection are always matching well with the experimental results. There are small variations in the ascending branches of GCII series (higher compressive strength). This needs to be investigated further with more experimental results in the future. The discrepancies between the experimental results and the model predictions may be due to the assumed sine wave function for the deflected shape.

## 6. Conclusions

The proposed constitutive relationship for confined/unconfined geopolymer concrete and the proposed analytical procedure to establish the load-deformation behaviour for eccentrically loaded slender geopolymer concrete columns compare well with the experimental results reported by Sumajouw et al. [8]. Conclusions resulted from this research are summarized below:

- The stress-strain relationship originally proposed by the authors for normal and high strength concrete [20] can be modified slightly and used for confined geopolymer concrete. It has been effectively used in the analysis of eccentrically loaded slender columns as it reflects both axial and lateral strain of confined geopolymer concrete.
- Proposed analytical procedure uses the confining pressure applied by the lateral steel which changes with lateral dilation of geopolymer concrete.
- With the increasing eccentricity, the strength of GPC columns decreases rapidly which is consistent with the experimental results as well as for NSC and HSC.
- Proposed analysis has good practical implications because the proposed model which was originally based on triaxial tests is more likely to work for a wide range of column configurations and sizes.
- The results discussed here for the slender columns not only depend on the moment-curvature of cross section, but also on curvature-deflection relationship of the column. The simplified sine-curve relationship is likely to have contributed to the slight discrepancies between the results which needs further investigation.

**Abstract:** This paper evaluates the influence of matrix properties on the behavior of a recently developed fiber reinforced engineered geopolymer composites (EGC) exhibiting strain hardening behavior under uni-axial tension. Randomly oriented short poly vinyl alcohol (PVA) fibers (2% v/v) were used to reinforce the relatively brittle low calcium (Class F) fly ash-based geopolymer matrix. The effect of matrix related parameters including activator to fly ash and sand to fly ash ratios on the matrix and composite properties of the developed fly ash-based EGCs including workability of the fresh matrix, density, compressive strength and uni-axial tensile behavior were evaluated. Experimental results revealed that the increase in the activator to fly ash ratio adversely affected the strain hardening behavior of EGC with reduction in ultimate tensile strength. The tensile strain capacity of EGC was significantly reduced when excessive amount of sand was added to the geopolymer matrix. However, the ultimate tensile strength of EGC was marginally increased.

**Keywords:** EGC, strain hardening, geopolymer, fly ash, PVA fiber.

## 1. Introduction

A special class of high performance fiber reinforced cementitious composites (HPFRCCs) with advanced ductility which is about 600 times the ductility of normal concrete in tension [1] has been referred to engineered cementitious composites (ECC) [2]. ECC is a micromechanics-based designed brittle matrix composite which utilizes a small amount of discontinues fibers (typically 2% or less by volume) and exhibits a tensile strain capacity of up to 6% [3]. High cement content is commonly found in the mixture design of several types of HPFRCCs, such as ultra-high performance fiber reinforced cementitious composites (UHPRCCs) [4-6] and ECC [7]. Typical ECC mix design contains considerably higher cement content than conventional OPC concrete [7]. Production of ordinary Portland cement (OPC) is responsible for almost 5% of total CO<sub>2</sub> emission which is the main cause of global warming in the world [8]. The high cement content in typical ECC mix design apparently compromises sustainability performance of this material [7]. Hence, it is essential to develop green ECC with lower cement content (i.e. lower global warming potential associated with CO<sub>2</sub> emission of OPC production) which sustain the tensile ductility properties but also include sustainability considerations. One of the solution to achieve this objective is partial replacement of OPC by supplementary cementing materials such as fly ash, palm oil fuel ash (POFA) and slag in the ECC mix design to reduce the use of OPC; thereby, reducing the global warming issues associated with the CO<sub>2</sub> emission of the cement industry [7,9]. However, a more sustainable approach to achieve this goal is to completely substitute the OPC binder in the ECC mix design by an alternative cement-less binder such as geopolymer.

Geopolymer is an emerging cement-less binder purported to provide a sustainable and environmentally friendly alternative to OPC. The term geopolymer was initially introduced by Davidovits [10]. Geopolymer is synthesized from materials of geological origin (e.g. metakaolin) or industrial by-products such as fly ash and slag that are rich in silica and alumina with high alkaline activators. In this study, a low calcium (Class F) fly ash which is an industrial by-product of coal-fired power stations [11] containing high amounts of silicon and aluminum was used as the source material. Production of fly ash based geopolymer requires approximately 60% less energy and has at least 80% less CO<sub>2</sub> emission compared to manufacture of OPC [12,13]. Recently, an initial study was conducted to demonstrate the feasibility of developing a geopolymer-based ECC, known as engineered geopolymer composite (EGC) where the OPC binder was completely replaced by fly ash-based geopolymer binder which exhibited strain hardening behavior in uni-axial tension, accompanied by multiple fine cracks [14]. However, the developed fly ash-based EGC possessed low to moderate compressive and uni-axial tensile strengths ranging from 17.4 MPa to 27.6 MPa and from 2.9 MPa to 3.4 MPa, respectively which may limit the widespread application of these composites in the construction industry. Following that study, Nematollahi et al. [15,16] evaluated the effect of different activator combinations on the matrix and composite properties of the recently developed fly ash-based EGC to improve its compressive and tensile strengths with relatively low concentration activator combinations. It should be noted that only fly ash (with no sand) was used in the matrix design of their

EGCs similar to the first generation of the conventional ECC that only utilized OPC and silica fume with no sand in the matrix [17,18]. Their experimental results revealed that although the concentration of the activator combinations was limited to 8.0 M to account for safety consideration; however, the developed fly ash-based EGC exhibited improved compressive strength, tensile strength and tensile ductility over 60 MPa, 4.7 MPa, and 4.3% on average, respectively with using the Na-based activator combination composed of 8.0 M NaOH solution (28.6% w/w) and Na<sub>2</sub>SiO<sub>3</sub> solution (71.4% w/w) with a SiO<sub>2</sub>/Na<sub>2</sub>O ratio of 2.0.

The behavior of randomly oriented short fiber reinforced composites such as fly ash-based EGCs are governed by three groups of parameters. The first group involves matrix related parameters such as compressive and tensile strengths, fracture toughness, elastic modulus, etc., while the second group consists of fiber related parameters such as fiber type, geometry and strength and so on, and the third group comprises matrix-fiber interface related parameters such as the frictional and chemical bond strengths [17]. Among these three groups, the focus of the current study is on the matrix related parameters. The geopolymer matrix properties such as compressive and tensile strengths, fracture toughness and elastic modulus are influenced by many parameters such as type of fly ash, type of alkaline activator, activator to fly ash ratio, sand to fly ash ratio, temperature and duration of curing and so on. For the purpose of the current investigation, activator to fly ash ratio (Act/FA) and sand to fly ash ratio (S/FA) were selected as the most significant parameters in governing the characteristics of the geopolymer matrix. Sand content can alter the matrix toughness, pre-existing flaw size distribution and fiber/matrix interface properties [19]. A systematic experimental program was conducted to understand the quantitative influence of these matrix related parameters on the matrix and composite properties of fly ash-based EGC with the aim of selecting an appropriate type of matrix for design of strain hardening EGC.

## 2. Micromechanics-based design criteria for strain hardening behavior

The pseudo strain hardening (PSH) behavior in fiber reinforced brittle matrix composite is a result of sequential development of matrix multiple cracking. A fundamental requirement for the multiple cracking behavior is that steady-state cracking prevails under tension. The condition for steady-state cracking was analyzed by Marshall and Cox [20] using J-integral method. When fiber bridging behavior is characterized by bridging stress-crack opening  $\sigma(\delta)$  relation, the condition for steady-state cracking, often referred as energy-based condition for PSH behavior, can be expressed in the following simple form:

$$J_{tip} \leq \sigma_0 \delta_0 - \int_0^{\delta_0} \sigma(\delta) d\delta \equiv J'_b \quad (1)$$

where  $J'_b$  is the complementary energy calculated from the  $\sigma(\delta)$  curve of the composite,  $\sigma_0$  is the maximum bridging stress corresponding to the crack opening  $\delta_0$  and  $J_{tip}$  is the crack tip toughness which for small fiber volume fraction can be determined from the following equation:

$$J_{tip} = \frac{K_m^2}{E_m} \quad (2)$$

where  $K_m$  and  $E_m$  are the fracture toughness and elastic modulus of the matrix, respectively [17]. Another condition for PSH behavior is that the tensile first cracking strength ( $\sigma_{fc}$ ) must not exceed the maximum fiber bridging strength ( $\sigma_0$ ). This condition, often referred as the strength-based condition, can be expressed in the following form:

$$\sigma_{fc} \leq \sigma_0 \quad (3)$$

where  $\sigma_{fc}$  is determined by matrix fracture toughness ( $K_m$ ) and the pre-existing flaw size [19]. When a brittle matrix shows PSH behavior, the ultimate strength of the composite ( $\sigma_{cu}$ ) coincides with the maximum bridging stress  $\sigma_0$ . Both criteria namely strength-based and energy-based conditions must be satisfied in order to achieve strain hardening composite; otherwise, conventional fiber reinforced concrete exhibiting tension softening behavior results [21]. Considering the random nature of fiber distribution and pre-existing flaw size in fiber reinforced composite, sufficient margin between  $\sigma_0$  and  $\sigma_{fc}$  as well as  $J'_b$  and  $J_{tip}$  should be obtained to ensure the possibility of PSH behavior [22]. In this regard, Kanda and Li [23] proposed two PSH performance indices namely stress-performance index ( $\sigma_0/\sigma_{fc}$ ) and energy-performance index ( $J'_b/J_{tip}$ ) to quantitatively evaluate the margin. Theoretically, both PSH performance indices must exceed unity to achieve PSH behavior in a fiber reinforced composite. The higher the performance indices values, the greater the possibility of saturated multiple cracking or saturated PSH behavior which results in higher tensile strain capacity of the composite. Unsaturated PSH behavior often results in small tensile strain capacity and large variation in tensile ductility of the composite [22]. Higher energy-performance index ( $J'_b/J_{tip}$ ) can be achieved by either

reducing  $J_{tip}$  which is correlated to  $K_m$  as shown in Equation (2), or increasing  $J'_b$ . Reducing  $J_{tip}$  is more desirable because low  $J_{tip}$  (i.e.  $K_m$ ) indicates low first crack strength [19].

### 3. Materials

The low calcium fly ash (class F) used in this study was supplied from Gladstone power station in Queensland, Australia. The sodium-based (Na-based) activator combination used in this study was composed of 8.0 M sodium hydroxide (NaOH) and D Grade sodium silicate ( $\text{Na}_2\text{SiO}_3$ ) solutions. NaOH solution was prepared with a concentration of 8.0 M using NaOH beads of 97% purity supplied by Sigma-Aldrich and tap water. The D Grade  $\text{Na}_2\text{SiO}_3$  solution was supplied by PQ Australia with a specific gravity of 1.51 and a modulus ratio ( $M_s$ ) equal to 2.0 (where  $M_s = \text{SiO}_2 / \text{Na}_2\text{O}$ ,  $\text{Na}_2\text{O} = 14.7\%$  and  $\text{SiO}_2 = 29.4\%$ ). NaOH and  $\text{Na}_2\text{SiO}_3$  solutions were mixed together with  $\text{Na}_2\text{SiO}_3/\text{NaOH}$  mass ratio of 2.5 to prepare the Na-based activator combination. Sieve graded high silica purity sands with maximum particle size of 212  $\mu\text{m}$  supplied by TGS Industrial Sand Ltd., Australia was used in this study. Properties of the PVA fiber used in this study supplied by Kuraray Co. Ltd., Japan are presented in Table 1.

### 4. Experimental procedures

#### 4.1. Mix proportions and mixing

In this study, four appropriate EGC mix proportions were designed through experiments using the principles of ECC development to establish strain hardening behavior in low calcium (Class F) fly ash-based EGC. Table 2 presents mix proportions of the fly ash-based EGCs used in this study. As shown in this table, two values of activator to fly ash ratios (0.35 and 0.45) with two values of sand to fly ash ratios (0.30 and 0.60) were selected. All EGCs were prepared in a Hobart mixer. To prepare the fly ash-based geopolymer matrix, fly ash and sand (if any) were dry mixed for about 3 min. Then alkaline solution as well as extra water in the mixture EGC35 were added and the mixing was continued for about 4 min. In each mix once a consistent matrix was reached, PVA fibers (2% v/v) were gradually added, taking care to ensure uniform fiber dispersion. The whole mixing procedure for each composite generally took 20-25 min.

**Table 1: Properties of PVA fiber**

Fiber type	Diameter ( $\mu\text{m}$ )	Length (mm)	Young's modulus (GPa)	Elongation (%)	Nominal Strength (MPa)	Density ( $\text{g}/\text{cm}^3$ )
RECS 15x8	40	8	41	6	1600	1.3

**Table 2: Mix proportions of the fly ash-based EGCs**

Mix designation	Fly ash	Activator	Water	Sand	PVA fiber
EGC35 <sup>1</sup>	1.0	0.35	0.014 <sup>2</sup>	---	0.02
EGC45 <sup>1</sup>	1.0	0.45	---	---	0.02
EGC45-S30	1.0	0.45	---	0.30	0.02
EGC45-S60	1.0	0.45	---	0.60	0.02

Note: All numbers are mass ratios of fly ash weight except W/GP solids ratios and fiber contents (volume fraction).

<sup>1</sup> Composed of only geopolymer paste with no sand.

<sup>2</sup> Extra water added to the activator.

#### 4.2. Casting, curing and testing of specimens

To determine flowability of fresh geopolymer matrix in each mix, mini slump tests also known as spread-flow tests were conducted. Each mix was tested twice. Details of the mini-slump test can be found in Nematollahi and Sanjayan [24]. The relative slump value was derived from the following equation:

$$\Gamma_p = (d/d_0)^2 - 1 \quad (4)$$

where  $\Gamma_p$  is relative slump,  $d$  is the average of two measured diameters of the matrix spread and  $d_0$  is bottom diameter of the conical cone, equals to 100 mm in this study [25].

For each mix design, compressive strength of the matrix specimens (before addition of the PVA fibers) and the composite specimens (after addition of the PVA fibers) were measured. In this regard, the fresh geopolymer matrices and composites were cast into standard 50 mm plastic cube molds and compacted using a vibrating table. For heat curing all molds were sealed to minimize moisture loss

and placed in an oven at 60° C for 24 hours. At the end of heat curing period, the specimens were removed from the oven and kept undisturbed until being cool and then removed from the molds and left in the laboratory at ambient temperature until the day of testing. All specimens were tested 3 days after casting. Previous studies have shown that age does not have considerable effect on strength of geopolymers after the completion of the heating curing period, thereby three-day compressive strength of geopolymer is equivalent to a typical OPC strength development after 28-days [26,27]. At the testing day the cube specimens were weighed to determine the density of the matrix and composite specimens. Compressive strength of all specimens were measured according to ASTM C109 [28]. For each mix, at least three matrix specimens and three composite specimens were tested in order to check the variability of performance under compression.

Uni-axial tension tests were conducted to evaluate the behavior of the developed EGC under tension. At least three coupon specimens with the dimensions of 400 mm×75 mm×10 mm were cast and cured similar to the cube specimens. All specimens were tested in uni-axial tension under displacement control using MTS testing machine with hydraulic wedge grips. Following Ahmed and Maalej [29], the displacement rate was 0.25 mm/min. Aluminum plates were epoxy glued onto the ends of the specimens to facilitate gripping. Care was taken to ensure proper alignment of the specimens with the machine hydraulic grips. Details of the uni-axial tension test can be found in Nematollahi et al. [15].

## 5. Results and Discussions

### 5.1. Workability, density and compressive strength

The average matrix workability of each mix in terms of relative slump value is presented in Table 3. According to this table, the EGC45 and EGC35 mixes exhibited the highest and the lowest matrix workability, respectively. In addition, as expected the matrix workability of the EGC45 mix was significantly (32%) higher than that of the EGC35 mix due to its higher Act/FA. Furthermore, as expected due to the addition of the sand, the workability of the mortar mixes was lower than that of the EGC45 mix (paste only mix with no sand) and the rate of decrease in workability depended on the sand content in the mortar mixes. Effect of the Act/FA on the matrix compressive strength of the EGCs is also presented in Table 3. According to this table, an increase in Act/FA from 0.35 to 0.45 resulted in a considerable decrease in compressive strength of the matrix. The matrix compressive strength of the EGC45 mix was 42% lower compared to that of the EGC35 mix. Similar trend was reported by other researchers for geopolymer paste and concrete [27,30]. This trend is somewhat similar to the well-known effect of water to cement ratio (W/C) on the compressive strength of the cement-based matrices [17,27]. The average matrix and composite densities of each mix are also presented in Table 3. As shown in this table, the EGC45-S60 and EGC35 composites exhibited the highest and the lowest matrix and composite densities, respectively. In addition, as expected matrix and composite densities of the mortar mixes were higher than those of the EGC45 mix (paste only mix with no sand). It should be noted that the composite density of each mix was relatively lower compared to its corresponding matrix density. This may be attributed to a fiber induced damage effect, which results in a composite with higher porosity compared with the matrix material alone [31].

**Table 3: Workability, density and compressive strength results**

Mix designation	Relative slump value	Density; (kg/m <sup>3</sup> )		Compressive strength, (MPa)	
		Matrix	Composite	Matrix	Composite
EGC35	6.9	1859	1804	54.6	63.7
EGC45	9.1	1899	1824	31.6	52.6
EGC45-S30	8.8	1928	1828	36.4	56.8
EGC45-S60	7.3	2041	1912	35.3	60.7

Effect of the sand content (S/FA) on the matrix compressive strength of the EGCs is also demonstrated in Table 3. According to this table, an increase in S/FA from zero to 0.3 resulted in a marginal (15%) increase in the matrix compressive strength. However, increase in S/FA from 0.3 to 0.6 (doubling the sand content) did not cause any significant change in the compressive strength of the mortar matrices. In other words, the matrix compressive strengths of both mortar matrices, regardless of their sand content, were almost comparable. These results are in good agreement with those published by Temujin et al. [32] where the compressive strength of the fly ash-based geopolymer mortar mixes remained almost constant with varying the sand content. Effect of the Act/FA and S/FA on the composite compressive strength of the EGCs are also presented in Table 3. According to table, in all mixes the compressive strength of the composite was higher than that of the corresponding matrix due to the addition of the PVA fibers (2% v/v). Moreover, as expected it was

observed that in all composite specimens crack propagation was restrained due to the bridging mechanism of the PVA fibers; thereby the specimens kept their original shapes after peak load resulting in a ductile failure mode. It should be noted that although the concentration of the activator combination was limited to 8.0 M to account for safety consideration; however, the compressive strength of all EGCs developed in this study was significantly higher than that of the fly ash-based EGCs developed by Ohno and Li [14] which ranged from 17.4 MPa to 27.6 MPa. This could be mainly due to the longer heat curing period (i.e. 24 hours at 60° C) employed in this study. Among mortar mixes, the EGC45-S60 composite exhibited the highest compressive strength (60.7 MPa) as it contained the highest amount of sand. The fact that the EGC35 composite without sand exhibited higher compressive strength (63.7 MPa) compared to that of the EGC45-S60 composite with sand could be attributed to their different Act/FA (0.35 versus 0.45).

**5.2. Uni-axial tensile performance**

Tensile stress-strain behaviors of the fly ash-based EGCs are presented in Figures 1 to 4. As shown in these figures, all EGCs, regardless of their Act/FA and S/FA, exhibited clear PSH behavior with tensile strain capacities ranging from 1.3% to 4.3%. The experimentally measured ultimate tensile strength and tensile strain capacity as well as the estimated first-crack strength, the average crack opening at peak load (i.e. average loaded crack width) of each composite are presented in Table 4. The uni-axial tensile performance of the fly ash-based EGCs developed in this study are comparable to those of the fly ash-based EGCs developed by Ohno and Li [14]. However, as shown in Table 4, the ultimate tensile strength of all EGCs developed in this study was higher than that of the EGCs developed by Ohno and Li [14] which ranged from 2.9 MPa to 3.4 MPa. After unloading, clear trace of all visible cracks was obtained by using a permanent marker. The average crack opening at peak load was estimated based on the tensile strain capacity, gauge length and the number of visible cracks. It should be noted that the number of multiple cracks formed during loading was more than that of the unloading specimens as many micro cracks appeared during loading completely closed after unloading; thereby, making them very difficult to detect on the specimen surface after unloading. According to Li et al. [19], the actual crack opening at peak load should be smaller than the estimated values shown in Table 4 because as mentioned earlier the actual number of micro-cracks developed during loading was more than the number of visible cracks after unloading. In the EGC35, EGC45 and EGC45-S30 composites crack distribution was uniform with almost equal crack spacing and enormous micro-cracks with tightly controlled crack width (i.e. saturated cracking behavior) were observed which corresponds to their significantly high tensile strain capacities. However, in the EGC45-S60 composite the crack distribution was not uniform with un-even and wider crack spacing and fewer number of visible cracks (i.e. un-saturated cracking behavior) which corresponds to its significantly lower tensile strain capacity.

**Figure 1: Tensile stress-strain responses of EGC35**

Figure 2: Tensile stress-strain responses of EGC45

Figure 3: Tensile stress-strain responses of EGC45-S30

Figure 4: Tensile stress-strain responses of EGC45-S60

**Table 4: Uni-axial tensile test results**

Mix designation	First-crack strength, $\sigma_{fc}$ (MPa)	Ultimate tensile strength, $\sigma_{cu}$ (MPa)	Tensile strain capacity, $\varepsilon_{cu}$ (%)	Estimated loaded crack width; ( $\mu\text{m}$ )
EGC35	$0.66 \pm 0.053$	$4.7 \pm 0.25$	$4.3 \pm 0.14$	$119 \pm 9.53$
EGC45	$0.45 \pm 0.095$	$4.3 \pm 0.45$	$3.0 \pm 0.19$	$94 \pm 17$
EGC45-S30	$1.3 \pm 0.27$	$5.0 \pm 0.47$	$3.6 \pm 0.15$	$103 \pm 3.63$
EGC45-S60	$1.6 \pm 0.25$	$5.2 \pm 0.51$	$1.3 \pm 0.15$	$107 \pm 20.0$

According to Table 4, the increase in Act/FA from 0.35 to 0.45 resulted in a 32% decrease in first crack strength of the EGC45 composite compared to that of the EGC35 composite. The lower first crack strength of the EGC45 composite implies its lower  $J_{tip}$  compared to that of the EGC35 composite which is beneficial for PSH behavior of the composite [19]. In addition, the ultimate tensile strength of the EGC45 composite was slightly (9%) lower than that of the EGC35 composite which could be attributed to the interfacial properties. In other words, the chemical bonding energy and the frictional bond strength of the EGC45 composite was lower compared to that of the EGC35 composite; resulting in lower fiber bridging strength [33]. The reasons for different tensile strain capacities of the EGC35 and EGC45 composites could be explained in terms of the two PSH performance indices  $\sigma_0/\sigma_{fc}$  and  $J'_b/J_{tip}$ . With regards to the stress-performance index, the  $\sigma_0/\sigma_{fc}$  of the EGC45 composite was 35% higher than that of the EGC35 composite. With regards to the crack tip toughness, as mentioned earlier, the lower first crack strength of the EGC45 composite indicates that the  $J_{tip}$  of the EGC45 was lower than that of the EGC35 composite. The lower the  $J_{tip}$  value, the higher the energy-performance index. On the other hand, with regards to the  $J'_b$ , the higher ultimate tensile strength of the composite indicates the higher peak bridging stress in the  $\sigma-\delta$  curve of the composite. In addition, the higher loaded crack width indicates the higher crack opening corresponding to maximum bridging stress in the  $\sigma-\delta$  curve of the composite [33]. Considering the ultimate tensile strength and the loaded crack width of the EGC35 and EGC45 composites as presented in Table 4, it can be concluded that the  $J'_b$  of the EGC35 composite is higher than that of the EGC45 composite. The higher the  $J'_b$  value, the higher the energy-performance index. Consequently, with regards to the energy-performance index, it can be inferred that the  $J'_b/J_{tip}$  of the EGC45 composite is slightly higher than that of the EGC35 composite. As mentioned in Section 2, the higher values of the two PSH performance indices, the greater the possibility of saturated PSH behavior which results in higher tensile strain capacity of the composite. Considering the higher PSH performance indices of the EGC45 composite, it can be said that the EGC45 composite should theoretically exhibit higher (or at least comparable) tensile strain capacity compared to that of the EGC35 composite. However, as shown in Table 4, the tensile strain capacity of the EGC45 did not exceed that of the EGC35 composite. This may be attributed to the poor fiber dispersion (fiber bundles) of the EGC45 composite as fiber bundles were observed during mixing which adversely affected the composite behavior. According to Li et al. [34], fiber bundling is not desirable as it decreases the effectiveness of the fiber reinforcement and weak spots may be introduced by the fiber bundles.

As shown in Table 4, the addition of sand to the matrices of the EGC45-S30 and EGC45-S60 composites resulted in marginal (16% to 21%) increase in the ultimate tensile strength of these composites compared to that of the EGC45 composite with no sand. However, the addition of sand resulted in considerable decrease in the tensile strain capacity of these composites. It should be noted that, as mentioned earlier, the EGC45 composite should theoretically exhibit higher (or at least comparable) tensile strain capacity compared to that of the EGC35 composite. Similar results were reported by Ahmed and Maalej [29] regarding the adverse effect of the sand addition on the strain hardening behavior of conventional ECC composites. The undesirable effect of the addition of sand on the strain hardening behavior of the EGC composites could also be explained in terms of the two PSH performance indices  $\sigma_0/\sigma_{fc}$  and  $J'_b/J_{tip}$ . As shown in Table 4, the addition of sand to the matrices of the EGC45-S30 and EGC45-S60 composites resulted in significant increase in the first crack strength of these composites compared to that of the EGC45 composite with no sand. This significant increase in the first crack strength of these composites is not desirable as it results in significant reduction in the strength performance index ( $\sigma_0/\sigma_{fc}$ ) of the composite. For instance, the first-crack strength of the EGC45-S60 composite (with S/FA=0.6) was significantly (256%) higher than that of the EGC45 composite with no sand; thereby, the stress performance index of the EGC45-S60 was considerably (66%) lower than that of the EGC45 composite with no sand. In addition, the significant increase in the first crack strength of the EGC45-S30 and EGC45-S60 composites implies that the crack tip toughness of these composites would be considerably higher than that of the EGC45 composite with

no sand [19] which is not desirable as it results in significant reduction in the energy performance index ( $J'_b / J_{tip}$ ) of the composite. In conventional cement-based composites, it is well established that high sand content results in a matrix with high fracture toughness, which in turn increases the first crack strength of the composite compared to the maximum bridging stress of the fibers and violates the conditions for saturated strain hardening behavior ([35,36]Li and Maalej, 1996; Akkaya et al., 2000). In summary, it can be said that the excessive use of sand in the matrix of the EGC45-S60 composite resulted in considerable increase in the first crack strength and crack tip toughness of the composite; thereby, the two PSH performance indices ( $\sigma_0 / \sigma_{fc}$  and  $J'_b / J_{tip}$ ) of the composite decreased significantly which hindered the use of this matrix and still ensure saturated PSH behavior in the composite. These results are in good agreement with those published by other researchers regarding the conventional ECC composites which indicate that the sand content must be limited in the matrix to sustain tensile ductility of the composite [17,19].

## 6. Conclusions

Strain hardening behavior in randomly oriented short PVA fiber reinforced fly ash-based EGCs were developed in this study. The effect of matrix related parameters including the activator to fly ash and sand to fly ash ratios on the matrix and composite properties of the developed EGCs were experimentally evaluated. All EGCs, regardless of their alkaline solution to fly ash and sand to fly ash ratios, exhibited clear PSH behavior under uni-axial tension similar to the conventional PVA-ECC. Experimental results revealed that the increase in the activator to fly ash ratio decreased the first crack strength, ultimate tensile strength and tensile strain capacity of EGC. With regards to the effect of sand content, the tensile strain capacity of EGC was significantly reduced when excessive amount of sand was added to the geopolymer matrix. However, the ultimate tensile strength of EGC was marginally increased. The adverse effect of the addition of sand on the strain hardening behavior of EGC can be attributed to the increase of matrix fracture toughness due to the excessive use of sand in the geopolymer matrix, which in turn increases the first cracking strength of the composite and suppresses the desirable strain hardening behavior and accompanying composite ductility in tension. This result indicates that the sand content must be limited in the geopolymer matrix to sustain tensile ductility of EGC.

## 7. Acknowledgments

The authors gratefully acknowledge Kuraray Co. Ltd. of Japan for supplying the PVA fibers used in this study.

**Abstract:** Brisbane West Wellcamp Airport (BWWA) became fully operational with commercial flights operated by Qantas Link in November 2014. BWWA was built with approximately 40,000 m<sup>3</sup> of geopolymer concrete making it the largest application of this new class of concrete in the world. Heavy duty geopolymer concrete was used for the turning node, apron and taxiway pavements using a slip form paving machine. The proprietary geopolymer concrete, known as Earth Friendly Concrete (EFC), was found to be well suited for this construction method due to its high flexural tensile strength, low shrinkage and workability characteristics.

This paper describes the geopolymer concrete pavements delivery from both a materials and construction viewpoint and notes differences to conventional concrete where they occurred. The authors conclude by reviewing earlier projects with this particular geopolymer concrete and discussing how this body of work could help to increase the use of geopolymer concrete in Australia and globally.

**Keywords:** geopolymer concrete, BWWA, pavement, flexural tensile strength

## 1. Introduction

Brisbane West Wellcamp Airport (BWWA) is Australia's first greenfield public airport to be built in 48 years. BWWA became fully operational with commercial flights operated by Qantas Link in November 2014. This project marks a very significant milestone in engineering - the world's largest geopolymer concrete project.

EFC was supplied by Wagners for the construction of the 435 mm thick heavy duty pavements in the aircraft turning areas. There were three distinct areas of geopolymer pavement including the turning node at the Northern end of the runway, the taxiway on the Western side of the runway and the hangars on the Eastern side of the runway.

In preparation for the project both product testing and construction trials were undertaken to ensure that this geopolymer concrete could meet the performance criteria of the contract specification as well as be placed in the intended method using a slip form paving machine. The construction trials highlighted a number of challenges which were overcome by some innovative and novel solutions.

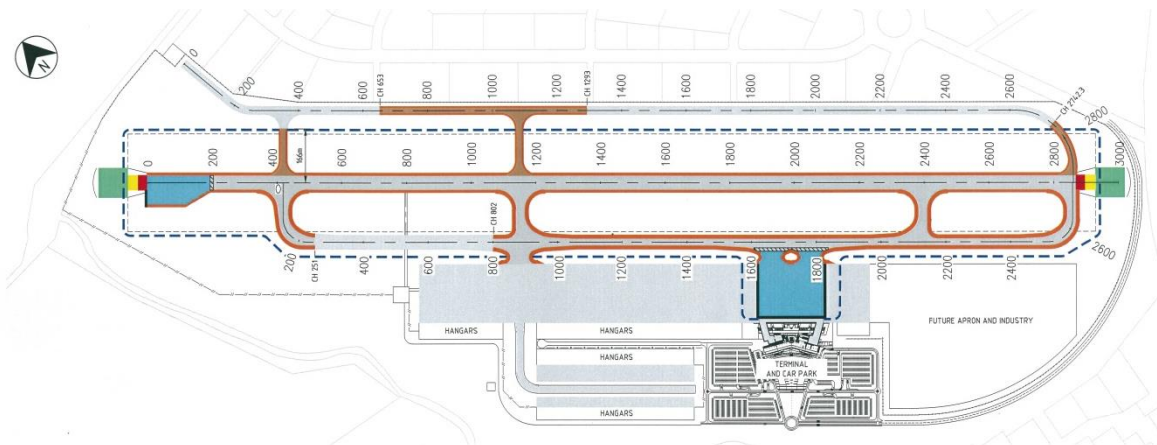

## 2. Project Outline

Figure 1 shows an overall plan and an aerial photograph of the completed pavement works at the BWWA site. The turning node is located at the Northern end of the runway and the apron is located on the Western side of the runway in front of the terminal and carpark. While not shown on the site plan, the private hangar pavement is located outside the boundary of the airport on the Eastern side of the runway which can be seen in the aerial photograph.

The private hangar pavement was constructed in the period May – July 2014 and served as a construction trial area to prove the intended geopolymer design mix and the pavement placement method. The pavement construction trials consisted of 10 individual pours of 5 m wide x 50 metres long that were placed by the paving contractor using a Gomaco slip form road paver.

In the 6 month period prior to pavement construction, Wagners had developed a geopolymer concrete design mix deemed suitable from laboratory trials and small scale pavement works around the BWWA site. The concrete materials specification written by independently commissioned ACG consulting engineers required:

- 4.8 MPa average flexural strength at 28 days of age, AS 1012.11 (1)
- 450 micro-strain maximum drying shrinkage at 28 days of age, AS 1012.13 (2)

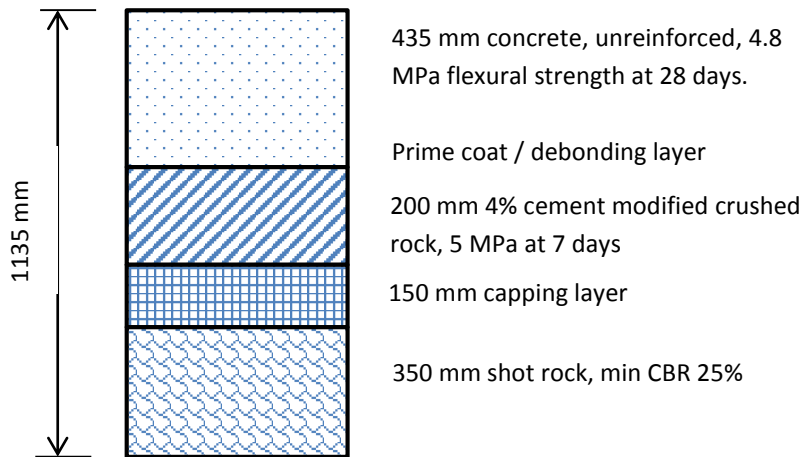

(pavement plan - excerpt from ACG Engineers drawings)

**Figure 1. Site plan and aerial photograph – BWWA.**

Following a successful trial phase, the geopolymer concrete mix and pavement construction method was approved by the engineers. Construction of the turning node pavements was undertaken during August and September 2014 and the apron pavements were constructed during October and early November 2014. BWWA was opened for its first commercial flight on 17 November 2014.

The pavement design was undertaken by ACG Engineers and is shown in Figure 2.

(pavement design by ACG Engineers)

### 3. Geopolymer Concrete Mix

The proprietary geopolymer concrete mix used in this project follows approximately 10 years of work by Wagners developing a commercial product that is produced and handled in a similar manner to conventional concrete. The project mix was developed for the BWWA heavy duty pavements to suit placement with a slip form paving machine. Key criteria of the mix included:

- Workability, slump and slump retention suitable for transport in tippers and slip form pavement construction.
- Achieve specified flexural strength of 4.8 MPa

The summary mix parameters were:

- Total alumino-silicate binder comprising GGBS + Fly ash, 415 kg/m<sup>3</sup>
- Water:binder ratio 0.41
- Nominal 40 mm maximum aggregate size, conforming with 28 mm to AS 2758.1 (3)
- Chemical activator, 37 kg/m<sup>3</sup> solids content
- Proprietary water reducing admixture

Flexural strength testing was conducted by the project site NATA laboratory in accordance with Australian Standards AS 1012.11 at a frequency of 4 different loads taken evenly across the production of one work shift, as per the engineer's specification. The results achieved from making fresh concrete beam specimens across the turning node and apron pavements are shown in Table 1.

**Table 1. Flexural tensile strength results (28 days).**

No. of Samples	502
Average flexural strength (MPa)	5.8
Standard Deviation	0.6

#### 4. Geopolymer Concrete Production and Supply

The geopolymer concrete was produced in a twin mobile wet mix batch plant established on the BWWA project site as shown in Figure 3. The standard concrete production plants shown have been modified to accommodate the chemical activators which are added to the mix as a solution. An assembly of tanks and pumps are incorporated into the plant that mix, hold and accurately dispense the activators into wet mix bowl using an automated batch system.

A maximum supply capacity of 120 m<sup>3</sup>/hr was required to provide a continuous feed of concrete to the slip form paving machine which is shown in Figure 4. This requirement was successfully achieved using the plant configuration and several tipper trucks for delivery. An advantage of wet mix production is that concrete agitator trucks are not required for short transit times. The use of tippers allowed a significantly improved discharge rate at the paver face.

Figure 3. Geopolymer concrete twin batch plant.

Figure 4. Geopolymer concrete delivery to slip form paver.

#### 5. Geopolymer Concrete Pavement Construction

Aircraft pavement construction in Australia is normally undertaken by placing and compacting the concrete into and against steel side forms using a combination of internal mechanical vibration and vibrating beams. This method for the placement of deep lift heavy duty pavements has evolved from construction experience with Portland cement based concrete. The use of slip form paver machines as used in thinner concrete road bases have generally not been used in airport pavement construction due to concerns regarding incomplete compaction for thicker pavement bases.

Using geopolymer concrete in a series of successful trials at the hangar area demonstrated that a very high level of compaction could be achieved with a slip form paver machine. Steel side forms were chosen over the option of unformed extrusion to ensure the 435 mm thick pavements could be fully compacted at the sides without any loss in surface flatness. Slip form construction was adopted at

BWVA due to its efficiency and increased production rate compared to using a vibrating beam. It is estimated that a 30% reduction in the pavement construction program was achieved on this project compared with the traditional process.

The characteristic rheology and internal cohesion of the proprietary geopolymer mix at the specified slump allowed it to extrude considerably better than conventional concrete. This allowed for very efficient placement resulting in the noted speed gains. The level of admixtures and activators in the mix were able to be customised for the differing weather conditions and length of transit time across the project site. Winter to Summer (2°C minimum - 40°C Maximum, 5 minutes - 20 minutes transit time).

The proficiency of compaction using the slip form paving machine was validated by comparing in situ density test results with fresh concrete density results, (Table 2). In situ density was undertaken by using both the Nuclear density method (NDM) to AS 1289.5.8.1 (4) and in situ core density testing to AS 1012.14 (5) and AS 1012.12 (6). A density core specimen is shown in Figure 5.

**Table 2. Density measurements.**

	All areas	Turning node area – In situ testing				Apron area – In situ testing			
	Cast beams and cylinders	Core method middle	Core method top	Core method bottom	NDM method	Core method middle	Core method top	Core method bottom	NDM method
Max	2.540	2.500	2.540	2.510	2.511	2.490	2.490	2.590	2.520
Average	2.400	2.460	2.460	2.470	2.427	2.440	2.460	2.470	2.440
Min	2.280	2.420	2.410	2.410	2.312	2.400	2.430	2.380	2.370
No. Samples	1038	57	57	55	764	72	22	22	364
Standard Deviation	0.040	0.016	0.022	0.022	0.029	0.018	0.015	0.038	0.023

In situ density test specimen by coring method. Samples were cut into 3 sections – top, middle and bottom to detect compaction proficiency with depth of pavement, Table 2.

**Figure 5. Test core specimen.**

The geopolymer concrete required particular attention to curing and pre-curing evaporation control when placing exposed slab surfaces. It displayed very low bleed characteristics and the surface would rapidly dry out without intervening to maintain a moist sheen on the surface. From the supplier’s previous development work it was well understood that drying of this geopolymer concrete surface prior to initial set and the application of curing would render the extreme surface prone to wearing with time.

During trials on the hangar pavement area, a novel evaporation control and curing methodology was developed and adopted for the geopolymer concrete that well suited the slip form placement method. A new type of alkaline anti-evaporation spray was developed that reduced the evaporation rate while maintaining the alkalinity of the fresh geopolymer concrete surface that can be depleted through the application of traditional products. Curing consisted of applying a water based hydro carbon resin

curing compound, followed by covering with a geotextile to limit any thermal shock brought about by the difference of daytime and night time temperatures, Figure 6.

**Figure 6. Curing and side forms with dowels.**

Jointing design of the pavements followed conventional rules based on Portland cement concrete. In the direction of paving, joints were saw cut at 5 metres centres with isolation joints provided every 70 metres. Early age saw cutting was carried out as soon as possible, generally 1 to 5 hours after placement depending on the ambient temperatures as shown in Figure 7. Dowels were located between paving lanes as shown in Figure 6.

The geopolymer concrete’s lower shrinkage properties compared with conventional concrete would indicate that joint spacing could be increased compared with conventional concrete. However, this option was not pursued in order to maintain a low risk for this application of an innovative material. The supplier’s test data on this geopolymer concrete indicated an average 56 day drying shrinkage of 350 microstrain, tested to AS 1012.13 (2). A significant benefit and cost saving on future work would be to increase the joint spacing based on the higher flexural strength and lower shrinkage properties of this geopolymer concrete.

## 6. Commercialisation of Geopolymer Concrete

The pavements project at BWWA outlined in this paper is believed to be the largest commercial application of modern geopolymer concrete (defined by the authors as post-1970) in the world. Some 25,000 m<sup>3</sup> of aircraft pavement grade concrete was supplied and constructed over a 3.5 month period.

In addition to the pavements, a further 15,000 m<sup>3</sup> of geopolymer concrete was used throughout the BWWA project in a variety of applications including:

- Entry bridge to the airport, (Figure 9).
- Extruded kerb and road barriers, (Figure 9).
- Precast culverts.
- Site cast tilt panels for the terminal building.
- Footings, piles, pads and the tunnel slab for the terminal building.
- Footings, pads and site cast tilt panels for establishment of quarrying and concrete plants.
- Pavements for median strips and associated road works (some coloured).
- Sewer tanks.

**Figure 9. Other Geopolymer Concrete Works at BWWA.**

While alkali activated slag concrete has a history dating back to the 1930's in Eastern Europe (7), geopolymer concrete is still deemed a relatively new technology in modern concrete construction. The successful and rapid construction of the BWWA project serves as an excellent demonstration that geopolymer concrete is a viable alternative to Portland cement based concrete. Contractors, developers, specifiers and approval authorities can be confident that geopolymer concrete can be designed, produced and constructed within accepted quality control parameters at the commercial scale. However there exist a number of challenges to parties wishing to include geopolymer concrete in projects:

- No Australian or international standard for either manufacture or design
- Cost disadvantages due to lack of economies of scale
- Availability from suppliers
- Lack of older geopolymer structures in Australia to confirm long term durability.

The developers of the geopolymer concrete discussed here have made progress in overcoming these barriers as evidenced by the successful delivery of BWWA as well as a wide range of previous geopolymer concrete works, both commercial and internal projects with an R&D focus. This substantial body of work which includes results from independent durability studies by RMIT is reported by Glasby et al (8). A very significant previous project is the Global Change Institute (GCI) building in Brisbane on the University of Queensland campus that is reported by Bligh and Glasby (9). It is claimed to be a world first application of modern geopolymer concrete suspended floor beams in a multi-storey building.

It remains the case however that until significantly more progress is made on removing the barriers, new geopolymer concrete projects at the commercial scale will remain the domain of highly motivated parties that are willing to accept a price premium and 3<sup>rd</sup> party engineering certification of suppliers' data. One very positive step that the author is aware of is the writing of a Handbook on geopolymer concrete under a CRC grant that may lead to an Australian standard.

A key driver for the use of geopolymer concrete in Australia and elsewhere has been the environmental benefits of a concrete that utilises a large component of recycled material (slag and / or flyash) which completely replaces carbon intensive Portland cement (10). By using a figure of 80% reduced CO<sub>2</sub> emission compared to Portland cement, the binder content in this geopolymer concrete compared to a conventional 75% GP / 25% fly ash blended cement in an equivalent normal concrete, saved some 8,640 tonnes of CO<sub>2</sub> emissions in this project alone.

Another strong driver for geopolymer concrete is the performance and durability improvements that are possible due to the different chemistry of the binder. In this project the high flexural tensile strength coupled with low shrinkage of the particular proprietary geopolymer concrete used made it an ideal pavement concrete. In other projects, particular durability properties of acid, sulfate and chloride ingress resistance will offer high value to applications including sewer systems, marine structures and underground works through sulfate soils / ground waters. A cautionary note should be heeded that the term 'geopolymer' can apply to a wide range of alumino-silicate activated materials and their performance will vary depending on a range of factors, including:

- Source of alumino-silicate powder – type, reactivity, quality, etc.
- Alkaline activator chemicals
- Curing regime – ambient vs elevated temperature
- Total water and water:binder ratio for geopolymer concrete

Quality control during production and placement are extremely important in producing high quality geopolymer concrete, even more so than is the case for conventional concrete. Purpose made water reducing admixtures were a vital component in this proprietary geopolymer concrete having the necessary workability and slump retention at low water contents.

## **7. Conclusion**

The successful privately funded BWWA, Australia's first greenfield public airport in 48 years, is built on some 40,000 m<sup>3</sup> of geopolymer concrete making it the largest application of this new class of concrete in the world. This paper has reported on the heavy duty geopolymer concrete pavements that comprise the turning node, apron and taxiways. Production was undertaken using commercial scale concrete batch plants that delivered a continuous supply to a slip form paving machine and returned an excellent production rate. The proprietary geopolymer concrete proved an ideal material for the

construction method due to its high flexural tensile strength, low shrinkage and workability characteristics.

A comprehensive trial program leading up to the works ensured a suitable mix was developed that could be placed with a slip form paving machine. A new alkali anti-evaporation spray was developed that protected the geopolymer concrete surface from drying out prior to curing.

This successful application of geopolymer concrete at the full commercial scale should support future uptake of a truly novel and environmentally responsible technology.

# On Fly Ash Based Geopolymer Concrete and its Behaviour at Elevated Temperature

Tian Sing Ng, Stephen J. Foster and Samantha Milojevic

School of Civil and Environmental Engineering, University of New South Wales, Sydney, Australia

**Abstract:** This paper presents the results of an experimental investigation of the behaviour of two fly ash based geopolymer concretes following exposure to high temperatures up to 1000 °C. Two geopolymer concretes were manufactured using the same mixture proportion but the curing process was manipulated in order to achieve the target nominal compressive strengths of 20 MPa and 50 MPa. Residual compressive strength, static elastic modulus and density change were carried out for both mixes. Tests were also conducted for the 50 MPa high strength geopolymer concrete at hot state using a specially designed furnace–loading frame assembly. The hot-state deformation modulus, free thermal strains (FTS) and load induced thermal strains (LITS) were measured. In general, the compressive strength and elastic modulus decreased with increasing temperature. The FTS and LITS are found to be very different to that of Portland cement concrete where geopolymer concrete undergoes both expansion and contraction at different stages of heating. Further, stressed geopolymer concrete experienced an abrupt loss of stiffness and exhibited significant visco-plastic and deformation behaviours beyond 800 °C.

**Keywords:** Geopolymer; Elevated Temperatures; Fire; Stress-Strain; Hot strength; Residual strength; Modulus of Elasticity

## 1. Introduction

Over the last two decades, geopolymer concretes have emerged as novel engineering materials with the potential to form a substantial element of an environmentally sustainable construction and building products industry [1-2]. Geopolymer is a material resulting from the reaction of a material that is rich in silica and alumina with alkaline solution. Industrial waste materials, such as fly ash and blast furnace slag, are commonly used as the source of aluminosilicate to manufacture geopolymer concrete due to the low cost and vast availability of these materials.

Most of the research and investigation of fly ash based geopolymer concretes deal with their properties and behaviour at ambient temperature. Fire can cause substantial damage to concrete structures and the consequences could be enormous. At stake are not only lives but also can lead to significant financial losses. To evaluate the performance of fly ash based geopolymer concretes when exposed to a fire it is critical to know the effect of various temperature levels on the extent of deterioration of the concrete and the ability of the concrete to carry loads when exposed to a fire. Limited publications in this field of study are available in the literature. Most of the studies investigated the residual properties after cooling to normal room temperature [3-9] but the findings to-date is still not conclusive with some investigators observed strength losses and gains, respectively, on the concrete after exposed to elevated temperature. Little studies have also been carried out on the hot stressed and unstressed strength properties of fly ash based geopolymer concretes.

This study investigated the hot stressed and unstressed physical and mechanical properties of the fly ash based geopolymer concrete up to 1000 °C. The hot state deformation modulus, FTS and LITS of the concrete are reported herein. The residual strengths of the concrete after exposing to temperature up to 1000 °C were also investigated.

## 2. Experimental program

Fly ash based geopolymer concretes with target compressive strengths of 20 MPa and 50 MPa were studied initially. The authors have adopted two types of curing regime to achieve the two desired strengths of the geopolymer concrete, without changing the mixture proportions and initial chemical compositions. This manufacturing process is similar to that of undertaken by Pan et al. [3] and Sarker et al. [8]. Subsequently, however, it was found that the lower strength grade of geopolymer concrete obtained through this process is due to incomplete polymerisation of the concrete and, hence, the strength was not fully developed. This practice is not recommended in order to maximise the best performance of the concrete. Following this discovery, only the 50 MPa grade concrete was investigated.

## 2.1 Source materials and mix design

Aluminosilicate source materials used in this study are ASTM Class F fly ash (FA) from Eraring power station in New South Wales, Australia and ASTM Class F Kaolite high performance ash (HPA) from Callide power station in Queensland, Australia. The two sources of fly ash were blended based on the findings of Ng and Foster [12] to achieve the optimal characteristic. Small amount of ground blast furnace slag (GGBFS) supplied by the then Blue Circle Southern Cement Australia was also used. The addition of slag is found to promote faster hardening process and give early structural strength based on the authors' preliminary work and the study by Li and Liu [13]. Without the addition of slag, Hardjito and Rangan [14] observed that their fly ash based geopolymer concrete did not harden for at least 24 hours when the room temperature was less than 30°C. Further, most commercial geopolymer concrete also includes the use of slag. The chemical compositions of the FA, HPA and GGBFS are presented in Table 1 while their grading curves are given in Figure 2.

**Figure 2. Particle size distributions for FA, HPA and GGBFS.**

The alkaline activator was comprised of a mixture of 12 molar sodium hydroxide (NaOH) solution and sodium silicate solution. The sodium silicate solution was obtained from PQ Australia, under the commercial name of D<sup>TM</sup> with Na<sub>2</sub>O = 14.7 %; SiO<sub>2</sub> = 29.4%; and H<sub>2</sub>O = 55.9%, by mass of chemical components. The ratio of NaOH solution to the sodium silicate solution was 1:2.5 by mass. The activator was blended and stored for at least 24 hours prior to the manufacturing of the geopolymer concrete in order to allow equilibration.

Kiln dried Sydney sand with maximum particle size of 600 µm and 10 mm nominal size air-dried basalt aggregate were used as the fine and coarse aggregates in the geopolymer concrete, respectively. Table 2 presents the details of the fly ash based geopolymer concrete mix used in this study.

**Table 2. Fly ash based geopolymer concrete mix data (% by mass).**

## 2.2 Mixing and specimen preparation

The geopolymer concrete was produced using a horizontal pan type mixer. All the constituents were batched by an electronic balance. FA, HPA, fine aggregate and coarse aggregate were mixed for about 5 minutes. Following, the alkaline activator and water were added gradually and the product was mixed for

another fifteen minutes, making the total mixing time around twenty minutes. The reason for selecting a longer mixing time is that the rate of leaching and transportation of Al and Si atoms in the geopolymer mixture could be significantly increased, thus enhancing the strength of the geopolymer concrete [15]. Lastly, GGBFS was introduced gradually and mixing continued for a further 5 minutes. The GGBFS was added during the wet mixing rather than dry mixing in order to prevent rapid hardening of the mixture and to allow for a sufficient workable time for casting of the specimens.

The fresh geopolymer concrete was then cast as cylinder specimens of 100 mm diameter by 200 mm high. The geopolymer concrete was placed in the cylinder moulds in two layers and compacted on the vibration table. During the casting, two cylinders of 100 mm diameter and 200 mm height were cast with geopolymer mortar. The mortar was obtained by separating the coarse aggregate from the fresh geopolymer concrete using a 2.36 mm nominal size sieve.

After casting, all cylinder moulds were sealed with the cylinder lids to prevent excessive loss of moisture and were stored in a controlled environmental room at 50% relative humidity (RH) and 23°C for a period of 24 hours to allow the geopolymer concrete and mortar to be fully set, after which they were demoulded.

### **2.3 Curing regime**

Two types of curing regimes were initially adopted in order to achieve two desired strengths as discussed in Section 2 above. For the first curing method specimens labeled as 'GPC-AC' were continued to store in the controlled environmental room at 50% RH and 23 °C for a consecutive of seven days so as to achieve a nominal strength of 20 MPa. For the second method specimens labeled as 'GPC-HC' were cured under water in a hot water chamber at 80°C for seven days after they were demoulded in order to obtain a 50 MPa nominal strength.

### **2.4 Reference strength tests**

The stress-strain relationships for the two geopolymer concrete mixes were determined at ambient temperature after 28 days of casting and were used as the baseline data in this study.

### **2.5 Residual property tests after exposing to elevated temperatures**

An electric muffle furnace that is capable of heating up to 1200°C was used to heat the specimens to their desired temperatures. Five target temperature points were selected starting at 200 °C to 1000 °C, increments of 200 °C. Three cylinders were heated to the target temperature at a rate of 5 °C per minute from room temperature and allowed to soak at the target temperature for three hours to ensure uniform temperature distribution inside the cylinders. At the end of the soaking period, the furnace was turned off allowing the cylinders to naturally cool to room temperature. The cylinders were then tested to obtain the residual stress-strain relationship.

### **2.6 Hot state tests**

Two types of tests were undertaken: (i) hot state deformation modulus; and (ii) free and load induced axial thermal strains. The hot state tests were carried out in a purpose-built furnace-loading frame arrangement that allows simultaneous loading and heating of the specimens. The apparatus consisted of a vertical single zone split type furnace, and can be used to heat up to a maximum temperature of 1200 °C, and a stiff 1000 kN Instron servo-hydraulic controlled frame (Figure 3). A high temperature tolerant extensometer was used to measure the strains of the concrete.

#### **2.6.1 Hot state deformation modulus**

Five temperature points were selected for the measurements to be undertaken; 200 °C, 400 °C, 600 °C, 800 °C and 1000 °C. The cylinders were heated in the furnace-testing frame arrangement at a rate of 5 °C per minute to the target temperature and held at that temperature for 2 hours. Before the starting of heating, a small preload of 1 kN was applied during the heating to provide proper seating of the specimen and to engage the extensometer with the specimen. After the heat soaking period of 2 hours, which allowed uniform temperature distribution in the specimen, the cylinder was then tested for its deformation modulus while they were hot. The adopted measuring method was similar to that of prescribed by AS

1012.17 [16] with the specimens loaded to 40% of their residual compressive strengths that have been determined from Section 2.5 above.

(a) Arrangement of furnace with extensometer.

(b) Furnace and loading furnace during heating (furnace door was opened for photographic purpose only)

**Figure 3. Hot State Test Arrangement.**

### **2.6.2 Free thermal expansion (FTS) and load induced thermal strains (LITS)**

The cylinders were loaded at room temperature to one of the three initial loading levels: 0%, 5% and 10% of the room temperature uniaxial compressive strength. These loads were then maintained for the remainder of the test up to 800 °C.

## **3. Results and discussion**

### **3.1 Residual properties after exposing to elevated temperatures**

#### **3.1.1 Mass loss, volume change and density change**

Mass loss and volume change of the geopolymer concrete cylinders after exposure to the heating regime are calculated as a function of the concrete density. The density change predominantly takes place due to: loss of water reducing the mass of the specimen, swelling of high silicate phases at high temperatures resulting in expanding the volume of the specimen [11], increase in porosity caused by densification of the geopolymer gel during sintering [17] and bulk cracking caused by thermal incompatibility within geopolymer structures and fine and coarse aggregates [5, 6, 17]. Past thermogravimetric analyses [5, 6, 18] suggested that the vast majority of the mass loss taking place below 250 °C and is attributed to free or evaporable water loss. The mass loss between 200 °C and 300 °C may also likely due to the loss of water liberated from further geopolymerisation process [9]. The rate of mass loss is stabilised between 250 °C and 700 °C and after 700 °C, there is little change in the mass [5, 6].

Figure 4(a) shows the density curves for the mixes considered in this study as a function of exposure temperature. GPC-HC specimens show a steady and almost linear reduction in density over the temperature range. GPC-AC specimens, although having a lower strength value, are denser than GPC-HC specimens. When heated to 200 °C, a rapid reduction in the density is seen for GPC-AC specimens. As both GPC-AC and GPC-HC were made using the same mixture proportions, the difference is a direct result of the geopolymerisation or curing process. GPC-HC specimens were cured in 80 °C environment and it is therefore likely that (i) more free water was released during the curing process; (ii) more geopolymerisation occurred and the resulting water was expelled. The densities for both GPC-AC and GPC-HC specimens match at about 600 °C to 800 °C.

### 3.1.2 Physical colour change

The fly ash based geopolymer concrete experienced a range of colour changes through exposure to high temperature (Figure 4(b)). At 23 °C ambient temperature the GPC-AC specimen is dark grey in colour with traces of efflorescence (white salt deposits on or near the surface). The specimen colour progressively lightens through to 400 °C. The GPC-HC specimen is light grey at 23 °C, similar to that of GPC-AC specimen after exposed to 200 °C. After heating to 600 °C, there is a distinct change in colour in both mixes where the specimens become orange. Colour change can often signify a chemical reaction associated with a phase change, glass transition or melting point of a particular compound within the concrete. The colour develops further to a pinkish hue after heating to 1000 °C identifying continuation of the reaction. The colour changes of geopolymer concrete have been observed previously [8, 17] and are attributed to the iron oxidation in the fly ash [17]. In addition, during the experiment, when the cylinders were lightly tapped with a metal rod, the pitch of the note went up as the exposed temperature of the specimen increased; indicating the increase in the specimens porosity and brittleness.

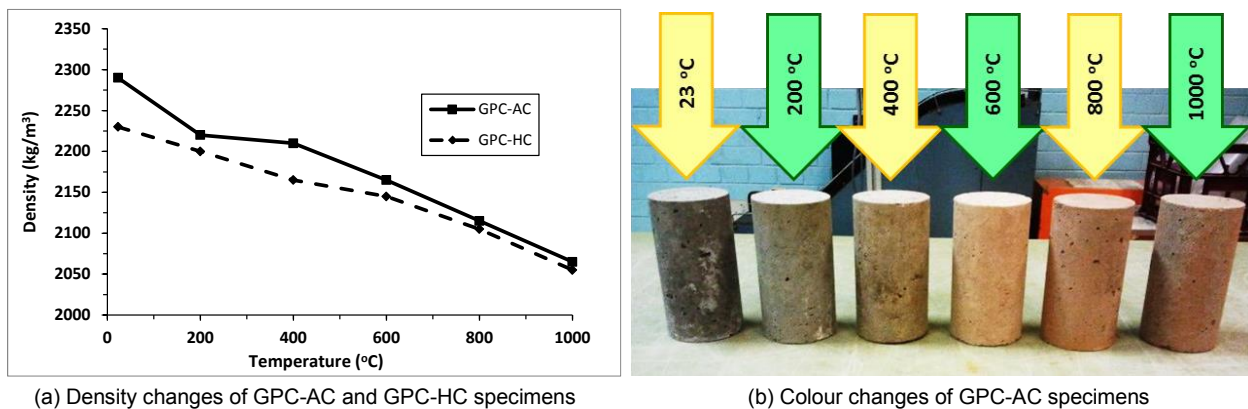

Figure 4. (a) Density; and (b) physical colour changes of specimens after heating.

### 3.1.3 Residual stress-strain relationship

Figure 5 shows the stress-strain relationships of GPC-AC and GPC-HC mixes after exposure to high temperatures while Figures 6(a) presents the residual compressive strengths for the mixes.

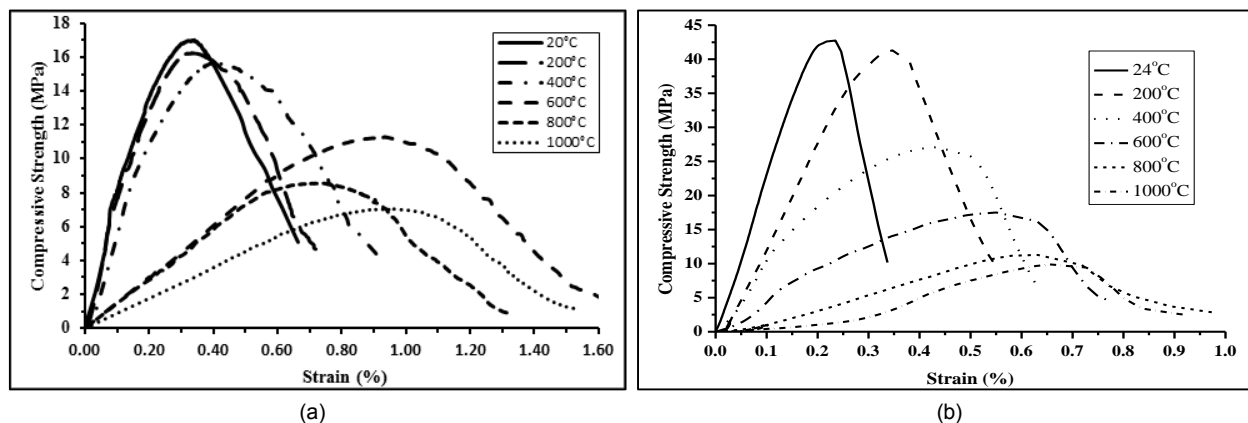

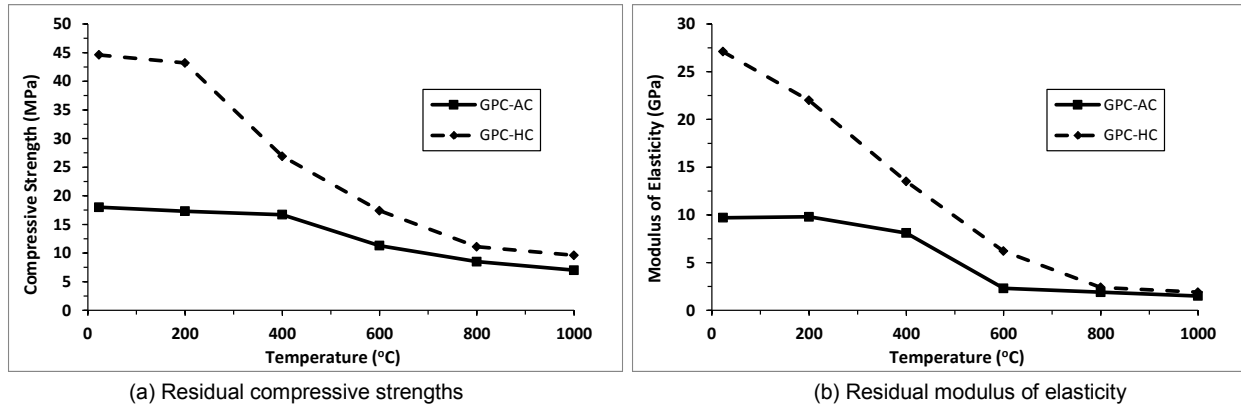

Figure 5. Residual compressive stress-strain curves for mixes (a) GPC-AC; and (b) GPC-AC.

Overall, the residual compressive strengths for both GPC-AC and GPC-HC mixes reduced with increasing temperature indicate the deterioration of geopolymer matrix during heating. GPC-AC specimens hold their initial strength steadily up to 400 °C while GPC-HC specimens only hold their initial strength up to 200 °C. The residual strengths for GPC-HC specimens decreased sharply with the increasing temperature beyond 200 °C, reaching 40% of the original value at about 600 °C. After exposure to 1000 °C, GPC-HC specimens have a compressive strength of approximately 20% of the initial strength. The strength

reduction for GPC-AC specimens with increasing temperature is relatively less than that of GPC-HC specimens. At 600 °C, GPC-AC specimens have a compressive strength of approximately 70% of the initial strength, further, GPC-AC specimens retained 50% of its original value at 1000 °C.

The compressive strengths for GPC-AC and GPC-HC specimens began to converge between 600 °C and 800 °C. Pan et al. [3] and Sarker et al. [8] also observed the strength convergence at about 650 °C to 800 °C for their lower and higher strength geopolymer concretes manufactured using the same mixture proportion but the curing process was manipulated in order to achieve different compressive strengths.

**Figure 6. Residual strength properties of the geopolymer concrete mixes.**

Pan et al. [3] suggested that two opposing processes occur in geopolymer concretes when heated: (i) further geopolymerisation and/or sintering at elevated temperatures leading to strength gain; (ii) the damage to the concrete due to thermal incompatibility between the geopolymer paste and the aggregates. Shrinkage of geopolymer paste was found to begin at 200 °C [5, 9] that would result in a steady deterioration from this point. Sintering of unreacted fly ash particles is unlikely to occur before the temperature reaches 800 °C as fly ash, which has been fired at high temperature up to 1600 °C in coal power station, only begin to sinter from 900 °C [20] but most research suggest the sintering temperature of fly ash is between 1100 °C to 1300 °C [21].

For GPC-AC specimens, it is likely that further geopolymerisation occurs with increasing temperature up to at least 600 °C. This is also supported by the observation from the density change studies, which indicated that the major amount of the density reduction for GPC-AC specimens, i.e. mass loss, occurred before 600 °C. As both the densities and residual strengths for GPC-AC and GPC-HC specimens have converged at about 600 °C, it is likely that the geopolymerisation process has completed for GPC-AC specimens or the remaining geopolymerisation rate for both GPC-AC and GPC-HC specimens is similar and the strength reduction is mainly due to the thermal incompatibility between the geopolymer paste and the aggregates, which causes internal damage and cracking within the concrete.

The schematic formulation of geopolymer can be shown in Equation (2) [1]. Geopolymerisation is a condensation polymerisation process and geopolymer is formed and hardened by loss of water. Higher temperature will provide for a more complete drying of the geopolymer. The more water is removed from the geopolymer bond, the higher will be its strength, due to more complete chemical reaction or polymerisation. The amount of water remaining in the geopolymer bond is governed by the temperature to which it has been exposed and its exposure duration.

From visual observation, GPC-AC specimens also showed trace of efflorescence but not on GPC-HC specimens as discussed in Section 3.1.2. The efflorescence product is found to be sodium carbonate heptahydrate (Na<sub>2</sub>CO<sub>3</sub>·7H<sub>2</sub>O) [22], which is likely due to the reaction of the unconsumed alkaline activator

with the carbon dioxide gases in the atmosphere. Zhang et al. [22] noted that fly ash based geopolymers synthesised at high temperature exhibit lower efflorescence than those synthesized at low temperature. This highlights that the lower strength grade of GPC-AC specimens is due to incomplete geopolymerisation and, hence, the strength was not fully developed. To maximize the full potential of the fly ash based geopolymer concrete and based on the above findings, heat curing is therefore recommended and a proper mix design is also required to increase the geopolymerisation process and reduce the unconsumed alkaline activator in the geopolymer.

The residual elastic moduli following exposure to high temperatures are plotted in Figure 6(b) versus exposure temperature. In the same manner as compressive strength, no appreciable change in modulus of elasticity for GPC-AC specimens was seen until 400 °C; thereafter, it dropped considerably to 20% of the original value at 600°C. For GPC-HC specimens, the modulus of elasticity reduced steadily up to 800 °C and thereafter it matched the modulus of elasticity of GPC-AC specimens.

### 3.2 Hot state deformation modulus

The hot state deformation moduli for GPC-HC specimens are presented in Figure 7 and are compared with the corresponding residual elastic moduli. The hot state elastic modulus shows a steady decline with increasing temperature. Both the hot deformation modulus and residual elastic modulus show no substantial difference up to 400 °C. However, the residual modulus was found to be lower than the hot state modulus for temperatures higher than 400 °C; this may be caused by micro cracking, which occurred during the cooling phase.

Figure 7. Hot state deformation modulus and residual elastic modulus for GPC-HC.

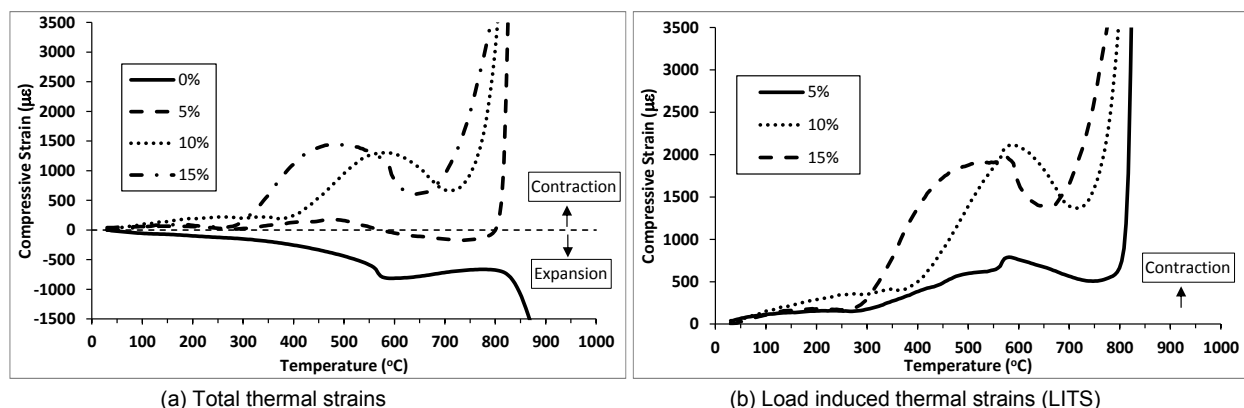

### 3.3 Free thermal expansion (FTS) and load induced thermal strains (LITS)

Figure 8(a) shows the evolution of axial thermal strains of GPC-HC cylinders when heated to 1000 °C under constant compressive load, plotted against the furnace temperature. The LITS is plotted in Figure 8(b). Positive strains indicate contraction; negative strains indicate expansion. Four loading levels were studied; 0%, 5%, 10% and 15% of the mean compressive strength obtained at ambient conditions. The results revealed very different behaviours for the different applied loads. Further, geopolymer concretes also exhibit non-linear and different thermal behaviour when compared to that of Portland cement concrete studied by Khoury [19] with both expansion and contraction occur when they are heated.

For no loading condition, the specimen expands freely by thermal expansion, which is the FTS component. A sharp expansion of the specimen occurred at about 560 °C to 570 °C and is likely due to the  $\alpha$ - $\beta$  phase change that occurs in the siliceous components in the mixes, mainly in the sand and the fly ash elements. At around 600 °C, the specimens appear to have contracted. Provis et al. [18] observed similar behaviour in the dilatometric study on geopolymer paste and suggested that densification attributed to a process resembling viscous sintering was commenced at this temperature. After heating to 800 °C, the specimens show a sharp and rapid expansion and this may be due to swelling of high silicate phases in the presence of alkalis above 800 °C or the specimens begin to melt.

When the specimens were heated while loaded, they initially shrunk progressively due to releasing of water from the specimen. Provis et al. [18] indicated that shrinkage occurs up to 250 °C as pore water is released

from the geopolymer gel and from 250 °C to 600 °C, shrinkage occurs gradually attributed to the loss of bound hydroxyls. Between 300 °C and 400 °C, the specimens were subjected to a rapid contraction. This contraction phase appears to be dependent on the applied load level. As the applied load increased, specimens contracted more rapidly and at a much lower temperatures. Pan and Sanjayan [9] observed the similar behaviour trend. While the actual reasoning may not be known, it is likely that the densification due to further geopolymerisation occurred and the geopolymer backbone or the polymer chain re-organised itself under the applied load. This remains as a hypothesis to be further researched. The specimens began to expand at about 570 °C, coincide with the  $\alpha$ - $\beta$  phase change that occurs in the siliceous components. Between 650 °C and 800 °C, the specimens experienced abrupt loss of stiffness and exhibited significant visco-plastic and deformation behaviours. Pan and Sanjayan [9] reported that the glass transition temperature for fly ash based geopolymer is 560 °C while Rickard et al. [11] and Provis et al. [18] argued that viscous flow of the aluminosilicate material causing sintering and subsequent densification and shrinking occur between 550 °C and 850 °C. Regardless, from structural engineering point of view, based on the observation from this study, the fly ash based geopolymer concrete, as a composite of geopolymer paste and aggregate, will deform excessively beyond 800 °C. Figures 9(a) and 9(b), respectively, show the deformed shapes of GPC-HC specimens subjected to 10% and 15% stress levels when heated to 800 °C. Physical tearing and rippling on the surface can be observed from Figure 9. The undulations and the exposed shapes of aggregates confirm that the aggregates were in solid state whilst the glass transitional geopolymer paste deformed and softened around them during the heating process.

#### 4. Conclusions

Experiments to evaluate the suitability for use in high temperature were conducted on two fly ash based geopolymer concrete mixes manufactured using the same mixture proportion but the curing process was

manipulated in order to achieve the target compressive strengths of 20 MPa and 50 MPa. The following conclusions were reached as a result of this study:

1. High strength geopolymer concrete demonstrates a steady loss in density when is heated up to 1000 °C. The reduction of density is likely due to loss of free or evaporable water, further geopolymerisation process occurred which caused additional water being expelled, densification of geopolymer gel that increased the overall concrete porosity, swelling of high silicate phases and internal damage and cracking caused by thermal incompatibility within the geopolymer structures and with the aggregates. The low strength geopolymer concrete, although is initially denser than that of high strength geopolymer concrete at ambient temperature, is subjected to drastically decrease in the density when is heated and its density converges with the density of the high strength geopolymer concrete at about 600 °C to 800 °C. This indicates that more geopolymerisation occurred and more water is released.
2. The fly ash based geopolymer concrete experiences a range of colour changes through exposure to high temperature, from grey to dark grey colour at ambient temperature to pinkish hue colour after heating to 1000 °C.
3. The compressive strength and modulus of elasticity of the high strength geopolymer concrete reduce after exposure to high temperatures but the low strength geopolymer concrete maintains its strength and modulus up to 400 °C before suffering strength and stiffness losses. Both strengths and moduli for the high and low strength geopolymer concretes converge at about 600 °C to 800 °C. The strength reduction and loss of stiffness indicate that the geopolymer concrete suffered considerable damage due to thermal incompatibility between the geopolymer paste and the aggregates. For the low strength geopolymer concrete, however, further geopolymerisation process occurs up to at least 400 °C, which supposedly leading to strength and stiffness gains, but the gains are compensated due to the thermal cracking.
4. The polymerisation process of the low strength geopolymer concrete that cured in the controlled environmental room at 50% RH and 23 °C for a consecutive of seven days is incomplete and, hence, resulting in the strength not fully developed. The unconsumed alkaline activator causes efflorescence on the concrete. To maximize the full potential of the fly ash based geopolymer concrete, a proper mix design and heat curing are required to increase the geopolymerisation process and reduce the unconsumed alkaline activator in the geopolymer.
5. The hot state deformation modulus of the high strength geopolymer concrete drops approximately linearly with increasing temperature.
6. The free and load induced thermal strains are found to be very different to that of Portland cement concrete, indicating that the geopolymer science is different to that of Portland cement concrete and the fundamental of Portland cement concrete cannot be used to explain the behaviour of geopolymer concrete.
7. Fly ash based geopolymer concrete, as a composite of geopolymer paste and aggregate, deforms excessively beyond 800 °C due to softening or melting of the geopolymer paste.

**Abstract:** Development of alternative binders is imperative due to the severe impacts related to the production of ordinary Portland cement such as carbon dioxide emissions, rapid consumption rate of limited natural resources and high demand. Geopolymer concrete has emerged as a potential alternative material for a number of special applications. Sugarcane bagasse ash is obtained as a by-product from sugar industries in enormous quantities in major sugar producing countries and its disposal is problematic due to land constraints and environmental restrictions. Bagasse ash has reactive silica content (more than 70%) and can be blended with other industrial by-products such as fly ash and slag which are rich in alumina, silica and calcium sources to develop sustainable and high quality alkali activated slag concrete. The present study deals with the development of slag–bagasse ash as well as fly ash-slag based alkali activated binder. The influence of different parameters such as type and dosage of activators and curing methods on the compressive strength of the composite is discussed in the paper.

**Keywords:** Sugarcane Bagasse Ash, Alkali activation, Geopolymer, Curing

## 1. Introduction

In consideration of the serious impact of carbon dioxide emissions from the cement manufacturing process on the environment, there is a need to develop useful alternatives to Ordinary Portland Cement (OPC). Production of OPC is responsible for approximately 6 to 7% of the world's carbon dioxide emissions (1). In this context, geopolymers have emerged as potential binders for the concrete industry.

Geopolymers are inorganic polymers produced by chemical action of inorganic source materials that are rich in aluminates and silicates, and alkaline liquids (1). Silicates and aluminates present in the source material get dissolved in the alkaline activator solution and subsequently polymerize into molecular chains and become the binder. Calcined clay, fly ash or slag can be used as source materials. The three dimensional polymeric chain and ring structure consisting of Si- O- Al- O bonds is the backbone of the geopolymer matrix (2- 3). Heat resistance, non- toxicity, excellent durability are other important properties which are beneficial for use in construction sector (4).

In most cases such as when using fly ash or calcined clay, geopolymer binders need heat curing which significantly increases cost and hampers the use of geopolymer system in practical applications (5). Alkali activated slag, on the other hand, attains good strength in ambient curing conditions (4 - 8). However, rapid loss of workability is widely reported in the existing literature for slag based alkali activated binder (2, 4 - 6). It is important to develop good strength and workable slag based alkali activated concrete with the help of ambient curing. This can be accomplished by a partial replacement of the slag with other source materials that are not as fast to react. This study deals with the formulation of alkali activated slag-based binary blends with good workability and strength at ambient curing conditions. Bagasse ash and fly ash are used in combination with slag in this study, which also explores the influence on strength of the activator type as well as the curing method (heat curing and ambient curing).

## 2. Material and Methods

### 2.1 Materials

In this study, sugarcane bagasse ash, ground granulated blast furnace slag (GGBFS), and Type F fly ash were used as aluminosilicate mineral to prepare the alkali activated binder. Ground Granulated Blast-furnace slag (GGBFS) was procured from Jindal Steel plant, India. Class F fly ash was collected from a local thermal power plant (North Chennai Thermal Power Station, India), while Sugarcane Bagasse Ash (SCBA) was collected from a nearby sugar industry from a disposal site. The oxide compositions of fly ash, bagasse ash and GGBFS were determined by X-ray fluorescence spectroscopy and results are given in Table 1 (OPC is included for comparison purposes).

**Table 1. Oxide compositions by X-ray Fluorescence**

Oxide composition	OPC (53 grade)	SCBA	Fly ash (Type F)	GGBFS
SiO <sub>2</sub>	20.68	72.95	59.32	32.38
Al <sub>2</sub> O <sub>3</sub>	4.12	1.68	29.95	21.06
Fe <sub>2</sub> O <sub>3</sub>	5.44	1.89	4.32	1.87
CaO	60.36	7.77	1.29	31.46
MgO	0.83	1.98	0.61	8.57
K <sub>2</sub> O	0.27	9.28	1.44	0.49
Na <sub>2</sub> O	0.23	0.22	0.16	0.36
SO <sub>3</sub>	2.46	3.52	0.17	-

Sugarcane bagasse ash (SCBA) is a by-product from the sugar manufacturing industry. Sugarcane bagasse is burnt in the cogeneration boilers as a fuel at 500-550°C and the residual ash is collected using bag-house filter. Raw sugarcane bagasse ash has fine reactive particles and fibrous unburnt carbon particles, which lead to a high loss on ignition (~21%). The removal of these unburnt carbon particles increases reactivity of bagasse ash (9). For this study, the sugarcane bagasse ash was processed based on a methodology proposed by Bahurudeen and Santhanam (10), which entails sieving the material through 300µm sieve to remove the unburnt particles, and further grinding to cement fineness (300m<sup>2</sup>/kg) to obtain maximum reactivity of sugarcane bagasse ash.

The physical properties of the source materials are presented in Table 2 (OPC is included for comparison purposes).

**Table 2. Physical properties**

Physical Characteristics	SCBA (as collected)	OPC	Fly ash (Type F)	GGBFS	Relevant standard
Specific Gravity	1.91	3.16	2.19	2.86	IS 4031-Part 11-2005 (15)
Specific surface area (Blaine)	145 m <sup>2</sup> /kg	310 m <sup>2</sup> /kg	330 m <sup>2</sup> /kg	360 m <sup>2</sup> /kg	ASTM C204-11 (11)
Loss on ignition	21 %	1.3 %	1.04 %	0.03%	IS 1727-2004 (12)
Consistency	50 %	30 %	29 %	30.5 %	IS 4031-Part 4-2005 (13)
Initial setting time	195 minutes	125 minutes	165 minutes	315 minutes	IS 4031-Part 5-2005 (14)
Final setting time	330 minutes	165 minutes	360 minutes	365 minutes	IS 4031-Part 5-2005 (14)
Soundness (expansion)	1.2 mm	1.61 mm	1 mm	0.67 mm	IS 1727-Part 3 (15)

After processing, the Loss on Ignition of SCBA comes down to 3-6%. Raw SCBA has a lower specific gravity compared to GGBFS and fly ash; however, this increases to 2.12 after processing(close to Type F fly ash). The soundness of processed SCBA when determined according to IS 4031(Part 3)-2005(15) was found to be 1.2 mm(well within the permissible limits).

The particle size distribution of the materials GGBFS, OPC, Type F Fly ash and sugarcane bagasse ash was determined by laser particle size analyzer and results are presented in Figure 1.

**Figure 1. Particle size distribution of source materials (OPC for comparison only)**

For preparation of the activator solution, Sodium Hydroxide (97% purity), Sodium Silicate, Potassium Hydroxide (97% purity) and Potassium Silicate laboratory grade reagents were used. The alkali solution of desired molarity was prepared by dissolving the appropriate mass of solid alkali in distilled water. This was allowed to attain thermal equilibrium over the duration of 24 hours. Then the alkali silicate was added to the hydroxide solution in the ratio of 1:1.5(alkali hydroxide: alkali silicate). This was allowed to attain constant temperature in a controlled environment of 25°C for at least 12 hours. The combination of alkali silicate and hydroxide to form alkali activator solution is known to give better strengths than alkali hydroxide used alone for alkali activated slag mortars (2, 16) due to the presence of additional silicate source for reaction.

Table 3 shows the activator modulus ( $\text{SiO}_2/\text{Na}_2\text{O}$  ratio) (also called water glass modulus) for the Sodium hydroxide based activator solutions used in this study. The silicate modulus of water glass (Sodium silicate) used in this study is 3.312 (8%  $\text{Na}_2\text{O}$  and 26.5%  $\text{SiO}_2$ ).

**Table 3. Activator Moduli**

Activator used		Activator Modulus
NaOH + Na <sub>2</sub> SiO <sub>3</sub>	6M NaOH + Na <sub>2</sub> SiO <sub>3</sub>	1.46
	8M NaOH + Na <sub>2</sub> SiO <sub>3</sub>	1.23
	6M NaOH + Na <sub>2</sub> SiO <sub>3</sub>	1.09

## 2.2 Methods

Mortar specimens for compressive strength testing were prepared in accordance with ASTM C109/C109M-13 (17). The mix details are presented in Table 4. The ratio of alkali activator solution to binder was fixed at 0.5:1 by weight and the ratio of binder to Indian standard graded sand (IS 383) (18) was kept at 1:2 by weight. 500g of binder was used to prepare 6 numbers of 50mm cubes. Four different types of mixes were cast and details of the mixes are presented in Table 4. Sand and binder were mixed for 1 minute in a Hobart mixer at low speed. Afterwards, the prepared activator solution was gradually added to the mix. 5 % of

additional water was added to the mix to achieve good workability and the mortar was further mixed for three minutes. The flow of the mortar was determined as per ASTM C1437-13 (19). Specimens were cast and kept in a controlled temperature (27 °C) environment for 24 hours.

The specimens were demoulded and then the first set was subject to ambient curing at room temperature (27°C) and the other set to heat curing at 65±5°C for 24 hours to compare the effect of curing on early age strength development. Compressive strength of specimens was determined after 3, 14 and 28 days of curing.

**Table 4. Mix details**

Molarity of Alkaline Hydroxide Solution	Activator Solution	GGBFS	BA	FA	Mix ID

### 3. Results and discussion

#### 3.1 Effect of replacement of GGBFS

All the four mixes as mentioned in section 2.2 are compared to evaluate the effect of replacement. 8M sodium based activator solution was used as the alkaline activator. In addition, alkaline activator to binder ratio of 0.5 was maintained for all the four mixes. The flow value of the reference mortar (slag only) was measured just after mixing and it was found to be 101%. On the other hand, a sudden loss of workability was observed for the slag mortar mix within 10 minutes, at which time no flow was observed. Similarly, the flow value was determined for other mixes and 121% and 98% flow values were obtained for slag-fly ash mix and slag-bagasse ash mix respectively with similar workability retention (45 minutes). Compressive strength at the end of 3 days, 14 days and 28 days was determined. Figure 2 shows the comparison of compressive strength of all the mixes determined using displacement controlled universal testing machine.

The reference mix (GGBFS only) showed higher strength compared to other mixes. In ambient cured specimens, a reduction in strength was observed with increase in the replacement. This is due to the formation of Calcium Alumino-Silicate Hydrate phases (20 - 21) in addition to poly-sialates from the polymeric reaction in the case of the GGBFS only binder, which causes better strength development. The C-A-S-H is precipitated within 24 hours of reaction, resulting in early strength gain and pore refinement (8). Although the

strengths of blended mixes were lower, they increased with curing duration as shown in Figure 2. At 3 days, the strengths for GGBFS only mix and the binary component mixes were similar, and this can be attributed to the reactive silica and alumina present in SCBA and Fly Ash which contributes to early alkali activation (formation of aluminosilicate polymers). However, at later ages, the latent hydraulic nature of slag results in additional strength gain with increase in curing duration as seen in Figure 2. Similar observation was previously reported for fly ash-slag blended alkali activated concrete (22).

Although the fly ash – GGBFS blend was slower to being with, there was no difference in strength at 28 days compared to the SCBA – GGBFS system.

**Figure 2. Effect of replacement of slag on compressive strength**

### 3.2 Effect of curing methods

To investigate the influence of type of curing on strength of alkali activated binders, the specimens were subjected heat curing and ambient curing as described earlier and results are shown in Figure 3. It is interesting to note that ambient cured reference mortar specimens showed higher strength compared to heat cured specimens. Although heat cured specimens showed increase in strength with respect to curing duration, the reduction in strength was clearly observed compared to ambient cured specimens for the same curing duration. The observed reduction in strength for heat cured specimens is due to the loss of water from the system, which possibly causes a reduction in the level of slag hydration. In addition, drying shrinkage has been reported as a main disadvantage for slag based alkali activated binders in previous literature (4). Curing at higher temperature (and subsequent cooling prior to testing) may lead to formation of cracks in the specimens and cause reduction in strength compared to ambient cured specimens. In the case of ambient cured specimens, the increase in curing duration led to an increase in strength.

Figure 3. Effect of curing on compressive strength of blends

### 3.3 Effect of activator solution

Strengths of mortar specimens with Sodium Hydroxide with Sodium Silicate solution and Potassium Hydroxide with Potassium Silicate solution were determined to find the influence of activator on alkali activation and strength development. Figure 4 depicts compressive strength of all the specimens activated with both types of alkali activators. Constant molarity of alkali activator solution was maintained (8M) for all the mixtures and the specimens were cured in ambient condition. For the reference mix and slag-fly ash mix, sodium hydroxide/sodium silicate contributes higher strength. This has been validated in other studies which show that a more heterogeneous and porous micro-structure is created when slag is activated with potassium based alkali activators (23- 25). It is interesting to note that strength of slag blended with SCBA mixtures was found to be increased for KOH/K<sub>2</sub>SiO<sub>3</sub> activators compared to sodium based activators. Potassium Hydroxide with Potassium Silicate activator proves to be beneficial for SCBA blended specimens and this could be attributed to the higher K<sub>2</sub>O content in SCBA, which, along with the alkaline potassium oxide that is present in activator, helps as a cationic link between oligomers.

Figure 4. Effect of type of activator on strength of mixes

### 3.4 Effect of molarity and activator modulus

Three different molarities (6, 8, 10 M) were adopted for NaOH/Na<sub>2</sub>SiO<sub>3</sub> activator to find the influence of molarity as well as activator moduli on strength development under ambient curing, and results are presented in Figures 5 and 6.

Figure 5. Effect of molarity on strength development in the alkali activated systems

The increase in molarity of the activator led to an increase in strength for the slag and slag-bagasse ash specimens. This is due to the increase in hydroxyl ion and alkali oxide concentration in the solution, which in turn accelerates the dissolution of  $\text{Si}^{4+}$  and  $\text{Al}^{3+}$  from the binder. Similar trend was reported in earlier literature for slag based activated binder (26). These in combination with calcium ion of slag form C-A-S-H gel phase. However, in fly ash slag blends there is decrease in strength with increase in molarity of alkaline activator beyond 8M (formation of Si-OH bonds rather than Si-O bonds). This may be due to the reduction in activator modulus, which inhibits the formation of fly ash reaction products (21).

Figure 6(a) and (b). Effect of activator modulus on compressive strength at 3 and 14 days respectively

#### 4. Conclusions

- Ambient cured specimens had higher strength compared to heat cured specimens, possibly as a result of loss of water and micro crack formation in heat curing.
- Compressive strength increased with decrease in the activator modulus due to increase in alkali oxide concentration. Nevertheless for fly ash-slag blends optimal activator modulus was found to be 1.23 (i.e. 8M Alkali hydroxide solution). Further increase in molarity led to reduction in strength.
- Sodium based alkali activator proved beneficial for the slag and slag-fly ash blended binders. On the other hand, slag-SCBA mix exhibited better performance with potassium based activators compared to sodium based activators.
- Replacing GGBFS with other binders decreased the strength due to decrease in the calcium content of the binder. However, to achieve good workability retention of slag based alkali activators, blending with other bagasse ash/ fly ash sources is recommended.

**Abstract:** Geopolymer concretes are manufactured from high-volume industrial waste materials and have emerged as an innovative engineering material with the potential to form Ordinary Portland Cement (OPC)-free concrete for both structural and non-structural applications. Utilising industrial waste materials to manufacture geopolymer concrete not only reduces carbon dioxide (CO<sub>2</sub>) footprint, but also resolves several issues associated with the dumping or disposal of high-volume waste materials. This paper studies the behaviour of a new industrial waste material known as granulated lead smelter slag (GLSS). The experimental program includes 32 mix designs to investigate the influence of incorporating GLSS with fly ash as fine aggregate, binder or both fine aggregate and binder. The paper also investigates the influence of particle size, activator dosage and mechanical properties of an optimised mix design. The results show little to no effect of GLSS as fine aggregate; however, it allows for a reduction of fly ash content, as it partially substitutes the polymerisation reaction that is reduced by the reduction of fly ash content. The results also show that the particle size of the slag plays an important role, as the compressive strength was significantly improved with super-fine particle size. Increase the activator-to-binder ratio (more than 0.4) has a detrimental effect on the compressive strength. Finally, the mechanical properties of geopolymer concrete (manufactured from 25% fly ash and 75% slag) were similar to that of 100% fly ash geopolymer concrete.

## 1. Introduction

Geopolymer concrete, also known as alkali-activated cement [1], inorganic polymer concrete [2], and geocement [3], has emerged as an innovative engineering material with the potential to form Ordinary Portland Cement (OPC)-free concrete for both structural and non-structural applications [4]. Geopolymer concretes are commonly formed by synthesising industrial aluminosilicate waste materials, such as metakaolin, fly ash and slags, with a highly alkaline activator solution. The polycondensation reaction of geopolymeric precursor and alkali polysilicates is known as geopolymerisation process. Geopolymer concrete relies on aluminosilicate molecules that join together to make very long molecules called polymers of which referred as geopolymeric aluminosilicate hydrate (A-S-H) gel. This process is called polymerisation and it differs from the process of conventional concrete, which relies on calcium silicate hydrate (C-S-H) gel to form a binder. Therefore, the chemical composition of a binder plays an important role in forming a certain gel. Yip et al. [5] and Yip and van Deventer [6] proved that it is possible to have geopolymeric aluminosilicate hydrate (A-S-H) gel and calcium silicate hydrate (C-S-H) gel forming simultaneously within a single binder. Thus, there is a compelling case to explore other types of slag-based geopolymer concretes as a sustainable alternative to traditional OPC concrete technologies.

Granulated lead smelter slag (GLSS) is an industrial waste material that is a by-product of heavy metal extraction during lead smelting process. The production of lead world-wide was estimated to be 3.9 million tonnes in 2009 from both primary and secondary resources [7], and the production of each ton of metallic lead generates around 100-350 kg of slag that is known as granulated lead smelter slag [9]. Given the potential suitability of GLSS for the use in structural and non-structural geopolymer concrete manufacture, it is of particular importance to understand the mechanical behaviour of GLSS-based geopolymer concrete. However, the studies on the behaviour of GLSS have so far focused on their characterisation and stability [8-12], and only one study to date has investigated the mechanical behaviour of geopolymer concretes with a 10% maximum substitution of fly ash with GLSS [7].

This paper presents the results of the first comprehensive experimental study on the behaviour of GLSS incorporated with fly ash as binder replacement and fine aggregate replacement to produce geopolymer concrete. Lead slags are typically available in the granulated form (sand sized fractions <2 mm) and are therefore less reactive than other types of geopolymer (i.e., fly ash <100 µm) due to the particle size [13-

14]. Therefore, this paper also investigates the effectiveness of super fine crushing to improve the GLSS reactivity as a geopolymer binder.

## 2. Experimental Program

A total of 32 mix designs were trialled to quantify the influence of granulated lead smelter slag (GLSS) on the compressive strength of fly ash geopolymer concrete. The mixture proportions of the mix designs are presented in Table 1. To investigate the influence of fly ash replacement with GLSS as a binder, five different GLSS ratios were investigated (0, 0.25, 0.5, 0.75, and 1). To investigate the influence of natural sand (NS) replacement with GLSS as fine aggregate, four different GLSS ratios were used (0, 0.5, 0.75, and 1). To investigate the influence of GLSS particle size, four different fractions of the GLSS grading were examined, including 550  $\mu\text{m}$ , 400  $\mu\text{m}$ , 250  $\mu\text{m}$ , and 150  $\mu\text{m}$ , and seven different grinding particle sizes D50 (D50 grain size of which 50% material passes) were examined, including 70  $\mu\text{m}$ , 63  $\mu\text{m}$ , 43  $\mu\text{m}$ , 20  $\mu\text{m}$ , 11  $\mu\text{m}$ , 8.2  $\mu\text{m}$ , and 5.8  $\mu\text{m}$ . In order to examine the degree of reactivity of the GLSS, three different alkaline-to-binder (a/b) ratios were investigated (0.37, 0.5, and 0.75). The mechanical properties of the optimised GLSS mix design were experimentally obtained and subsequently compared to those of fly ash geopolymer concrete.

**Table 1. Mixture proportions.**

Materials	Mixture proportions (kg/m <sup>3</sup> )
Binder	424.8
Coarse aggregate	1180.8
Fine aggregate	595.2
*NaOH with Na <sub>2</sub> SiO <sub>3</sub>	156.7
Superplasticiser	31.2
Water	9.84
*Except for mixes 17 and 19, which had 212.4 kg/m <sup>3</sup> of NaOH with Na <sub>2</sub> SiO <sub>3</sub> , and mixes 18 and 20, which had 318.4 kg/m <sup>3</sup> of NaOH with Na <sub>2</sub> SiO <sub>3</sub> .	

### 2.1 Material Specifications

The basis of the mixtures used in this investigation was low-calcium class-F according to ASTM C618-08 [15] fly ash produced at Port Augusta Power Station in South Australia and granulated lead smelter slag (GLSS) from the Nystar lead zinc smelter in Port Pirie (locally called 'black sand'). The chemical compositions of the fly ash and GLSS were determined by X-ray fluorescence (XRF) and are documented in Table 2. For all the mixes, the alkaline solution phase consisted of a combination of sodium silicate (Na<sub>2</sub>SiO<sub>3</sub>) and 14 molar sodium hydroxide (NaOH), pre-mixed with a ratio of Na<sub>2</sub>SiO<sub>3</sub>-to-NaOH of 1.5.

**Table 2. Chemical compositions by mass (%).**

Oxides	Fe <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	MgO	SO <sub>3</sub>
Granulated lead smelter slag	33.8	27.5	7.4	19.4	2.1	-
Fly ash	2.8	49.0	31.0	5.4	2.5	0.3

### 2.2 Testing Procedures

The experimental program consisted of the following two stages: (i) examining the behaviour of GLSS and developing a geopolymer concrete mix with high-volume of GLSS and a compressive strength of normal concrete, and (ii) examining the engineering properties of the optimised mix. The mixing procedures of all stages were accomplished by mixing the dry components for three minutes followed by the addition of liquid starting with water, alkaline solution and superplasticiser where applicable. The specimens in the first stage were heat-cured for 24 hours, and for allowing heat-curing period comparison, some specimens were heat-cured for 48 hours at a temperature of 70°C. The heat curing was applied to accelerate the curing time, so the specimens can be tested prior to 28-day. Thus, all specimens were placed in a fog room after heat curing and tested seven days after casting. Three replications were made for each mix. In the second stage, the optimised mix design was manufactured at a larger scale to examine the

engineering material properties, including compressive strength, stress-strain relationships, splitting tensile strength, flexural strength and modulus of elasticity. Both curing methods, 24-hour heat curing and ambient curing, were considered. All specimens in this stage were tested at 28-day of age.

### 3. Results and Discussion

Table 3 summarises the mix designs in terms of the parameter investigated in each mix design. The mixes were designed to investigate (1) the influence of granulated lead smelter slag, which includes (i) effect of GLSS as fine aggregate, (ii) effect of GLSS as a binder, and (iii) effect of GLSS particle size, (2) the influence of activator dosage, and (3) influence of curing period.

**Table 3. Description of mixtures.**

Mix No	Binder			Fine aggregates		GYP	a:b	Heat-curing period (Hour)	Slump (mm)	Density (kg/m <sup>3</sup> )	Strength at 7 days (MPa)

### 3.1 Influence of granulated lead smelter slag

In order to study the influence of granulated lead smelter slag (GLSS) on the behaviour of fly ash-based geopolymer concrete, the GLSS was substituted as fine aggregate, binder or both fine aggregate and binder.

#### 3.1.1 Effect of granulated lead smelter slag as fine aggregate

Granulated lead smelter slag (GLSS) was investigated as fine aggregate in two different mixture proportions. First, the natural sand (NS) was completely replaced with GLSS in a 100% fly ash-based geopolymer concrete (mixes 13 and 16). Second, 50% of the binder (i.e., fly ash) was replaced with GLSS alongside with the complete replacement of the NS with GLSS (mixes 3 and 7). The results show the utilisation of GLSS in a mixture proportions with 100% fly ash as a binder has little to no influence on the compressive strength of fly ash-based geopolymer concrete as shown in Figure 1(a). This is due mainly to the condensation polymerisation reaction that took place within fly ash-based geopolymer concrete in which the reaction was optimum. On the other hand, the utilisation of GLSS in a mixture proportions with 50% fly ash as a binder has a significant influence on the compressive strength of fly ash-based geopolymer concrete as can be seen in Figure 1(b). This indicates the GLSS contributed in the polymerisation reaction because when the fly ash content is reduced, the polymerisation reaction is also reduced, which in turn reduces the strength (as seen in mixes 1 to 4). However, once larger quantity of granulated lead smelter slag (GLSS) is added, the polymerisation reaction is substituted and hence the strength is enhanced (as seen in mixes 5 to 8).

(a) 100% fly ash geopolymer concrete.

(b) 50% fly ash geopolymer concrete.

**Figure 1. Effect of GLSS as fine aggregate on compressive strength.**

### 3.1.2 Effect of granulated lead smelter slag as a binder

The volume of fly ash was progressively replaced with granulated lead smelter slag (GLSS) to have fly ash ratios of 1, 0.75, 0.50, 0.25 and 0, as can be seen in mixes 21-25. It is evident from Figure 2 that the compressive strength decreased in proportion to the decrease of fly ash content. That is because the reduction of fly ash content affects the heterogeneous chemical reaction that is involved in the geopolymerisation between solid aluminosilicate oxides and alkali silicate solutions. It should be noted that the reaction contribution of GLSS is not optimum due to the particle size, which is relatively coarse compared to the particle size of fly ash. It is worth mentioning that the replacement of fly ash with GLSS up to 25% has little to no influence on the strength of geopolymers. This observation is in agreement with the findings previously reported by Ogundiran et al. [7].

Figure 2. Influence of fly ash-to-GLSS ratio on compressive strength.

As the significance of the research is to utilise high volume of GLSS while maintaining the compressive strength in the range of the normal concrete strength (>20 MPa), mixture 24 (25% FA and 75% GLSS) was chosen to be the optimised mixture for further research.

### 3.1.3 Effect of granulated lead smelter slag particle size

The fineness of the binder has the most significant influence on the properties of the hardened concrete, even more so than the chemical and mineralogical composition of the binder [16-17]. The natural particles of GLSS are relatively large, angular and irregular, and for handling, health and environmental reasons, GLSS is produced as sand (i.e., <2 mm). To allow comparisons in reactivity of the GLSS to particle size, different fractions of GLSS were examined (i.e., fractions retained on the 550  $\mu\text{m}$ , 400  $\mu\text{m}$ , 250  $\mu\text{m}$  and 150  $\mu\text{m}$  sieves) as 50% substitution for fly ash (mixes 1-4 and mixes 5-8). The results showed that those size fractions did not have any significant influence on the final compressive strength. This can be attributed to the significant difference in the particle sizes of fly ash compared to GLSS, as slag of 150  $\mu\text{m}$  grading is still relatively coarse compared to that of fly ash ( $D_{50}$  of 12  $\mu\text{m}$ ).

To determine the influence of particle size of GLSS, different super fine crushed fractions of the slag were tested (mixes 25-32). It was found that the fineness of the binder has a significant effect on the reactivity of GLSS in geopolymer concrete, as can be seen in Figure 3. These results clearly demonstrate the effectiveness of super fine crushing the GLSS to grain sizes equal to or even finer than that of fly ash ( $D_{50}$  of 12  $\mu\text{m}$ ). That can be attributed to the significant increase in the surface area with reduced grain size, which consequently improves the reactivity of GLSS. It should be noted that the pozzolanic reaction takes place mainly on the surface of the particles [34]. Nevertheless, super fine crushing GLSS does require additional processing and energy, and the potential use of the oversize fraction was studied using a combination of fine GLSS and over size GLSS (mix 29). The combined

fraction ( $D_{50}$  of 20  $\mu\text{m}$ ) achieved a compressive strength of 48 MPa, suggesting that the fine fraction is providing most of the binder reactivity. The relationship between strength and various grain sizes ( $D_5$ ,  $D_{20}$ ,  $D_{50}$  and  $D_{80}$ ) is plotted in Figure 4. It can be seen that the compressive strength generally increases with reduced particle size of the slag.

Figure 3. Influence of grainsize on strength of 100% GLSS geopolymer concrete.

Figure 4. Strength versus grain size relationship of 100% GLSS geopolymer concrete.

### 3.2 Influence of activator dosage

Three different activator-to-binder ratios were used for the activation of slag geopolymer concrete, including 0.37, 0.5 and 0.75. These ratios were chosen to examine whether the reactivity of GLSS improves with an increase of the activator dosage using 50% fly ash and 50% GLSS geopolymer concrete mixes with two different fine aggregates, natural sand (mixes 3, 17, 18) and GLSS (mixes 7, 19, 20). It can be seen in Figure 5 that the compressive strength declined with the increase of the activator to binder dosage ratio. It can also be seen that the behaviour of the mixes that contain GLSS as fine aggregate attained higher compressive strength, which reflects the increase reactivity of the GLSS compared to the natural sand.

Figure 5. Influence of activator to binder (a/b) ratio in GLSS geopolymer concrete.

### 3.3 Mechanical properties of optimised mix design

Therefore, tests to determine the full-compression stress-strain relationships, the elastic modulus, the flexural strength and indirect tensile strength of slag geopolymer concrete have been undertaken on both ambient and heat-cured specimens tested after 28-day of casting. All the specimens were manufactured from mix 24, which utilises 75% of GLSS as the fly ash binder replacement. The results were then compared to that of 100% fly ash geopolymer concrete.

The full stress-strain relationships for both heat and ambient cured specimens are shown in Figure 6, together with Hognestad's [18] and Collins et al.'s [19] models. It is evident that the expressions of Hognestad [18] and Collins et al. [19] provide reasonable accuracy for slag geopolymer concrete stress-strain relationships.

Figure 6. Stress-strain relationships.

The weight of three cylinders per mix was measured in order to calculate the density ( $\rho$ ) of a particular mix. The density, along with the respective compressive ( $f_c$ ), of each particular mix, is presented in Table 3. It can be noted that the density of fly ash geopolymer concrete is marginally lower than the equivalent OPC concretes, ranging between 2350-2355 kg/m<sup>3</sup>. It can also be noticed that the density slightly increased with the addition of raw feed GLSS and significantly increased to 2700 kg/m<sup>3</sup> when utilising super fine crushed GLSS. This is probably as a result of the high iron content of the GLSS, as well as a lower porosity of the geopolymer concrete when using super fine crushed GLSS.

Table 4 presents the results of splitting tensile, flexural strength and elastic modulus of slag geopolymer concrete, as well as fly ash geopolymer concrete results of ambient and heat cured specimens. The table also presents the results of prediction models of ACI [20]. It can be observed that the mechanical properties of slag geopolymer concrete are similar to those of fly ash geopolymer concrete.

**Table 4. Mechanical properties of slag and fly ash geopolymer concretes.**

Mix	Compressive strength (MPa)	Splitting tensile strength (MPa)	Flexural strength (MPa)	Elastic modulus (GPa)	American Concrete Institute (ACI [20])		
					Splitting tensile strength (MPa)	Flexural strength (MPa)	Elastic modulus (GPa)
Ambient-cured 25% FA & 75% GLSS	31.7	4.1	4.0	30.7	3.0	3.5	25.6
Heat-cured 25% FA & 75% GLSS	35.9	4.4	4.8	29.9	3.2	3.7	26.8
Ambient-cured 100% FA	32.3	3.1	4.2	27.0	3.0	3.5	25.8
Heat-cured 100% FA	49.8	5.1	5.3	30.1	3.7	4.4	30.3

#### 4. Conclusions

This paper has presented the results of an experimental study that was undertaken to investigate the influence of granulated lead smelter slag (GLSS) on the compressive strength of fly ash geopolymer concrete. The investigation involved the influence of (i) GLSS as fine aggregate, (ii) GLSS as a binder, (iii) particle size of GLSS, and (iv) activator-to-binder (a/b) ratio. The study also investigated the mechanical properties of the optimised mix design. The results showed that utilising GLSS as fine aggregate improved strengths when the volume of fly ash was reduced, and had little to no effect on 100% fly ash geopolymer concrete. The compressive strength of fly ash geopolymer concretes decreased in proportion to increasing fly ash binder replacement with GLSS. Nevertheless, strengths in excess of 20 MPa were still obtained by replacing fly ash with 75% GLSS. It was also shown that different fractions of GLSS between 550  $\mu$ m and 150  $\mu$ m did not have any significant influence on the compressive strength of geopolymer concrete. However, when the GLSS was super fine crushed to produce fractions with  $D_{50}$ 's less than 20  $\mu$ m, the size fractions had a significant positive impact on the compressive strength and density of geopolymer concretes. Increasing the activator-to-binder ratio above 0.4 had a negative impact on the compressive strength of geopolymer concretes. Moreover, the mechanical properties of the optimised geopolymer concrete mix design, which contained 25% fly ash and 75% GLSS as a binder and 100% GLSS as fine aggregate, were found to be similar to that of 100% fly ash geopolymer concrete.

**Abstract:** Alkali aggregate reaction (AAR) is one of the main durability problems in Portland cement concrete, as it can cause significant expansion and cracking in concrete structures. Geopolymer is a new sustainable binder which is used as an alternative to Portland cement. Geopolymer binder is produced by activating alumino-silica sources using alkali activator. This work presents how AAR expansion varies with binder ingredients in geopolymers. Results show that geopolymer mortar specimens with at least 30% fly ash have negligible AAR expansion. In fly ash and slag blended geopolymer binder based mortars, microstructure changes are due to zeolite crystalline products in the pores instead of typical AAR products found in 100% alkali activated slag.

## 1. Introduction

Geopolymer is a novel binder which has given promising results, comparable or better than of Ordinary Portland Cement (OPC) binders in terms of sustainability, mechanical properties and durability. This binder is produced by the reaction of alumino-silicate rich source materials such as coal fly ash, slag etc. with highly alkaline activators. Geopolymer concrete has commonly been used for applications like footpaths, wall panels, pavements, footpath panels and sewer pipes [1]. However, use of geopolymer in large scale structural applications has been hindered due to lack of durability assessments and long term performance data.

OPC concrete can suffer from deterioration problems like alkali aggregate reaction (AAR). AAR is caused by the reaction between alkali hydroxide present in the hydrated cement and reactive phases that may be present in the aggregates. This reaction creates highly hydrated AAR gel in the concrete, which is an expansive product and can induce magnificent expansion and cracking of the affected elements. Major structures have suffered due to alkali-aggregate reaction reducing their service life or requiring large repair costs [2-4]. One approach to reduce AAR is the use of non-reactive aggregate in the concrete. However, this method is not always possible due to practical difficulties in acquiring non-reactive aggregates locally.

In previous studies, It has already been identified that AAR expansion can be reduced using supplementary cementitious materials like low calcium fly ashes [3]. This is due to factors such as reduction in alkalinity of pore solution and lower availability of calcium in the binder [5]. Geopolymer has a silica based polymer structure which has shown superior durability compared to OPC. It has less CaO and higher Na<sub>2</sub>O compared to OPC. Previous studies showed that the pH value of pore solution is above 11.5; which is adequate to attack reactive silica phases in aggregate [6]. However, AAR formation in geopolymer concrete is different from that of OPC concrete due to crossed link SiO<sub>4</sub> and AlO<sub>4</sub> in geopolymer compared to C-S-H in OPC. Therefore, it is worthwhile to identify the susceptibility geopolymer binder to AAR expansion. Geopolymer binder which is formed after a series of chemical reactions between silicon, aluminium and alkali hydroxides does not have hydrated phases or free calcium, which is an important factor in the expansion problems. Instead geopolymer contains three dimensional silicon polymer networks which can resist most of the above durability issues of OPC concrete.

Davidovits [7] stated that geopolymer based mortar bars which contained high alkali content (Na<sub>2</sub>O= 9.2%) have shown less expansion level compared to Portland cement binder based mortar bars. Kupwade-Patil and Allouche [8] reported that, mortar bars of alkali activated fly ash did not create any expansive gel due to absence of calcium. Although, they did not provide initial curing condition used in

their study, it is well known that 100% class F fly ash based geopolymer needs to be cured at elevated temperature (over 23 °C)[9]. García- Lodeiro et al.[5] also compared alkali aggregate reaction of alkali activated 100% class F fly ash binder with Portland cement binder using accelerated mortar bar method (1M NaOH, 80 °C). They reported that fly ash based geopolymer mortars showed less expansion compared to OPC mortars due to AAR. However, they cured samples initially at elevated temperature (85 °C). Expansion measurements after elevated curing are not ideal as expansion can occur before the zero measurement due to acceleration of AAR reaction at elevated temperature.

Although some aspects of AAR formation in class F fly ash based geopolymer has been studied so far, AAR in geopolymer mortars or concrete formulated with calcium rich material (i.e slag) and other aluminosilicate material has not been fully investigated. Bakrev et al. [10] and Puertas et al. [11], reported that concrete made with 100% alkali activated slag can show larger expansions than OPC concrete. However, addition of a calcium rich source into geopolymer systems is necessary as it enhances the setting behavior and mechanical properties of geopolymers [12]. Ground granulated blast furnace slag is mostly used as the calcium source in geopolymer systems due to its high reactivity in alkaline environment. The reaction product of slag contains calcium silicate hydrate (C-S-H) as well as geopolymer network. Despite the fact that slag improves the engineering properties of geopolymer binder excess Ca in geopolymer system can create phases like portlandite  $\text{Ca}(\text{OH})_2$  which may facilitate AAR. Fly ash and slag blended geopolymer binders contain less Ca, but their AAR susceptibility has not been thoroughly studied in the past.

This reports the results of accelerated AAR expansion tests conducted on geopolymer systems which were initially cured at room temperature (23 °C) prior to the accelerated testing in 1M NaOH at 80 °C. The analysis includes geopolymer with different fly ash to slag ratio and different with different aggregates that exhibit different levels of reactivity and different alkali contents. The microstructural features of representative specimen are also reported.

## 2. Experimental

### 2.1 Materials

#### 2.1.1 Geopolymer solids

A commercial Australian class F fly ash and ground granulated blast furnace slag from were used as main aluminosilicate source materials in geopolymer mixes. Anhydrous solid sodium silicate was used as alkali activator. General purpose (GP) cement was used for comparison. Table 1 shows the bulk chemical composition of source materials used in this study.

**Table 1: Bulk chemical composition of material**

Oxides	GP Cement	Slag‡	Fly ash
SiO <sub>2</sub>	19.3	32.0	51.5
TiO <sub>2</sub>	0.30	0.51	1.5
Al <sub>2</sub> O <sub>3</sub>	5.5	13.0	27.6
Fe <sub>2</sub> O <sub>3</sub>	2.9	0.40	11.8
Mn <sub>3</sub> O <sub>4</sub>	0.20	0.30	0.15

† indicate the presence of limestone in the cement			

### 2.1.2 Aggregates

Three types of aggregates including one non-reactive and two reactive were used in this study to identify the AAR behaviour.

- Non-reactive basalt (NR)
- Moderately reactive aggregate (R1) of gneiss origin
- Reactive aggregate (R2) of dacite origin

Aggregates were crushed and sieved according to (ASTM C-1260) to obtain required size range.

## 2.2 Test procedures

### 2.2.1 Geopolymer binder preparation for mortar bar expansion test

All geopolymer binders were formulated using material proportions shown in the Table 2. OPC binder was used to prepare specimens in the study. Total binder and crush aggregates masses were kept constant at 440 g and 990 g, respectively, in all tests. In geopolymer binders, the total solid content (combination of alumino-silicate source material and alkali activator) was considered as the binder. The mixing procedures followed that of RTA T363. The flow of each mortar mixture was measured using small flow table (ASTM C230). The mortar samples were cured in fog room at 23 °C for 24 hours. De-moulded samples were then cured further 3 days in the same curing condition before exposure to accelerated curing environment (1M NaOH, 80 °C). In this study, accelerated mortar bar test was used to measure expansion due to AAR. Shayan et al.[13] demonstrated that RTA-T363 test method, gives more reliable results compared to ASTM C-1260 procedures particularly for slowly reactive aggregates. Hence, all the mortar bar tests were conducted according to RTA-T363 procedures,

**Table 2: Binder formulations with different aggregates**

	Mix *	Aggregate type	Fly ash wt. (%)	Slag wt. (%)	OPC wt. (%)	Na <sub>2</sub> O wt. (%)
1	70F30S_4	NR	70	30	0	4%

\* F and S refer to fly ash and slag, respectively. The numerals refer to percentage of each component in the binder. Number 4 and 6 refer to percentages of Na<sub>2</sub>O content in the binder.

### **2.3 NMR technique for structure analysis of binders**

Geopolymer paste prepared using fly ash, slag and solid alkali activator was ground after 28 days to get NMR spectroscopy. <sup>29</sup>Si measurements were done at a bruker advance 3300 spectrometer operating at 59.6 MHz.

### **2.4 Scanning Electron microscopy (SEM) and Energy dispersive X-ray (EDX) analysis**

After mortar bar expansion measurements were conducted, sectioned mortar bars were subjected to SEM and EDX analysis. Samples were gold coated before analysis.

### 3. Results and Discussion

#### 3.1 AAR expansion of geopolymer based mortar bars

Length change of the mortar bars was measured using a digital comparator until the age of 21 days. The measurements were taken as described in Shayan et al. [14]. Three companion mortar bars were made for each test and the averages of the expansion values are shown in **Figure 1**, **Figure 2** and **Figure 3**.

Figure 1a) and b) show the expansions of the mortar bars in geopolymer binders with NR aggregate. Fly ash slag blended geopolymer and OPCNR show almost no expansion in 21 days. The expansion level was very low even though the alkali content was increased in the binder to (6% Na<sub>2</sub>O). This showed that neither the NR aggregate nor the binder undergo expansion under the curing condition of the accelerated mortar bar test. The expansion limit of this test [14] note that values  $\geq 0.1\%$  expansion in 10 days indicate reactive aggregates and values  $\geq 0.1\%$  expansion in 21 days indicate slowly reactive aggregates. Expansion of NR basalt in geopolymer mortars was well below these limits. Reference OPC mortar bars also had high volume stability in presence of NR basalt aggregate. Basalt is minerally a silica-deficient, mafic rock, absent of free silica minerals, thereby it is not susceptible to AAR. The behavior of the binders in combination with reactive aggregates was also examined using two reactive aggregate types R1 and R2.

The two reactive aggregate types R1 and R2 are known to cause magnificent expansion when used in OPC concrete specimens containing elevated levels of alkali. Figure 2 (a/b) shows the expansion behavior of geopolymer based mortar bars with R1. The results show that 100S\_4, 100S\_6 and OPC binders caused large expansion in combination with R1 aggregate. Figure 2 also illustrates that OPC mortar bars exceed the acceptable expansion level in 10 days indicating the aggregates to be reactive. In 21 days, the expansion reached about 0.3%. Mortar bars with 100S\_4 showed a slower expansion rate compared to OPC but it also exceeded the 0.1% expansion limit in 21 days. Increase of the alkali content to 6% Na<sub>2</sub>O (100S\_6), increases the expansion up to 0.2% in 21 days. No significant expansion was observed in geopolymer systems with 30-70% fly ash. The expansion was slightly lower at the higher alkali content. This is probably because the geopolymer matrix becomes denser as a result of extensive reaction of fly ash and alkali in higher alkaline environment preventing AAR expansion in mortar bar.

Figure 3 illustrates the expansion behaviour of mortar bars containing R2 aggregate. Again mortar bars made with OPC binder showed significant expansion (0.2% and 0.4% in 10 days and 21 days respectively). The specimens made with alkali activated slag binder and R2 aggregate also showed significant expansion (0.1% and 0.2%, in 10 days and 21 days respectively). Moreover, the expansion of specimen made with alkali activated slag slightly exceeded that specimen containing OPC binder at high alkali content (6%) being 0.3% and 0.45% expansion in 10 and 21 days, respectively. Even though, specimens with 100S\_6 showed higher rate of expansion during the early period of measurements, the 21 days expansion values for specimens containing OPC and 100S\_6 were similar. These results show that slag-based geopolymers mortar containing high alkali content behave similar to OPC mortar, ie, the slag does not suppress AAR at high alkali content. However, fly ash and slag blended geopolymer binders show no expansion at either 4% Na<sub>2</sub>O or 6% Na<sub>2</sub>O contents. The results so far show that 70% slag usage in geopolymer synthesis is safe with respect to AAR.

Slag addition to geopolymer synthesis increases the setting characteristics as well as the mechanical properties of the binders. Alkali activated slag creates calcium silicate hydrates (C-S-H) as the main reaction product while the introduction of class F fly ash into alkali activated slag mix generates Na<sub>2</sub>O-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>-H<sub>2</sub>O geopolymer matrix, C-S-H and (Ca/Na)-A-S-H phases as main products. When slag increases in the geopolymer synthesis, C-S-H percentage is also increased, resulting in durability issues like AAR. Hence, it is important to identify the optimum level of slag addition into geopolymer systems without causing AAR.

Figure 4 shows the AAR expansion of geopolymer mortar containing different levels of slag. Beyond 70% slag content, the mortar bars showed magnificent expansion. The rate of expansion also increases with higher slag content in the geopolymer. OPC mortars also have the same durability issue as the high slag based geopolymers due to high calcium contents. The results show that more than 80% slag content in the geopolymer can cause high AAR expansion in the later stages of testing.

Figure 4: Expansion of geopolymer mortar bars containing different slag content and R2 aggregate at 6% Na<sub>2</sub>O

Figure 5 analyses the expansion behavior of geopolymer and OPC systems as a fraction of CaO content. It shows that a CaO fraction below 0.15 results in geopolymer systems without AAR expansions. Figure 5 also shows that CaO fraction significantly influences towards the AAR expansion of geopolymer mortars. 100% slag and Portland cement systems have calcium in form of Ca(OH)<sub>2</sub> which helps to maintain high alkaline levels in the concrete pore solution [15]. Thomas [16] reported that Ca<sup>2+</sup> can

replace alkali ions in the AAR gel, thereby more  $\text{Na}^+$  ions are released into the pore solution, allowing further reaction and expansion. He also showed that when class F fly ash is blended with OPC, it produced AAR gel with no harmful expansion (no expansion and cracking). This was attributed to low viscosity of AAR gel which can be dispersed into binder through pores. In presence of high calcium environment, the gel viscosity increases preventing it from being dissipated in the pores, eventually leading to expansion.

**Figure 5: Expansion variation with CaO fraction in the binder (total oxide molar =  $\text{Na}_2\text{O} + \text{CaO} + \text{K}_2\text{O} + \text{Al}_2\text{O}_3$ ) (note: R2 aggregate was used in this study)**

Alkalinity of geopolymer systems is one of the key parameters that control the reaction mechanism and structural characteristics of the binder. Influence of alkalinity in geopolymer systems for AAR can be discussed using Figure 6. Figure 6, which shows the expansion of geopolymer mortar bars in the presence of two different alkali levels. In this comparison, a reactive aggregate (R2) was used. Geopolymer mortar bars with 30-70% slag showed negligible length change at 4 and 6% alkali content. However, mortar bar made with 100% alkali activated slag expanded 0.45% in 6% alkali environment compared to 0.2% length change at 4% alkali level.

**Figure 6: Expansion variation of mortar bars with different alkali level and R2 aggregate (in 21 days)**

### **3.2 NMR spectra variation of different binders**

NMR is used to investigate the structure of silica species in crystalline as well as in amorphous form. Advantage of this analytical tool is that it can identify the nearest neighbour and next nearest neighbour in the atomic environment. Moreover, mobility of the associate protons can also be identified in NMR-MAS spectra. Hence, NMR-MAS spectroscopy was employed to examine atomic structures in various binders.

Figure 7 shows the  $^{29}\text{Si}$  spectra of 70F30S, 50F50S and 100S binders. In NMR spectroscopy, 'Q' is used to represent different silica species,  $\text{Q}^4$  denotes  $\text{SiO}_4$  tetrahedra which connects to four other atoms of the same type via shared oxygen atoms and  $\text{Q}^3$  denotes three oxygen bonded tetrahedral and so on.

70F30S and 50F50S geopolymers show signal at -110 to -120ppm indicating complete mixing of  $\text{SiO}_4$  and  $\text{AlO}_4$  units ( $\text{Q}^4$ ). Furthermore, 70F30S and 50F50S geopolymers also show shifts correspond to  $\text{Q}^3$  (-110 to -100 ppm),  $\text{Q}^2$  (-100 to -92 ppm) and  $\text{Q}^1$  (-94 to -84) and  $\text{Q}^0$  (-85 to -75 ppm) species apart from silica tetrahedral. On the other hand 100S shows signal around -85 to -79 ppm which corresponds to  $\text{Q}^1$  type species. It is observed in Figure 7, when fly ash was mixed with slag, this signal shifted towards negative direction. Provis et al.[17] stated that when  $^{29}\text{Si}$  NMR spectra signal is shifted towards negative direction the structure has higher connectivity.

The  $\text{Q}^4$  based structure found in geopolymer has rigid well organized framework preventing additional substitution of ions in alkali surroundings. Therefore, the structural changes are not easily allowed in geopolymer binders.  $\text{Q}^1$  species generates a chain type structure in 100S (mainly C-S-H) which is less polymerized compared to geopolymers. The chain type structure can be altered and rearranged in alkali environment. These results suggest that binders with  $\text{Q}^1$  chain type structure may favour AAR development in mortar in the presence of reactive aggregates.

Figure 7:  $^{29}\text{Si}$  Spectra for geopolymer binders (activator content = 4%  $\text{Na}_2\text{O}$ )

### 3.3 Microstructural features of binders

Microstructural features of the binder were analysed using Scanning electron microscopy (SEM) and EDX Energy dispersive X-ray (EDX). Square sections (75×75×5 mm) were prepared for examination after the completion of expansion measurements. As discussed earlier, the ingredients of the binder significantly impact the AAR expansion. The combination of OPC or 100S with reactive aggregate caused excessive mortar bar expansion, whereas the use of at least 30% fly ash in binder prevented the expansion during the test period. SEM/EDX analysis was used to compare microstructural features of mortars incorporating the different aggregates in combination with 50F50S, 100S and OPC binders.

Figure 8, Figure 9 and Figure 10 show the different forms of products found in mortars with different binders in the presence of reactive (R1 and R2) and non-reactive aggregates (NR). Figure 8(a) shows a formed product in 50F50S geopolymer which contain NR aggregate. According to EDX composition, this product has zeolite-like composition. Figure 8(b) shows alkali activated 100S also shows a zeolite-like product but with less aluminium and high calcium compared to Figure 8(a). Figure 8(c) shows a reaction product found in OPC mortars in the presence of NR aggregate which has not been analyzed yet using EDX. Rosettes products in mortars in the presence of R1 aggregate with OPC and 100S binders are shown in

Figure 9(b) and Figure 9(c). These AAR products were found throughout the OPC and 100S specimens. Figure 9(a) shows that fly ash blended binder based mortars in the presence of R1 aggregate, formed zeolite-like product with less Al content compared to the product shown in Figure 8(a).

Figure 10 shows the composition of binder and AAR products of mortars in the presence of reactive aggregate R2. Area 'A' as marked on each image was analysed the binder composition. The EDX spectrum of OPC binder shows higher Ca and lower Si typical of calcium silicate hydrate, whereas the EDX spectrum corresponding to 100S also shows enhanced peak intensity for Si compared to Ca (unlike C-S-H). Even though, both spectra (OPC and 100s) show a composition of calcium silicate hydrate, Ca/Si ratio in OPC binder is higher than that of slag binder. It was observed that 50F50S binder generated a matrix rich in Al, Si, Na and Ca consistent with a hydrated calcium aluminium silicate type phase. Mg noted in the in the EDX spectrum of 50F50S binder originates from the slag.

Area 'B' marked on each image represents AAR products. As shown in Figure 10 all the mortars formed AAR products in the presence of R2 aggregate. The main reaction products formed in these binders were identified as typical AAR product like rosette-type crystals as seen in Figure 10. Most of the AAR related products found in the mortars in the presence of reactive aggregates are similar in nature. Observed AAR products were rich in Si, Na and Ca, but poor in Al which is typical of composite of AAR products.

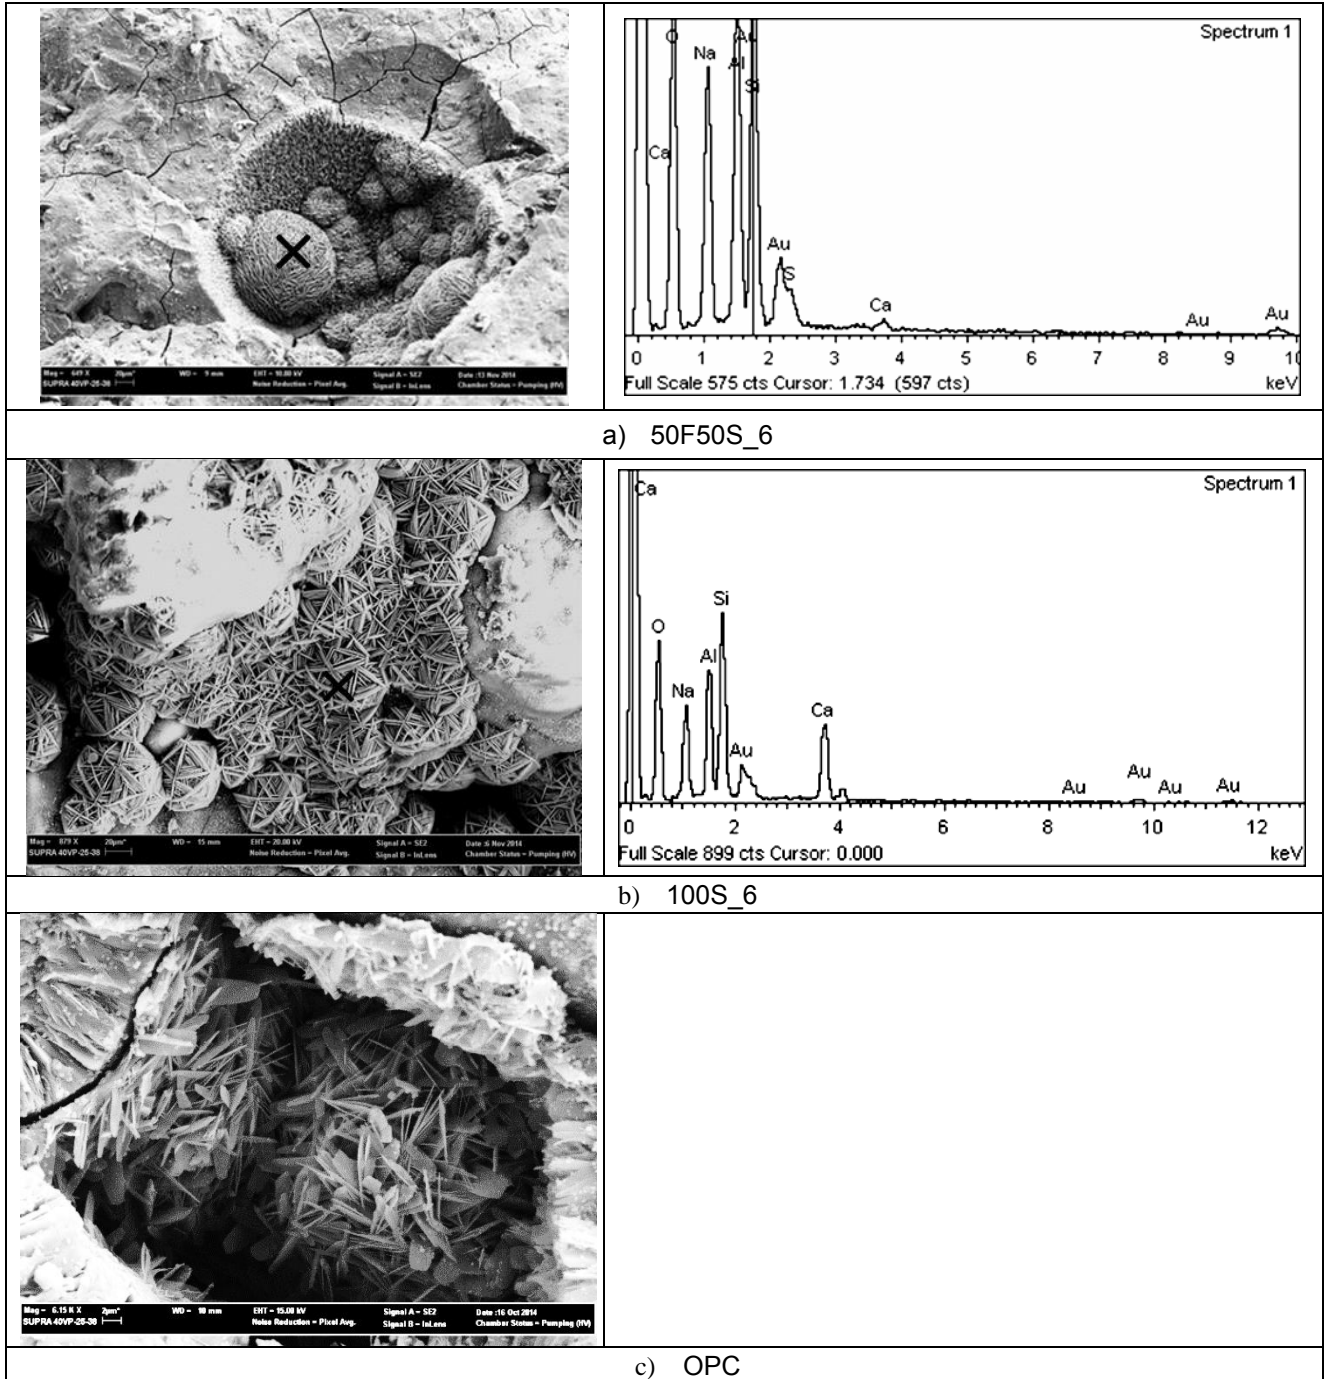

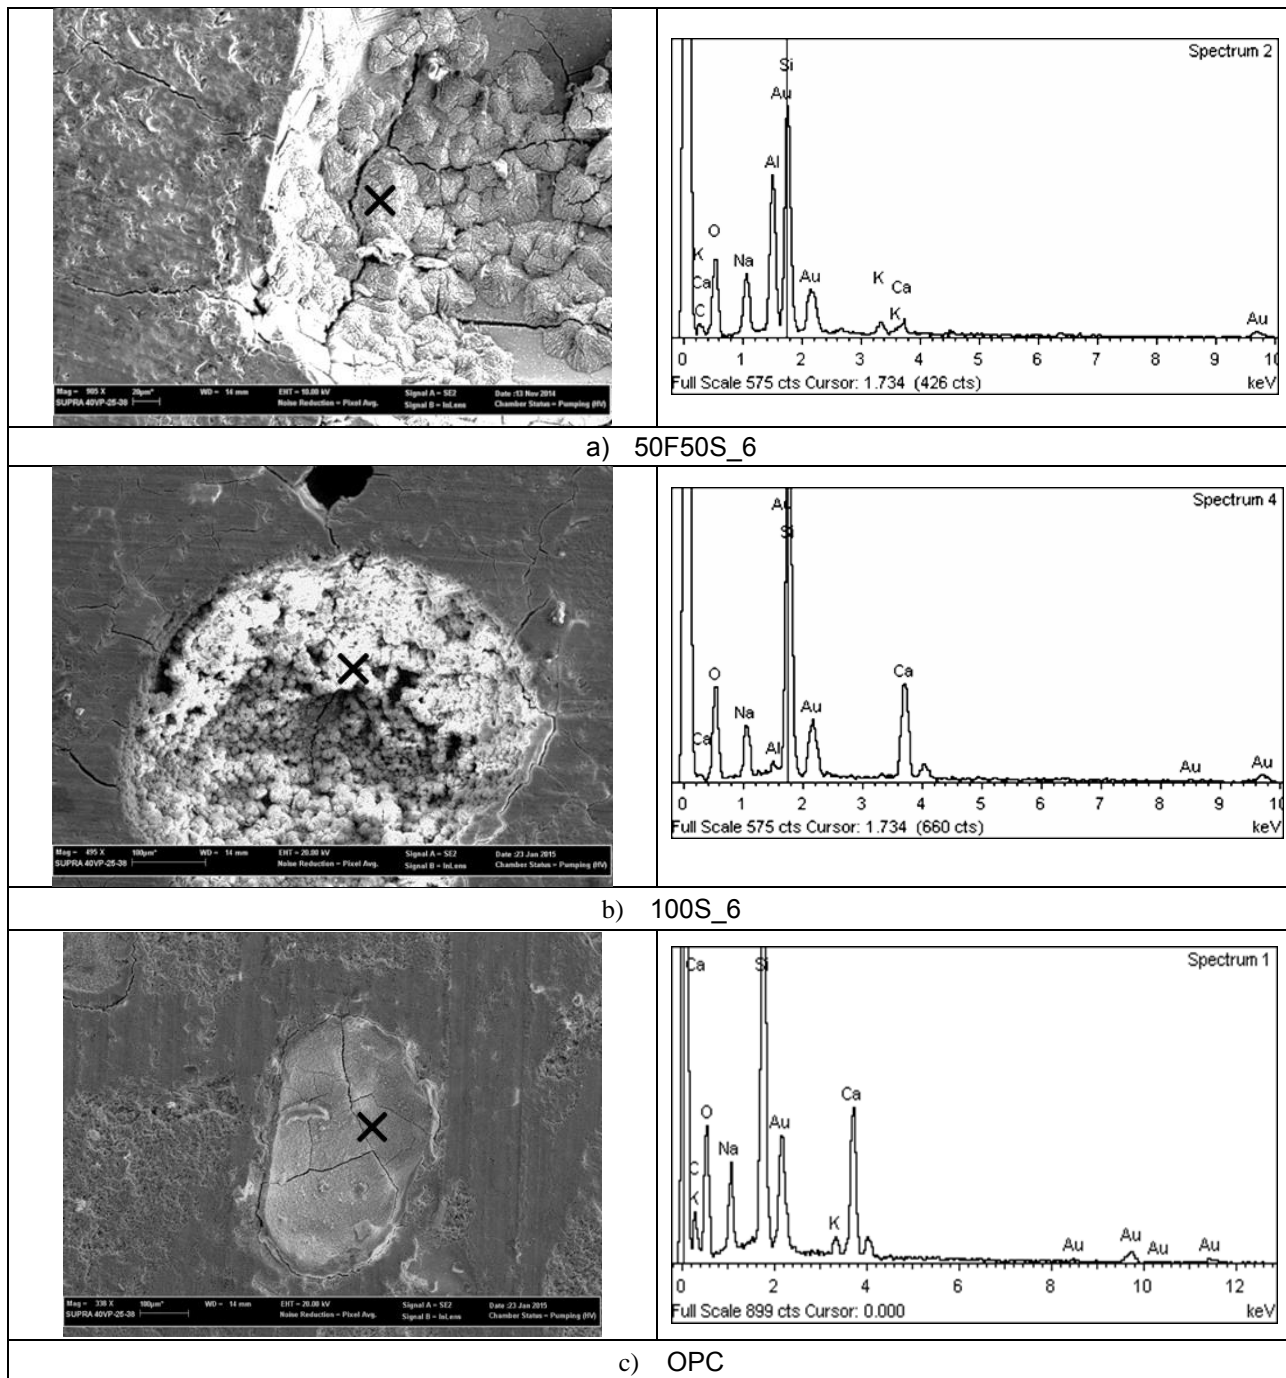

Figure 8: Reaction products found in mortars with different binders in the presence of NR basalts (EDX spectrum for OPC binder to be done). Each EDX spectrum represents the composition of the area marked on the corresponding image.

**Figure 9: Reaction products found in mortars with different binders in the presence of reactive aggregate R1. Each EDX spectrum represents the composition of the area marked on the corresponding**

**Figure 10: Reaction products found in mortars with different binders in the presence of reactive aggregate R2**

**Figure 11** shows that mortar specimens made with slag-fly ash blended geopolymer exhibit clear microstructural differences compared to those made with 100S. Whereas in the latter AAR products, such as the rosettes shown in Figure 11a, were present. In the fly ash blended geopolymer mortars, the composition of the observed products revealed large Al contents, indicating Na-aluminosilicate materials (**Figure 11(b)**). The Si/Al ratio in these products was found as approximately 1, whereas typical AAR products (As seen in **Figure 11(a)**) contain very small Al contents. The products formed in slag-fly ash blended geopolymers could belong to zeolite type phases generated in addition to geopolymer gel. García-Lodeiro et al.[5] also observed similar products in their fly ash based geopolymers.

EDX spectrum C in (Figure11) shows that AAR gel was present in this mortar (50F50S), and that the geopolymer phases were formed in association with the AAR gel.

#### 4. Conclusions

The following conclusions can be drawn from this work:

1. The accelerated mortar bar test was used to analyze the performance of OPC, 100S and 50F50S binders in combination with two reactive aggregate and one non-reactive aggregate. At least 30% fly ash is needed in alkali activated slag to reduce the AAR expansion.
2. MAS-NMR  $^{29}\text{Si}$  spectroscopy results showed that alkali activated slag contains  $\text{Q}^1$  and  $\text{Q}^0$  species which are less polymerized (chain type structures). However, when fly ash was introduced into alkali activated slag (70F30S and 50F50S),  $\text{Q}^4$  and  $\text{Q}^3$  species were generated forming more stable 3 dimensional structures.
3. SEM and EDX analysis showed that OPC and alkali activated 100S mortars produced type typical AAR product such as rosettes, in the presence of reactive aggregates. On the other hand, fly ash and slag blended geopolymer generated zeolitic type products which contain significantly higher aluminum content compared to its binder composition.
4. AAR expansion could be related to the type of geopolymer reaction product that form in the binder and could be controlled by using at least 30% fly ash in the geopolymer composition.

# Rheological Properties of sodium carbonate Alkali-Activated Fly Ash/Slag pastes with Different Superplasticisers

Ahmed Abdalqader<sup>1</sup> and Abir Al-Tabbaa<sup>2</sup>

<sup>1</sup>PhD Candidate, Cambridge University Engineering Department

<sup>2</sup>Professor of Civil & Environmental Engineering, Cambridge University Engineering Department

**Abstract:** Alkali-activated fly ash/slag (AAFS) is a newly evolved type of alkali-activated material and a promising environmentally friendly alternative binder to Portland cement. The rheological properties of this type of binder were examined using a number of different commercial superplasticisers. Mini slump tests, flow table tests, and a rheometer were used to investigate the flowability and rheology of these binder pastes. It was found that increasing the sodium carbonate activator dosage increased the viscosity and the yield stress of the paste. The results also showed that the lignosulphonate-based admixture was the most efficient superplasticiser in improving the rheological properties of these mixtures.

**Keywords:** fly ash, slag, superplasticiser, rheology, lignosulphonates.

## 1. Introduction

The need for alternative and more sustainable binders to Portland Cement (PC) has fuelled significant research efforts in construction materials over the last few decades (1–4). The rapid growth in research and development related to alkali-activated materials (AAMs) has indeed indicated that the use of such systems as primary binders in the construction industry offers great potential in addressing not only the challenges of the damaging effect of PC on the environment, but also of the waste management problems related to the aluminosilicate solid waste materials from many industries (2,5–8). Ground granulated blast-furnace slag (GGBS) from the pig iron industry and pulverised fuel ash or fly ash (FA) from the burning of pulverised bituminous coals in power station furnaces (9) are the most used precursor materials in alkali activated systems.

Extensive research has been conducted on the activation of GGBS or FA. However, a growing literature has focused on the activation of a blend of both materials in part because of the limited availability of each and in part due to their potential synergetic effects (7,10–14), the purpose being to enhance the advantages and eliminate the disadvantages of the activation of each material alone (13,14). Because of their relatively low cost, low carbon footprint, and wider availability, the use of carbonate-based activators offers advantages over conventional activators, such as sodium hydroxide and sodium silicate, because of their low cost, availability, and low carbon footprint compared to the aforementioned activators (15).

More attention has, recently, been paid to understanding the role and mechanism of sodium carbonate ( $\text{Na}_2\text{CO}_3$ ) in the activation of GGBS and/or FA (13,14,16–18). Nevertheless, most research has concentrated on the mechanical properties of pastes, mortars, and concrete and the microstructural analysis of the reaction products. In contrast, very few studies have considered the rheological properties of AAMs (19–22); and to the authors' best knowledge, none have been conducted on  $\text{Na}_2\text{CO}_3$ -activated fly ash/slag. Like PC, AAMs display visco-plastic behavior (23). However, it is notable that there have been many conflicting reports with respect to the rheological properties of alkali-activated cement suspensions, with the majority of the studies indicating that admixtures have variable or inconsistent effects on these systems. Different behaviour and mechanisms with different superplasticisers have been reported in alkali-activated slag (AAS) and alkali activated fly ash (AAFA) (19,21,22,24–27). For example, some studies found that adding a superplasticising admixture based on selected sulphonated naphthalene polymers to AAFA improved the workability (27,28). On the other hand, other studies reported that neither polycarboxylate, vinyl copolymer-based admixtures, nor naphthalene-based superplasticisers had any influence on the workability (29,30). Palacios and Puertas (22) showed that naphthalene-based admixtures significantly increased the flow rate in NaOH-activated slag while polycarboxylate, melamine-based and vinyl copolymer admixtures led to a slight improvement in the flowability of the same system. However, the same admixtures exhibited no influence on the workability of waterglass-activated slag (22).

As alkali-activated fly ash/slag (AAFS) systems are still in their infancy and are an evolving field of research, there is a lack of studies on the rheological properties of these systems, and no research on systems activated by  $\text{Na}_2\text{CO}_3$ . Thus, the aim of this study was to investigate the effect of different commercial superplasticisers, activator dosage, and reactive magnesia incorporation on the rheological

properties of Na<sub>2</sub>CO<sub>3</sub>-activated fly ash/slag with reactive magnesia. The effects of these superplasticisers on the microstructure and mechanical properties of these mixes will be reported elsewhere.

## 2. Experimental materials and methodology

### 2.1 Materials used

The GGBS used had basicity ( $K_b = \frac{\text{CaO}+\text{MgO}}{\text{SiO}_2+\text{Al}_2\text{O}_3}$ ) and hydration modulus ( $\text{HM} = \frac{\text{CaO}+\text{MgO}+\text{Al}_2\text{O}_3}{\text{SiO}_2}$ ) values of ~1.0 and ~1.60, respectively. The GGBS was mainly amorphous, with merwinite (Ca<sub>3</sub>Mg(SiO<sub>4</sub>)<sub>2</sub>) identified as the only crystalline phase present. The FA is classified to meet the requirements of BS 3892: Part 1 for use with PC. The MgO 92/200 has a reactivity of 170s according to the acetic acid test, which indicates medium reactivity according to the classification of Jin and Al-Tabbaa (31). The chemical compositions of all materials are shown in Table 1. Sodium carbonate was supplied as a powder of 99% purity and was dissolved in the mix water.

**Table 1. Chemical composition and physical characteristics of the materials used (based on the suppliers' datasheets)**

Component	GGBS	FA	MgO92/200
CaO %	39.24	6.8±3.6	1.9
SiO <sub>2</sub> %	36.79	49.3±6.2	0.9
Al <sub>2</sub> O <sub>3</sub> %	11.51	24.1±0.4	0.1
Fe <sub>2</sub> O <sub>3</sub>	0.42	9.7±1.3	0.8
MgO %	8.10	1.1±0.2	93.5
SO <sub>3</sub> %	1.03	3.3±1.3	-
K <sub>2</sub> O %	0.63	3.5±0.3	-
Na <sub>2</sub> O %	0.37	1.2±0.1	-
SSA (m <sup>2</sup> /g)	0.545	2.600	15.9

Clinkerless systems were prepared from GGBS, FA, and MgO and activated by Na<sub>2</sub>CO<sub>3</sub>. Each material was given an appropriate notation for simplicity: G, F, M, and N refer to GGBS, FA, MgO, and Na<sub>2</sub>CO<sub>3</sub>, respectively. The ratio of the GGBS to FA was fixed at 3:1 by weight. MgO replaced between 0-10% of GGBS+FA and the content of Na<sub>2</sub>CO<sub>3</sub> varied from 0-10% by the weight of the total binder as an addition (Table 2). All mixes had water to binder (w/b) ratio of 0.31. Different commercial superplasticisers (SP) were used in this study in liquid forms:

(SP-A) a modified polycarboxylate-based high range water reducing/superplasticising concrete admixture;

(SP-B) a modified polycarboxylate-based mid-range water reducing/plasticising concrete admixture; and

(SP-C) a modified lignosulphonates-based water reducing/plasticising admixture were added to each mix at a dosage of 1%.

**Table 2. The cement paste mix proportions used in this study by % weight**

Mix ID	GGBS %	FA %	MgO %	Na <sub>2</sub> CO <sub>3</sub> % - forms part of the mix water
M0N5	75	25	0	5
M5N5	71.25	23.75	5	5
M10N5	67.5	22.5	10	5
M0N10	75	25	0	10
M5N10	71.25	23.75	5	10
M10N10	67.5	22.5	10	10

The mixing and sample preparation procedures are presented separately under each heading below and all mixing and tests were conducted in the laboratory at a room temperature of 20 °C ±1 °C.

## 2.2 Experimental procedure

### 2.2.1 Mini-slump test

The mini-slump test was developed to assess the early stiffening of cement paste in the first 60 minutes of hydration. To monitor the workability loss, the average diameter of the mini slump spread was plotted against time. Initially, all dry materials (GGBS, FA, MgO) were mixed for homogenisation. After dry mixing, 80% of the total water was added and mixed for 60s. Subsequently, the remaining water was added along with the superplasticiser and mixed for 60s. Then 2-minute-rest was applied and followed by a final mixing of 2 minutes. Between each stage the side walls were cleaned. After mixing the paste, the mini-slump test was performed using a small slump cone (Fig. 1). The paste was taken and poured into the cone. Excess paste was then removed by levelling the paste to the height of the cone and collected on the wide flange. Slight tapping was given on the flanges to release the entrapped air (if any). The mini-slump cone was lifted with a motion rapid enough without obstructing the flowing paste but slow enough to avoid disturbing the paste. After following a standard mixing schedule, samples of the paste were tested, at 2, 5, 10, 30, 45 and 60 minutes. For the last four readings, samples were remixed for 120s before performing the test. The diameter of the paste spread was recorded in two directions at right angles and the average was calculated (32). The test was replicated.

Figure 1. (left) Mini-slump cone dimensions, (middle and right) Test in action.

### 2.2.2 Flow table test

The standard flow table spread was determined in according to European standard EN 1015-3 (33) using an automatic table set (Figure 2). The test was conducted on cement paste rather than mortar. The truncated cone mould (larger base at the bottom) with its funnel in the centre was set on the disc of the flow table. The paste was introduced into the mould in two layers, each layer being compacted at least 10 times by a tamper to ensure uniform filling of the mould. Excess paste was then skimmed off with a palette knife and the disc was carefully cleaned of any paste or water. After 15s, the mold was lifted vertically and the disc was jolted 15 times at a constant frequency of one per second to spread out the paste. The diameter of the paste spread was measured in two directions at right angles and the average was stated to the nearest mm. The test was replicated.

**Figure 2. Flow table apparatus.**

### **2.2.3 Rheological studies**

Viscometric studies were conducted to explore the change in rheology due to the addition of the SP. The tests were performed on a coaxial cylinder type-smooth walled rheometer. The diameters of inner and outer cylinder were 11.76mm and 19.05mm respectively. The effective length of the inner cylinder was 39.3mm and the depth of the outer cylinder was 86.2mm (Figure 3). The volume of the sample taken was 10.4ml (34). In order to find the best test procedure, a preliminary study of the paste at a constant shear rate of  $50\text{s}^{-1}$  was conducted. The purpose of this test was to find out the time at which the test should start in order to eliminate the influence of the early changes in the paste due to the dissolution rate. To study the rheological parameters of yield stress and plastic viscosity, a shear profile was set up based on (32) who used similar apparatus. The procedure consisted of pre-shearing at  $30\text{s}^{-1}$  in 60s to erase any previous shear history due to mixing, and was followed by a 30s pause to stabilize the paste. Then it was followed by ramping up the shear rate from 0 to  $60\text{s}^{-1}$  in 105s, which data being recorded after every 15s, and finally the shear rate was ramped down from 60 to  $0\text{s}^{-1}$  in 90s, which data also being recorded after every 15 s. The yield stress and plastic viscosity values were calculated from the log-log scale of plotting shear rate (1/s) versus shear stress ( $\text{N/m}^2$ ) and were the average of at least three trials. The mixing time of all the mixes was fixed at 6 minutes. Immediately after mixing, the paste was transferred into the container of the used rheometer and left to rest for 5 minutes before running the test based on the results obtained from the preliminary study.

**Figure 3. (left) Rheometer, (right) inner and outer cylinder.**

### 3. Results and discussion

#### 3.1 Flow loss

Figure 4 shows the effect of both the activator dosage and MgO content on the paste spread with and without SP. For the sake of brevity, only the results of the mini-slump spread of mixes with SP-C are presented. In general, the flowability of the mixes without any SP (Figure 4-a) was low because of the low solution/binder ratio. The initial slump in this case varied in a small range between 39 mm and 44 mm. On the one hand, when the MgO content was 0%, the spread decreased with increasing the activator dosage from 5% (solid line) to 10% (dashed line). The flow loss in both cases increased gradually with time. This can be attributed to the viscosity of the alkali solution, which increased when increasing the activator dosage (35). This effect was clearer with the addition of SP-C in Figure 4-b. On the other hand, by adding MgO, the trend is unclear but, generally, the same behaviour can be observed. Mixes containing 5% (square shapes) and 10% MgO (triangle shapes) and activated by 10% Na<sub>2</sub>CO<sub>3</sub> (dashed lines) lost their flowability after 30 minutes and no longer would be cast in the cone. Adding SP-C This trend was also observed when adding SP-C as in Figure 2-b with higher fluidity and an extension of the fluidity of mix M5N10 to 45 minutes instead of 30 minutes. The negative effect of MgO on the flowability can be interpreted by the physical properties of MgO. Firstly, the irregular shape of its particles could lead to an increase viscosity and, secondly, its high specific area results in a higher water demand (36). This decrease in fluidity has been observed in PC-based cement with different MgO contents (37).

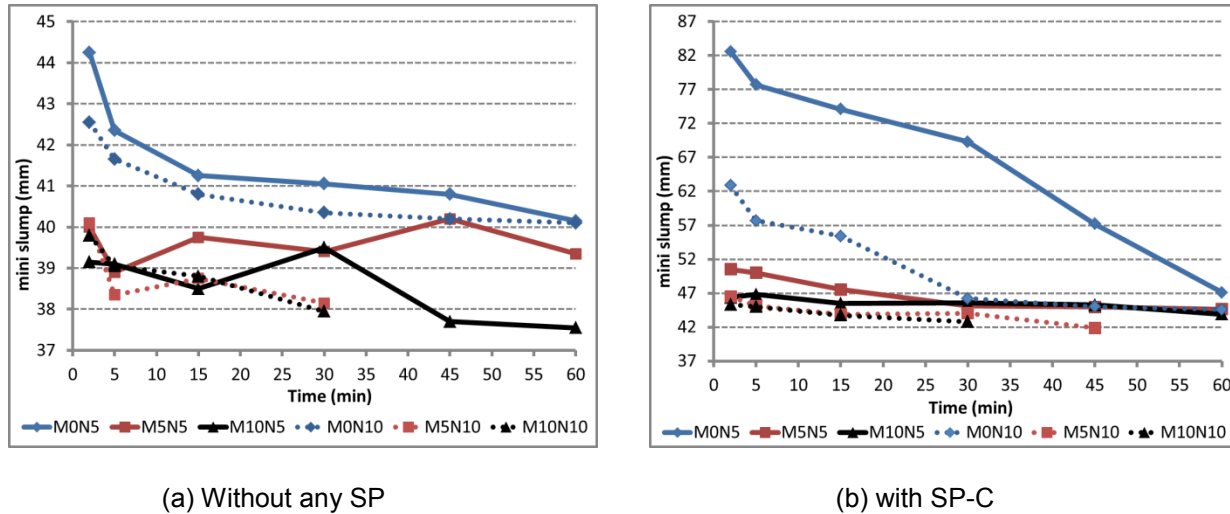

Figure 4. Effect of activator dosage and MgO inclusion on mini slump.

The effect of different superplasticisers on mix M0N5 is presented in Figure 5. It is clear that the addition of superplasticisers based on polycarboxylic ethers (SP-A and SP-B) had an insignificant influence on the fluidity of the mix with an initial increase of ~ 2% and 18%, respectively. It was also observed that a naphthalene-based admixture (not presented here) had no influence of the fluidity of this mix. However, lignusulphonate-based admixture exhibited salient influence on the fluidity of the observed mix.

Figure 5. Effect of different SPs on mini-slump of mix M0N5.

The fluidity increased more than 80% from around 44 mm to more than 82 mm, then, decreased with time to reach 47 mm after 60 minutes. The same trends were noticed in all mixes with different degrees as shown in Figure 2-b. As SP-C is more effective in improving the workability of these mixes, results are hence presented for mixes without SP and with SP-C only.

### 3.2 Flow table

Figure 6 depicts the flow table results of all mixes without SP and with SP-C. Following the trend seen in the mini-slump tests, SP-C effectively improved the flowability of all mixes. For example, adding 1% of SP-C increased the spread of M0N5, M5N5, and M10N5 by 47%, 24%, and 17%, respectively. This indicates that this superplasticiser is more efficient with MgO-free mixes.

Figure 6. Effect of different SPs on mini-slump of mix M0N5.

### 3.3 Rheological parameters

The change in shear stress at constant shear rate was monitored for the first 30 minutes in order to define the best time to start the rheological test. This strategy was followed to alleviate the influence of the changes at early stages. It is clear from Figure 7 that there were many changes in the values of shear stress (viscosity follows the same behaviour) at the first 200 s in most of the mixes before the graph reached a plateau. Based on that, it was decided to run the test after 5 minutes. Another distinctive feature from the graph is that it confirms that increasing both the activator dosage and reactive magnesia

results in increasing the shear stress. This indicates that the attractive interparticle forces increase with increasing these factors.

Figure 7. Shear stress change with time at constant shear rate.

### 3.3.1 Determination of plastic viscosity and yield stress

Figure 8 depicts the lower part of the flow curve in a log-log scale of different trials of Mix MON5. As noted, the lower part of the curve can be fitted to a straight line corresponding to the equation proposed by Bingham model (Eq. 1) to describe the rheological behaviour.

$$\tau = \tau_0 + \mu\dot{\gamma} \quad (1)$$

Where  $\tau$  is the shear stress applied to the paste,  $\dot{\gamma}$  is the shear rate,  $\mu$  represents the plastic viscosity of the system at any given time and  $\tau_0$  is the yield stress.

Figure 8. Flow curve of Mix MON5.

Figure 9 shows the yield stress (left) and the plastic viscosity (right) of all mixes without adding any superplasticisers and with the addition of SP-C (lignosulphonate-based admixture). It is clear that this superplasticiser decreased both the yield stress and the viscosity for all samples which made the pastes more fluid and hence less viscous. Again, it can be deduced that increasing the activator dosage and MgO content increased the yield stress and the plastic viscosity. The effect of increasing the activator dosage can be attributed mainly to the increase of the viscosity of the activation solution with concentration.

The yield stress varied between 8-15 Pa and 5-11 Pa in samples without and with SP-C, respectively. Different factors can influence the yield stress of a suspension such as the viscosity of the fluid, the interparticle forces (interaction potential and or steric forces and van der Waals forces), and particle jamming (38). The significant decrease of the yield stress when adding this SP may correspond to the increase in the net surface charge due to the absorption of the SP on the particles, thereby increasing the repulsive forces between particles.

Similarly, plastic viscosity decreased with adding SP-C from a range of ~ 1.8-4.3 Pa.s to a range of ~ 1.1-3.7 Pa.s without SP and with SP, respectively. The plastic viscosity relies on the volume friction of solid particles and the packed density (39). The results indicate that the viscosity is in the same range available in the literature review of AAMs (19,40,41). The viscosity ranges in both cases were higher the minimum viscosity required to prevent segregation as proposed by Nanthagopalan and Santhanam (32).

Organic admixtures based on sulphonic acids such as SP-C contain both a hydrophilic (sulphonic) and a hydrophobic (lignin) group. The electrical charge resulting from the adsorption of these compounds on the surface of binder particles generates the repulsive forces that increase paste fluidity (19). The effect of lignosulphonate-based admixture on workability of AAMs systems has been previously reported with some contradictions. Ren et al (41) concluded that the separation addition of lignosulphonate-based superplasticiser and the alkali solution led to better rheological properties than simultaneous addition. Criado et al (19) studied the influence of different admixtures, among them was a lignosulphonate-based one (Lig), on the workability of alkali activated fly ash and they found that Lig admixture had no effect on the workability.

**Figure 9. Rheological parameters of all mixes without and with superplasticisers (left) Yield stress, (right) Plastic viscosity**

#### 4. Conclusions

This study investigated the effect of different commercial superplasticisers, sodium carbonate activator concentration and the incorporation of MgO on the workability and rheological properties of AAFS. Based on mini-slump test results, the lignosulphonate-based admixture was the superplasticiser most effective in increasing the flowability of the mixes. It was found that the rheological properties largely depend on the activator dosage and the content of MgO. Increasing the contents of both parameters leads to a reduction in the fluidity of the mixes, thus increasing the yield stress and the plastic viscosity values. The addition of 1% lignosulphonate-based superplasticiser improves the rheological properties of all mixes. When introducing this admixture a maximum reduction in yield stress and plastic viscosity at 50% and 40% respectively. Additionally, this study demonstrates that the optimum timing for running a viscometric study for the mixtures used is 5 minutes, as at this point the shear stress stabilises at a constant shear rate.

**Abstract:** Alkali-activated concretes containing fly ash as a prime aluminosilicate source have slow strength development at ambient temperatures. This is also relevant for acid and neutral granulated blast-furnace slags activated with a weak activator such as sodium carbonate. In order to accelerate hardening of the alkali-activated concretes on construction sites, direct electric curing can be used. Three alkali-activated cements were used to produce concrete mixes. Two cements contained fly ash and were activated with sodium hydroxide and sodium silicate ( $M_s=1.125$ ) respectively. The third cement was based on neutral granulated blast-furnace slag activated with sodium carbonate. The effect of duration of pre- and isothermal curing on compressive strength of the alkali-activated concretes was investigated. Electric properties of the alkali-activated cements were obtained.

**Keywords:** fly ash, GBFS, alkali activation, direct electric curing, strength.

## 1. Introduction

Alkali-activated cements have been used for over 70 years (1). Intensive research on these cements during recent decades is driven not only by the need of human society to reduce the CO<sub>2</sub> emissions associated with Portland cement production which is responsible for about 5 % of global anthropogenic CO<sub>2</sub> emissions (2), but also by several other advantages, such as resistance to chemical attack, fire resistance and low permeability, that alkali-activated cements can offer (3-7).

Various aluminosilicate precursors can be used to produce alkali-activated cements (8), but granulated blast-furnace slag (GBFS) and fly ash appear to be the most promising precursors for large-scale industrial production of alkali-activated cements. This is due to the more favourable rheological properties and lower water demand achievable when compared to mixes based on calcined clays (9).

One of the main barriers to the widespread use of alkali-activated cements and concretes is the slow strength development of fly ash alkali-activated cements at ambient temperatures. Curing temperatures from 60 to 80 °C are essential for alkali-activated fly ash cements to achieve good structural strength (10, 11). Alkali-activated slag cement has slow strength development when neutral or acid GBFS is activated with sodium carbonate (12). In the case of slag, the problem of slow strength development at ambient temperatures can be overcome by using different accelerating admixtures (12-14), while fly ash must be heat cured to overcome the thermal activation barrier which is a crucial aspect in the strength development of alkali-activated fly ash cements (10). Normally dry heat or steam curing is used to accelerate strength development of alkali-activated cements (10-12, 15). These types of curing are not easy to implement on construction sites, but almost all construction sites have electric power supply.

Electric power can be used for direct electric curing (DEC) of concrete when alternating electric current is passed through the bulk of fresh concrete to accelerate the curing process by means of direct ohmic heating (16-19). Direct electric curing needs much less initial capital investment in equipment and has substantially lower running cost in comparison to externally applied heat (steam, autoclave, etc.) (16-18). It is also a lot easier to provide DEC on a construction site than external heating.

Direct electric curing of Portland cement concretes has been used for decades (16-19) but there is no available information on alkali-activated concretes. This curing method has huge potential to increase in situ use of alkali-activated concretes. Power supply companies like Eskom in South Africa, will benefit, not only because the power demand will shift towards off-peak hours (16), but also the by-product of the electric power production process (which is fly ash in case of coal power plants) will be utilized in the production of a "green" construction material.

The aim of this research was to do a preliminary investigation on DEC of alkali-activated concretes and to determine the electric properties of alkali-activated cements.

## 2. Materials and methods

### 2.1 Materials

Unclassified low calcium fly ash and GBFS were used. The chemical composition of fly ash and GBFS determined by X-ray fluorescence is presented in Table 1. The specific gravity of the fly ash and GBFS were 2240 kg/m<sup>3</sup> and 2900 kg/m<sup>3</sup> respectively.

**Table 1. Chemical composition of fly ash and GBFS (LOI = loss on ignition at 1000 °C).**

Material	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	Fe <sub>2</sub> O <sub>3</sub>	MgO	K <sub>2</sub> O	Na <sub>2</sub> O	TiO <sub>2</sub>	SO <sub>3</sub>	Other elements	LOI
Fly ash	56.2	30.7	4.5	4.4	0.5	0.8	0.3	1.6	0.4	0.3	0.3
GBFS	34.9	14.4	37.1	0.9	8.0	0.7	<0.01	0.7	2.0	1.1	0.2

Commercially available sodium hydroxide flakes (98.0 % purity), liquid sodium silicate (15.0 % Na<sub>2</sub>O, 29.5 % SiO<sub>2</sub>, remainder H<sub>2</sub>O), sodium carbonate (99.0 % purity) and tap water were used to prepare activator solutions. The specific gravity of the liquid sodium silicate was 1540 kg/m<sup>3</sup>.

Crushed dolomite stone (9.5 mm) and dolomite sand with a fineness modulus of 3.86 and 9.0 % passing the 75 µm sieve were used as the coarse and fine aggregates respectively. The specific gravity of the aggregates was 2860 kg/m<sup>3</sup>.

### 2.2 Mix design and preparation of concrete mixes

Alkali-activated concrete mix compositions are presented in Table 2.

**Table 2. Mix designs and workability of alkali-activated concretes.**

Mix	Binder, mass (kg/m <sup>3</sup> )	Activator	Na <sub>2</sub> O <sub>eq</sub> (wt.%)	Sand (kg/m <sup>3</sup> )	Stone (kg/m <sup>3</sup> )	Slump/Flow (mm)
S50	GBFS, 500	Na <sub>2</sub> CO <sub>3</sub>	4	650	1207	15/–
F40	Fly ash, 400	Na <sub>2</sub> SiO <sub>3</sub> +NaOH	9	668	1240	80/–
F50	Fly ash, 500	Na <sub>2</sub> SiO <sub>3</sub> +NaOH	9	584	1085	–/545
F35	Fly ash, 350	Na <sub>2</sub> SiO <sub>3</sub> +NaOH	9	709	1317	0/–
F35H	Fly ash, 350	NaOH	9	717	1331	0/–

Basic fly ash and slag mixes, used to investigate the influence of duration of precuring and isothermal curing on properties of alkali-activated concretes, contained 400 kg/m<sup>3</sup> (20) and 500 kg/m<sup>3</sup> (14) of binder respectively. All fly ash mixes had an activator concentration 9 % Na<sub>2</sub>O<sub>eq</sub> of fly ash mass (11). The slag mix was activated using sodium carbonate at 4 % Na<sub>2</sub>O<sub>eq</sub> (12, 21). Silicate modulus (Ms) of sodium silicate activator, produced from commercial sodium silicate (Ms=2) and sodium hydroxide, was 1.125 (22). Water/binder (GBFS or fly ash) ratio was designed as low as possible at 0.35 for all mixes (11). Fine to total aggregate ratio was kept constant at 0.35 by weight in all mixes. The activator solutions were prepared and cooled down to room temperature before mixing (11). All materials were pre-conditioned at 20±1 °C for at least 16 hours before mixing. The mixing was done in a pan mixer producing a homogeneous concrete mix. Workability of the alkali-activated concrete mixes was determined according BS EN 12350 (23). After workability testing, concrete was cast into modified moulds and vibrated.

### 2.3 Experimental set up

A rig for DEC of alkali-activated concretes used in this study (Figure 1) was designed taking into account previous research (16, 19). It consisted of modified moulds (Figure 2), a power supply with a capacity of 300 VA, maximum current 12 A and output voltage 0–250 V (ACDC Dynamics, South Africa), a temperature controller (TC600, Rhomberg, Australia), a digital ammeter (Rhomberg, Australia) and a digital voltmeter (Rhomberg, Australia). The modified moulds (100×100×100 mm) made from dielectric plastic and stainless steel plates (electrodes) (Figure 2), were placed in a 50 mm thick polystyrene shell to limit energy losses and were kept in a closed containment box for safety during the DEC process (Figure 1). The lid of the containment box consisted of a 50 mm thick polystyrene plate sealing the moulds to prevent extensive moisture loss during the DEC process which is critical for strength development of AAC (15) and the DEC process itself (18, 19, 24). Three rows of the modified moulds were connected in parallel with each row consisting of 4 moulds connected in series. The modified moulds are removable for ease of casting fresh concrete and were constructed in such a way that the electric current traverses the full area of the specimen (24), ensuring an equal electric field generated throughout the specimen. To eliminate the possibility of a short circuit while obtaining the true temperature of the concrete mix, a thermocouple with mineral insulation was placed in the centre of one mould used for temperature control measurements as shown in Figure 2,b.

Figure 1. DEC rig.

(a) Modified mould

(b) Modified mould for temperature measurements

Figure 2. Modified moulds.

## 2.4 Experimental procedures

All mixes were cured following a standard temperature cycle consisting of precuring, heating, and isothermal curing (25, 26). Precuring was done in closed containment box (Figure 1) to prevent extensive evaporation at  $25 \pm 1$  °C. After the isothermal phase, the DEC rig was switched off, and concrete specimens were demoulded immediately without any gradual cooling. Concrete mixes containing GBFS (S50, Table 2) and 400 kg/m<sup>3</sup> of fly ash (F40, Table 2) were precured for 2 and 4 hours. The alkali-activated slag concrete mix was isothermally cured for 8 hours and the fly ash mix for 8 and 16 hours. Alkali-activated concrete mixes containing 350 and 500 kg/m<sup>3</sup> of fly ash (F35, F35H, F50, Table 2) were only precured for 4 hours and isothermally cured for 8 hours. During the heating phase, the temperature increased at a rate of  $20 \pm 1$  °C/h (26). The temperature of the isothermal phase was set at 60 °C (11, 19), and this was maintained automatically by the temperature controller. Ammeter and voltmeter readings were recorded every 5 minutes during the heating phase. After demoulding, concrete specimens were stored in a fog room at  $90 \pm 5$  % relative humidity and  $20 \pm 1$  °C until testing. Three concrete specimens were tested at 1, 7 and 28 days according to BS EN 12390-3 (27).

The resistivity,  $\rho_c$ , of alkali-activated concrete mixes was calculated using the following formula:

$$\rho_c = \frac{RA}{L} \quad (1)$$

Where  $\rho_c$  – resistivity of concrete,  $\Omega \cdot m$ ;

$R$  – resistance of a concrete sample,  $\Omega$ ;

$L$  – length of a concrete sample, m;

$A$  – cross-sectional area of a concrete sample, m<sup>2</sup>.

Calculation of resistivity of alkali-activated cement pastes was done according to the formula found by Whittington et al (24) for Portland cement pastes. The formula was modified to take into account coarse porosity caused by the incomplete compaction of concrete mixes:

$$F = 1.04((1 - Por)\varphi)^{-1.20} \quad (2)$$

Where  $F$  – formation factor;

$Por$  – porosity of alkali-activated concrete samples at 1 day (measured by hydrostatic weighing);

$\varphi$  – theoretical fractional volume of alkali-activated cement paste in concrete mix.

$$Por = 1 - \frac{m}{(m - m_w)\gamma} \quad (3)$$

Where  $m$  – mass of concrete sample in air, kg;

$m_w$  – mass of concrete sample in water (hydrostatic weight), kg;

$\gamma$  – theoretical relative density of alkali-activated concrete.

$$F = \frac{\rho_c}{\rho_p} \quad (4)$$

Where  $\rho_p$  – resistivity of alkali-activated cement paste,  $\Omega \cdot m$ .

Temperature coefficient of resistivity was found from the following formula:

$$\rho_{p2} = \frac{\rho_{p1}}{1 + \alpha(T_2 - T_1)} \quad (5)$$

Where  $\rho_{p1}$ ,  $\rho_{p2}$  – resistivity of alkali-activated cement paste at temperature  $T_1$  and  $T_2$  respectively,  $\Omega \cdot m$ ;

$T_1$ ,  $T_2$  – temperature of concrete mix, °C;

$\alpha$  – temperature coefficient of resistivity, °C<sup>-1</sup>.

### 3. Results and discussion

#### 3.1 General observations

Workability of alkali-activated fly ash concrete mixes strongly depends on fly ash content at constant water/binder ratio (Table 2). Concrete mixes containing 350 kg/m<sup>3</sup> of fly ash had zero slump, but they could be properly compacted by vibration due to thixotropy of the mixes. Mix F50 had very high workability.

Thermal expansion of the plastic parts of the moulds resulted in an air gap between the electrodes and samples shortly after the heating phase. This was the case for concrete mixes containing GBFS, as well as fly ash mix activated with sodium hydroxide (S50, F35H, Table 2). Thus, these mixes were gradually cooling down for 8 hours. The thermal isolation of the containment box did not allow fast energy dissipation, therefore temperature only dropped to 48 °C before demoulding. Fly ash concrete mixes activated with sodium silicate did not lose contact with the electrodes due to the high adhesion to metal surfaces.

#### 3.2 Resistivity

Resistivity of all alkali-activated cement pastes and concrete mixes during the heating phase is presented in Table 3.

**Table 3. Physical and electric properties of alkali-activated cement pastes and concretes.**

Mix-Precurring (h)	Fractional volume, $\varphi$	Por	$\rho_{c1}$ ( $\Omega \cdot m$ ) <sup>1)</sup>	$\rho_{c2}$ ( $\Omega \cdot m$ ) <sup>2)</sup>	Formation factor, $F$	$\rho_{p1}$ ( $\Omega \cdot m$ ) <sup>1)</sup>	$\rho_{p2}$ ( $\Omega \cdot m$ ) <sup>2)</sup>	$\alpha$ , ( $^{\circ}C^{-1}$ )
S50-2	0.351	0.019	1.53	0.82	3.74	0.41	0.22	0.024
S50-4	0.351	0.018	1.62	1.03	3.73	0.43	0.28	0.020
F40-2	0.333	0.034	3.32	1.39	4.06	0.82	0.34	0.045
F40-4	0.333	0.029	3.39	1.37	4.03	0.84	0.34	0.045
F50-4	0.416	0.026	2.62	1.06	3.08	0.85	0.35	0.045
F35-4	0.291	0.035	4.35	1.63	4.77	0.91	0.34	0.045
F35H-4	0.284	0.034	0.89	0.64	4.91	0.18	0.13	0.020

<sup>1)</sup>  $\rho_{c1}$ ,  $\rho_{p1}$  – resistivity of alkali-activated concrete and cement paste at the beginning of the heating phase respectively;

<sup>2)</sup>  $\rho_{c2}$ ,  $\rho_{p2}$  – minimal resistivity of alkali-activated concrete and cement paste during the heating phase respectively (some mixes had a jump in resistivity due to the air gap that developed between the sample and the electrodes).

It can be seen that the resistivity of alkali-activated concretes containing cement paste of a certain composition (F35, F40, F50, Table 3) depends on the fractional volume of alkali-activated cement paste as the resistivity of the aggregates is several orders of magnitude higher than that of the paste, resulting in electric current being conducted through the paste, i.e. through the path of least resistance (24). Results show that formula (2) derived for Portland cement concretes by Whittington et al. (24) can be applied with success to alkali-activated concretes; the maximum and minimum resistivity of alkali-activated cement pastes in concretes with different paste content (F35, F40, F50, Table 3) are almost equal as it should be because the composition of the pastes is the same (Table 2). Only alkali-activated cement paste of mix F35 had slightly high resistivity at the beginning of the heating phase but it could be attributed to samples' compaction. Duration of precurring did not have any significant influence on the resistivity of alkali-activated concretes (S50-2 and F40-2 compare to S50-4 and F40-4 respectively, Table 3). The high value of minimum resistivity of mix S50-4 could be caused by the air gap that developed between the samples and the electrodes; this mix reached only 58 °C. The resistivity of the alkali-activated cement pastes strongly depends on type of activator used. Sodium hydroxide gives the lowest resistivity (F35H, Table 3) followed by sodium carbonate (SC50, Table 3; despite significantly lower concentration) and sodium

silicate (F35, Table 3). Lower resistivity leads to lower power demand during the heating phase (Joule–Lenz law):

$$Q = I^2 R t = \frac{U^2 t}{R} \quad (6)$$

Where  $Q$  – generated heat, J;

$I$  – current strength, Amp;

$U$  – potential, V;

$t$  – time, sec.

Change in the resistivity of alkali-activated concretes during the heating phase can be seen in Figure 3.

**Figure 3. Electric resistivity development of alkali-activated concretes during the heating phase.**

The decrease in resistivity of alkali-activated concretes correlates to the behaviour of Portland cement concretes (16, 24). It is important to note that the resistivity of alkali-activated concretes (Figure 3) and cement pastes (Table 3) is significantly lower in comparison to Portland cement concretes and pastes (24).

The temperature coefficient ( $\alpha$ , Table 3) of all alkali-activated concrete mixes depends only on the composition of the alkali-activated cement paste, not the paste content in the concrete mix. The significance of the results is confirmed by the low standard deviation of the results of alkali-activated concrete mixes containing fly ash and sodium silicate (F35, F40, F50, Table 3);  $\alpha_{av}=0.0453 \text{ } ^\circ\text{C}^{-1}$ , st.dev.= $\pm 0.0027 \text{ } ^\circ\text{C}^{-1}$ . It is important to note that temperature coefficient of alkali-activated concrete mixes containing fly ash and sodium silicate is considerably higher than the value of  $0.022 \text{ } ^\circ\text{C}^{-1}$  found by Whittington et al. (24) for Portland cement paste. The higher value of the temperature coefficient indicates that fly ash activated with sodium silicate drops its resistivity faster than Portland cement paste. The degree of hydrolysis of electrolytes increases with temperature rise but it is more complex in case of sodium silicate solution due to its colloidal nature. Also, mobility of sodium ions in sodium silicate solution significantly increases with temperature rise. These two factors are responsible for the significant drop in the resistivity of alkali-activated cement paste containing sodium silicate. Thermal coefficients of alkali-activated concretes containing GBFS with sodium carbonate and fly ash with sodium hydroxide are similar to the thermal coefficient of Portland cement paste (24) and are comparable with a value of  $0.025 \text{ } ^\circ\text{C}^{-1}$  for most electrolytes.

### 3.3 Compressive strength

Compressive strength results are presented in Figure 4.

Figure 4. Compressive strength of alkali-activated concretes.

It is important to note that alkali-activated concrete containing GBFS had extremely low strength when precured for 2 hours and isothermally cured for 8 hours (S50-2-8, Figure 4). The reason for this phenomenon is not clear and can be studied in future. Alkali-activated slag concrete mix precured for 4 hours showed much higher strength which was equal to the strength of steam cured alkali-activated slag concretes with similar composition (14). High standard deviation of 1-day strength of S50 mix precured for 4 hours should be noted. Alkali-activated slag concretes were not cured for 16 hours due to the air gap described earlier; the concretes were cooling down gradually for 8 hours rather than being cured at 60 °C. It can be seen that, although the duration of precuring significantly affects strength development of alkali-activated slag concretes, it has much less effect on the strength of alkali-activated fly ash concretes, maximum difference is 10.8 % (F40 mixes, Figure 4), but compressive strength of alkali-activated fly ash concretes precured for 4 hours was always higher.

Variation of precuring and isothermal curing time showed that 4 hours of precuring and 8 hours of isothermal curing were the best in this study for alkali-activated fly ash concretes (F40 mixes, Figure 4). Precuring for 2 hours gave slightly lower strength and higher standard deviation of the strength at 28 days in comparison to 4 hours. Duration of isothermal curing affects compressive strength of alkali-activated fly ash concrete more when precuring is longer, and the effect on early strength is more significant than 28-d strength. Isothermal curing for 16 hours is therefore not economic due to higher power demand and marginally higher strength at 28 days.

Fly ash content did not significantly affect the compressive strength of alkali-activated fly ash concretes containing sodium silicate (compare F40-4-8, F50-4-8 and F35-4-8, Figure 4). Fly ash content can thus be chosen depending on specific application (required workability). Mix F35 is however the cheapest because it contains the least amount of fly ash and the activator amongst the mixes. To bring the cost of alkali-activated fly ash concrete down even more, sodium silicate was replaced by a sodium hydroxide activator. Unfortunately, it is not possible to compare actual performances of alkali-activated fly ash concretes containing sodium silicate (F35-4-8, Figure 4) and sodium hydroxide (F35H-4-8, Figure 4) due to the air gap that developed when the concrete mix activated with sodium hydroxide was cured. Previous studies conducted by our research group (28) showed that NaOH-activated fly ash concrete of similar

composition cured in dry heat could gain compressive strength up to 45 MPa at 28 days. Therefore F35H mix could gain higher strength if properly cured.

#### 4. Conclusions

The resistivity and the temperature coefficient of resistivity were found for three different alkali-activated cement pastes. The resistivity of alkali-activated concrete depends on the resistivity of cement paste.

Whittington's equation can be successfully used for predicting the resistivity of alkali-activated concretes, which is one of the main input parameters for the design of DEC equipment (transformer), based on content of a specific alkali-activated cement paste with known resistivity.

The resistivity of alkali-activated concretes is lower than that of Portland cement concretes. The decreased resistivity can potentially reduce the total power demand for DEC of alkali-activated concretes.

Pre-curing for 4 hours and isothermal curing of 8 hours can be suggested for practical application. The isothermal curing can be organized during the off-peak hours between 10 p.m. and 6 a.m. and will require less power in comparison with isothermal curing for 16 hours. The compressive strength will not be significantly compromised by the reduced isothermal curing time.

Alkali-activated fly ash concretes containing sodium silicate showed a very good response to DEC which opens new perspectives for much wider application of the material.

# Investigation on Engineering Properties of Powder-activated Geopolymer Concrete

Kamal Neupane<sup>1</sup>, Daksh Baweja<sup>1</sup>, Rijun Shrestha<sup>1</sup>, Des Chalmers<sup>2</sup>, Paul Kidd<sup>2</sup>

<sup>1</sup>University of Technology Sydney, NSW; <sup>2</sup>Cement Australia Pty. Limited, Darra, Qld

Geopolymer is an inorganic binder, generally synthesized by the activation of aluminosilicate materials by strong alkali solution. Several previous researches on geopolymer concrete around the world suggested that geopolymer concrete possess superior mechanical and durability properties over ordinary Portland cement (OPC) concrete, such as higher compressive, indirect tensile and flexural strength and better resistant to sulphate and acidic environment.

Two types of powder-activated geopolymer binders were used as binding materials. A detailed study in engineering properties (workability, compressive strength, indirect tensile strength and modulus of elasticity) of different grades (40, 50, 65 and 80 MPa) of geopolymer and OPC concretes with two workability levels (normal-workable and super-workable) was carried out. Geopolymer as well as OPC concrete cylinders were cured at ambient temperature. The compressive and indirect tensile strength development of geopolymer concrete at early age was relatively lower than OPC concrete; however, there was a continuous and higher growth in concrete strength at later age. Normal-workable geopolymer concrete exhibited higher 28 days indirect tensile strength than OPC concrete of same grade. Measured modulus of elasticity of geopolymer normal-workable concrete was similar to OPC concrete of same grade and complied with Australian Standard 3600 [1] relationship; despite, lower value of modulus of elasticity geopolymer concrete was reported in several previous investigations. Modulus of elasticity of geopolymer super-workable concrete was lower than normal-workable concrete of same strength level and below than estimated value using Australian Standard 3600 [1] relationship.

**Key word: powder-activated, normal-workable, super-workable, indirect tensile strength, modulus of elasticity**

## 1. Introduction

Geopolymer binder is generally synthesized by the chemical reaction between aluminosilicate compounds, such as fly ash and blast furnace slag with alkali activator solution. In this process, aluminium and oxygen atoms create a tetrahedral chain of  $\text{SiO}_4$  and  $\text{AlO}_4$  to shared oxygen atoms, known as geopolymerization process [2]. The silicon and aluminium compound in source material are activated by alkaline solution to form the geopolymer paste that binds the aggregates and other less reacting materials. As production of geopolymer binder produces significantly less amount of greenhouse gases compared to Portland cement (OPC), it has been regarded as sustainable construction material [3-5]. During the last two decades, several studies have been done to evaluate the chemical, microstructural and engineering characteristics of geopolymer binders and concrete in pursuit of an environmental friendly alternative binding material [6-10]. Industrial by-product such as fly ash and blast furnace slag are the most common source material for geopolymers because of their suitability in geopolymer and availability around the world [11, 12].

As fly ash based geopolymer concrete takes longer time to set and harden in ambient condition and develops significantly lower early age strength, therefore, most of the past researches were carried out by curing in elevated temperature [10,13,14]. The engineering properties of ambient temperature cured geopolymer concrete are still limited. Addition of blast furnace slag can play a significant role to reduce the setting time and increase early as well as later age strength of fly ash based geopolymer concrete in ambient temperature [15,16]. It was suggested that presence of calcium compound accelerate the geopolymerization process and there is the coexistence of geopolymeric gel and calcium-silicate-hydrate (C-S-H) in slag-fly ash based geopolymer paste, where C-S-H gel is responsible for developing early age strength [17-19].

Investigations on geopolymer binder around the world showed that concrete from geopolymer binder possessed superior engineering properties, such as higher compressive, tensile and flexural strengths than OPC concrete [13,20,21]. However, in several investigations, modulus of elasticity of geopolymer concrete (normal-workable) was found lower than OPC concrete of same grade, and also lower than estimated modulus of elasticity according to Australian Standard 3600 [1] and ACI 318 [22] equations [13, 21, 23].

Super-workable concrete is very similar to self-compacting concrete (SCC) in fresh and hardened concrete properties which generally contains higher amount of sand and binder in concrete mix than normal-workable concrete [24]. Super-workable concrete or self-compacting concrete generally contains higher amount of sand, binder and water compare to the normal-workable concrete with addition of mineral additives and high range water reducer [25]. These ingredients can bring significant differences in mechanical properties of super workable concrete despite same binding material. Previous investigations showed that some mechanical properties, such as indirect tensile strength and modulus of elasticity of SCC are relatively lower than normal-workable concrete of same grade because of significantly difference in mix compositions of concrete [26, 27]. The mechanical behaviour of SCC has not been addressed separately in structural concrete standards, such as Australian Standard 3600 [1] and ACI 318 [22].

This paper is an investigation of engineering properties (workability, compressive strength, indirect tensile strength and modulus of elasticity) of geopolymer concretes from two powder-activated geopolymer binders (Geopolymer 1 and Geopolymer 2) at ambient temperature curing at various ages (up to 90 days). Concrete of four strength grades (40, 50, 65 and 80 MPa) and two workability levels; normal-workable and super-workable were investigated. The engineering properties of geopolymer concrete were compared against the result of OPC concrete of same grade and relationship of mechanical properties suggested in concrete standards of current practice, such as Australian Standard 3600 [1], ACI 363R [28] and ACI 318 [22].

## **2. Experimental Program**

### **2.1 Materials**

Powder-activated geopolymers; Geopolymer 1 and Geopolymer 2 recently developed by Cement Australia, QLD were used as binding materials. The activators (combination of sodium silicate, sodium hydroxide and other alkalis), low calcium fly ash and ground granulated blast furnace slag are blended together to make these binders. Geopolymer 1 have 70% fly ash and 30% ground granulated blast furnace slag in source material and Geopolymer 2 contained 40% of fly ash and 60% of slag.

Ordinary Portland cement (type GP) was selected to produce control concrete for comparison. This GP cement complied with Australian Standard 3972 [29].

Crushed coarse gravels from river source of maximum sizes of 10 mm or 20 mm were used as coarse aggregates. A combination of medium and fine river sand was used as a fine aggregate.

Two types of chemical admixtures were used to produce the OPC concrete; normal water reducer (type WR) and high range water reducer (type HWR) which complied with Australian Standard 1478.1 [30].

### **2.2 Concrete mixing and testing of fresh concrete properties**

Normal-workable concretes from both OPC and geopolymer binders were mix design according to BRE method [31]. Based on preliminary studies, amount of binder and water content were adjusted for geopolymer concrete compared to Portland cement concrete for a comparable strength and workability. The mix design of super-workable concrete was based on recommended guidelines of practice [24, 32].

Concrete of four strength grades; 40, 50, 65 and 80 MPa were produced from OPC and geopolymers binders with two workability levels; normal-workable and super-workable concretes. Both OPC and geopolymer concretes were mixed in the same way in a rotating pan mixer of 65 litres capacity. Geopolymer concretes of both workability levels were mixed without addition of any chemical admixtures. OPC normal-workable concrete of Grade 40 and 50 MPa were prepared with addition of normal water reducing admixture and Grade 65 and 80 MPa concretes were prepared with addition of high range water reducing admixture. All super-workable OPC concretes were produced with addition of high range water reducing admixture.

The workability of normal-workable concrete was assessed by the slump test and slump flow (spread) and  $T_{500}$  (time to reach 500 mm circle) for super-workable concrete.

### 2.3 Casting, curing and testing of concrete specimens

Sufficient numbers of 100 mm by 200 mm concrete cylinders were cast from all three types of binders to determine compressive strength, indirect tensile strength and modulus of elasticity of concrete. A minimum five numbers of specimens were tested for 28 days and three numbers of cylinders were tested at any other age.

After casting, both OPC and geopolymer concrete cylinders were left in standard laboratory temperature (23°C) for 24 hours. Geopolymer concrete cylinders were wrapped with plastic sheet immediately after the demoulding as shown in Figure 1 to prevent the moisture loss. Small amount of water was sprayed prior to sealing the cylinders. The geopolymer cylinders were stored in the lab condition (23°C) until testing. OPC concrete cylinders were moist cured in lime saturated water at 23°C until testing.

Figure 1: Curing of geopolymer concrete cylinder

The compressive strengths and indirect tensile strength of concretes of different grades and workability were tested according to Australian Standard 1012.9 [33] and Australian Standard 1012.10 [34] at the ages of 1, 3, 7, 28, 56 and 90 days. Modulus of elasticity of concretes was measured according to Australian Standard 1012.17 [35] at the age of 28 days.

## 3. Results and Analysis

Amount of water required on concrete mixes was based on comparable workability of concretes of different grades (average 120 mm slump for normal-workable concretes and 500–700 mm flow for super workable concretes). Concretes of different grades and workability levels were produced with the similar types (same source and grading) of aggregates. Therefore, the aggregate type is not considered as test variable.

### 3.1 Workability

The average water content in geopolymer concrete with Geopolymer 1 and Geopolymer 2 were 112 kg/m<sup>3</sup> and 121 kg/m<sup>3</sup> respectively. The average water content in OPC concrete for comparable workability was 166 kg/m<sup>3</sup>, although it was produced with addition of water reducing admixtures. In average, normal-workable concrete from geopolymer binders required around 30% less amount of water than from OPC for same workability.

The lower water demand in geopolymer concrete is due to high proportion (around 50%) of fly ash present in binder which is responsible to improve the workability of concrete because of its round shaped particles [36]. Fly ash itself is spherical and can be dispersed easily in the alkaline environment without addition of any admixtures [37]. The major difference between Geopolymer 1 and Geopolymer 2 binder is the proportion of fly ash which can be responsible for lower water demand in concrete from Geopolymer 1 than Geopolymer 2 for same level of workability.

In case of super-workable concretes, concrete from Geopolymer 2 binder required slightly less amount of water (around 7%) than OPC concrete for the comparable workability.

### 3.2 Compressive strength development

Figure 2 shows the compressive strength development of Grades 50 and 65 MPa concretes from different binders and workability levels. Similar trend of compressive strength development was observed in concretes of other grades. In both geopolymer and OPC concretes, compressive strength increased with time at a decreasing rate. For the same strength grade, geopolymer concrete exhibited relatively lower early age (1-3 days) compressive strength than OPC concrete. However, the later age (from 28-90 days) strength development was significantly higher in geopolymer concrete than in OPC concrete.

Figure 2: Compressive strength development 65 MPa grade concretes

The amount of binder required for the same 28-day compressive strength was significantly lower in geopolymer concrete compared to OPC concrete. In Grade 50 concrete, 295 kg/m<sup>3</sup> Geopolymer 2 binder and 395 kg/m<sup>3</sup> Portland cement developed 63.5 MPa and 62.0 MPa of 28-day compressive strength, respectively. Geopolymer 2 needs slightly less amount of binder than Geopolymer 1 for the same 28-day compressive strength which was due to the difference in slag content in those binders by 30%.

Compressive strength development of medium grade (40 and 50 MPa) geopolymer concrete at ambient curing condition was relatively lower at early age (1 to 3 days) compared to the OPC concrete. However, OPC concrete with Portland cement only (no supplementary cementitious materials added) are not common in field; generally Portland cement is replaced by 20 to 40% of fly ash or slag or combination of both. Partial replacement of Portland cement (20% to 40% by weight) by fly ash and slag or their combinations resulted significantly reduction in early age strength in previous studies. Johari, Brooks et al. [38] suggested around 60% reduction in 1 day compressive strength and 30% reduction in 3 day compressive strength due to replacement of Portland cement by 40% (by weight) of slag. Therefore, comparing with the early age strength results of OPC concrete having 20% to 40% of fly ash or slag, geopolymer concrete can attain same level of early age compressive strength to OPC concrete of same grade. High strength geopolymer concrete (65 and 80 MPa) exhibited significant early age strength equal to OPC concrete of this study. There was an average 18% growth in compressive strength in geopolymer concrete from 28 to 90 days period when compared to 7% increase in OPC concrete in for the same period.

### 3.3 Indirect tensile strength development

The Indirect tensile strength development of Grades 50 and 65 concretes is presented in Figures 3. The development of tensile strength was in similar pattern for all grades of concretes. Medium grade geopolymer concrete attained relatively lower indirect tensile strength than OPC concrete of same grade; however, the strength development at later age was significantly higher. The 28 days indirect tensile strengths of geopolymer normal-workable concretes were higher (15 to 20%) than OPC concretes for all strength grades. Both OPC and geopolymer super workable concretes exhibited lower indirect tensile strength (around 15%) than normal-workable concretes of same grades.

Figure 3: Indirect tensile strength development of Grades 50 and 65 MPa concretes

The early age development of indirect tensile strength of geopolymer concretes was significantly higher than compressive strength development at the same age. In Grade 50 MPa concretes, average indirect tensile strength development at 3 days was 53% of 28 days strength compared to average 35% of compressive strength at the same age. There was no significant development in indirect tensile strength of geopolymer concretes after 28 days compared to the post 28-day development in compressive strength. The average growth in indirect tensile strength from 28 to 90 days in geopolymer concretes was 12% when compared to 18% growth in compressive strength for that period.

#### 3.3.1 Formulation of relationship with compressive strength

The indirect tensile strength of normal-workable and super-workable concretes of same strength grade was different. So, these two types of concretes were analysed separately.

##### 3.3.1.1 Normal workable concrete

No equation has been suggested to define the relationship of mechanical properties of geopolymer concretes in any structural concrete standards so far. There are several concrete standards to define the relationship of mechanical properties of OPC concrete, some of them are as follows.

According to ACI 363R [28] indirect tensile strength concrete can be calculated as follows. (1)

$$f_{sp} = 0.59 \sqrt{f_c} \text{ MPa} \quad (\text{for } 21 \text{ MPa} < f_c < 83 \text{ MPa})$$

where,

$f_{sp}$  = characteristic indirect tensile strength of concrete

$f_c$  = characteristic compressive strength of concrete

Australian Standards 3600 [1] suggested following relationship between axial tensile and compressive strength of concrete applicable for 20 MPa to 100 MPa grade concretes.

$$f_{ct} = 0.36 \sqrt{f_c} \quad \text{MPa} \quad (2)$$

where,

$f_{ct}$  = characteristic axial tensile strength of concrete

Due to the differences in source material, alkali activators and their proportions, the results of indirect tensile strength were also diverse in previous investigations, hence, difference models were proposed. Some of them are as followings.

$$\text{Sofi, Van Deventer et al. [23]: } f_{sp} = 0.5 \sqrt{f_c} \quad \text{MPa} \quad (3)$$

$$\text{Tempest [39]: } f_{sp} = 0.616 \sqrt{f_c} \quad \text{MPa} \quad (4)$$

Concrete Institute of Australia [40], recommended a very similar equation to AS 3600 [1] for geopolymer concrete which is as follows.

$$f_{ct} = 0.4 \sqrt{f_{cm}} \quad \text{MPa} \quad (5)$$

In above equations, the recommend equation by Concrete Institute of Australia [40] estimates lowest value of tensile strength for geopolymer concrete.

The relationship between indirect tensile strength and compressive strength of different grades of concretes is plotted in **Figure 4** including results at different ages (3 to 90 days).

**Figure 4: Relation between indirect tensile strength and compressive strength**

The line of ACI 363R is closely located to the data points of geopolymer concretes in lower range of compressive strength; however, there is a bigger gap in high strength range. Australian Standard 3600 [1] estimates lower value of indirect tensile strength, hence, it is located far below than data points of geopolymer concretes of this study.

A best fit line's equation for Geopolymer 1 and Geopolymer 2 normal- workable concretes, valid for the data range of 20 MPa to 110 MPa can be proposed as following.

$$f_{sp} = 0.67 \sqrt{f_{cm}} \quad \text{MPa} \quad (6)$$

In **Figure 4** all the data points of Geopolymer 1 and Geopolymer 2 normal workable concretes were located within the  $\pm 10\%$  range from this proposed line, hence this proposed equation can be used safely for design purpose. The line of ACI 363R is close with lower error range ( $-10\%$ ) of proposed model.

The difference in source materials and alkali activators can bring a lot of variations in engineering properties of geopolymer concrete as a final product of geopolymerization [9]. As such, significant variations in compressive strength, indirect tensile strength results of geopolymer concrete were observed among previous studies around the world.

### 3.3.1.2 Super workable concrete

In the current study, the indirect tensile strength of super-workable concrete was found lower than normal workable concrete of same compressive strength by 15%. Some investigations were done in the past to compare the mechanical properties of OPC based self-compacting concrete. Jalal, Mansouri et al. [25] postulated lower splitting tensile strength of self-compacting concrete compared to normal workable concrete of same grade. On the contrary, Das and Chatterjee [41] found splitting tensile strength of self-compacting concrete slightly higher than normal workable concrete of same compressive strength and it was suggested due to improved microstructure and less porosity in super workable concrete. Kim [42] postulated a relationship model for splitting tensile strength of self-compacting concrete as following.

$$f_{sp} = 0.68 \sqrt{f_{cm}} \quad (7)$$

Cattaneo [43] also suggested that self-compacting concrete possessed similar or even higher indirect tensile strength than normal workable concrete and proposed an equation as following.

$$f_{sp} = 0.277 (f_{cm})^{2/3} \quad (8)$$

Indirect tensile strength results of super workable concretes of this study and previous results are plotted in **Figure 5**.

**Figure 5: Indirect tensile and compressive strength of super workable concretes**

In **Figure 5**, OPC super workable concrete exhibited slightly higher splitting tensile strength than geopolymer super workable for the same level of compressive strength. The line representing AS 3600 [1] was located below the data points of geopolymer super workable concrete.

As the data points and proposed model for self-compacting concrete were diverse in previous investigations, they may not be applicable to estimate the indirect tensile strength of geopolymer super-workable concrete. A relationship between indirect tensile strength and compressive strength of geopolymer super workable concretes can be proposed for the range of 20 MPa to 100 MPa.

$$f_{sp} = 0.58 \sqrt{f_{cm}} \text{ MPa} \quad (9)$$

In **Figure 5**, all the data points of geopolymer super workable concretes of this study are located inside the  $\pm 10\%$  error range of the proposed equation. The line representing the equation suggested by Cattaneo [43] is located close to the data points of geopolymer super workable concretes despite her claim that SCC possess similar or higher tensile strength than normal workable concrete. The model proposed by Kim [42] estimates higher indirect tensile strength than this study. The binder types, use of mineral additives, proportions of sand and amount of binder in concrete mix are the major factors for the diversity of tensile strength results in previous investigations.

Super workable concrete were produced with smaller (maximum 10 mm) size of coarse aggregates, higher amount of binder and higher proportion. Walker & Bloem [44] found that tensile strength of concrete increase with the maximum coarse aggregate size. This was due to the reduction in area of aggregate-paste interface in concrete which is the weakest zone in concrete. Rao and Prasad [45] also found an increase in tensile strength of concrete with increase in maximum size of aggregate from 40 to 75 MPa. In current study, the average proportions of coarse aggregate in normal and super workable concretes were 61% and 49% of total aggregates respectively. Besides, the amount of binder in super workable concrete was significantly higher than in normal workable concrete. Those two ingredients contribute to make higher volume of mortar (binder and sand matrix) in the concrete mix which has lower tensile strength than aggregate rock, hence the lower tensile strength of concrete. Nikbin, Beygi et al. [46] found a decrease in tensile strength of concrete while the coarse aggregate proportion was decrease from 60% to 40%.

Mechanical properties of any material, such as compressive strength and indirect tensile strength are the function the constituent material. Geopolymer and Portland cement are based on different chemistry, therefore the material property of concretes from those materials should be different. Chemically, geopolymer binders are formed by the polymeric structure resulting from cross linking of polysilicate chains having a strong covalent bond [47]. This may be a reason for geopolymer concrete possessing higher indirect tensile strength than OPC concrete of same compressive strength level.

### 3.4 Modulus of elasticity

The experimental results of modulus of elasticity of concretes of different grades are presented in **Figure 6**. Figure shows that geopolymer concrete possessed similar elastic modulus to the OPC concrete of same strength grades. However, super- workable concretes possess relatively less elastic modulus than normal-workable concrete.

**Figure 6: Experimental data of modulus of elasticity**

Previous investigations suggested that modulus of elasticity of concretes also depends on the types and properties of coarse aggregates used; higher the modulus of elasticity of aggregate resulted higher modulus of elasticity of concrete [48, 49]. The majority of aggregate rock used in this experiment was greywacke having average modulus of elasticity 38.7 GPa [50] when compared to 49.0 GPa of limestone and 42.0 GPa of quartzite aggregates [51]. Therefore, the modulus of elasticity results could be different if other aggregates types were used.

#### 3.4.1 Relationship between modulus of elasticity and compressive strength

In some concrete standards of current practice modulus of elasticity of concrete is estimated from its density and compressive strength.

Modulus of Elasticity ( $E_c$ ) recommended by ACI 318 [22] is as following. (10)  
 $E_c = 0.043\rho^{1.5} \sqrt{f'_c}$  MPa

Modulus of elasticity recommended by Australian Standard 3600 [1] is as following (11)  
 $E_c = \rho^{1.5} (0.024 \sqrt{f_{cm}} + 0.12)$  MPa; when  $f_{mc} > 40$  MPa  
 Where,  $\rho$  = cylinder density ( $\text{kg/m}^3$ ) and  $f_{cm}$  = mean compressive strength (MPa) and  
 $f'_c$  = characteristic strength of concrete (MPa)

There are some publish investigations about the modulus of elasticity of geopolymer concrete synthesized from different types of source materials and activators. Most of the previous investigations were carried out in elevated temperature curing because of lower early age strength of fly ash based geopolymer concrete.

Tempest [39] postulated a model to estimate the modulus of elasticity from compressive strength as follows.

$$E_c = 3421 \sqrt{f'_c} \text{ MPa} \quad (12)$$

Modulus of elasticity of fly ash based geopolymer concrete reported by Diaz-Loya, Allouche, et al.[10] were similar with the results of this study but for the lower range of compressive strength.

Hardjito and Rangan [21] found that accelerated cured fly ash based geopolymer concrete possessed relatively lower modulus of elasticity then recommended by AS 3600 [1].

**Figure 7: Relationship of compressive strength and modulus of elasticity**

All above relationships and results are plotted in **Figure 7**. In this figure, the line representing Australian Standard 3600 [1] equation is close to data points of geopolymer as well as OPC concrete. This value has a range of  $\pm 20\%$ . However, in this plotting all normal-workable concrete data points are located well inside the  $\pm 10\%$  range of that line. Modulus of elasticity value is said to be overestimated by ACI 318 [22] because none of any data point are located above this line.

### 3.4.2 Compliance with AS 3600 and ACI 318

Measured modulus of elasticity of geopolymer concretes was compared with estimated values using Australian Standard 3600 [1] and ACI 318 [22] in this study. The calculated modulus of elasticity using Australian Standard 3600 [1] were very close to the measured results of geopolymer concretes for the same compressive strength. The ratios of measured to estimated value were in between 0.93 to 1.02 with an average of 0.98 for geopolymer concretes of different grades. Hence, modulus of elasticity for geopolymer binder concretes can be closely estimated using Australian Standard 3600 [1] equation. Equation suggested by ACI 318 [22] over estimates the modulus of elasticity of geopolymer concretes with an average 0.86 measured to estimated ratio.

### 3.4.3 Modulus of elasticity of super-workable concrete

In **Figure 6**, the modulus of elasticity of super workable concrete was relatively lower than normal-workable concrete for the same level of compressive strength. Similar to indirect tensile strength, modulus of elasticity of a lower self-compacting concrete was reported in some previous investigations. Holman, Myers et al. [26] found that SCC possessed relatively lower modulus of elasticity than normal-workable concrete despite higher compressive strength. Leemann and Hoffmann [52] study showed that self-compacting concrete possessed around 16% lower modulus of elasticity than normal-workable concrete of same compressive strength. Another study by Dinakar, Babu et al.[53] postulated a relationship to estimated modulus of SCC elasticity as following.

$$E_c = 4180 \sqrt{f_{cm}} \quad (\text{MPa}) \quad (13)$$

Similarly, Persson [54] postulated following relationship of modulus of elasticity of SCC.

$$E_c = 3750 \sqrt{f_{cm}} \quad (\text{MPa}) \quad (14)$$

The moduli of elasticity of super-workable concretes are presented in **Figure 8**. In this figure, modulus of elasticity of super-workable concrete are located far from the line of AS 3600 [1]. Therefore, a model can be formulated representing the best fit line of the data points of Geopolymer 2 super-workable concrete.

$$\text{Modulus of elasticity } (E_c) = \rho^{1.5} 0.034 \sqrt{f_{cm}} \quad \text{MPa} \quad (15)$$

Where,  $\rho$  = cylinder density ( $\text{kg/m}^3$ ) and  $f_{cm}$  = mean compressive strength (MPa).

In **Figure 8**, all the data points of super workable concrete located within the  $\pm 10\%$  range from the proposed model, so this equation is safe for design practice. The relationship model proposed by Persson [54] is very close with the proposed model of this study, whereas equation proposed by Dinakar, Babu et al.[53] was slightly overestimate the modulus of elastic of super workable concrete but located within 10% range.

**Figure 8: Modulus of elasticity of super-workable concretes**

#### 3.4.3.1 Factor affecting the modulus of elasticity of super-workable concrete

Concrete as a composite material is affected from the properties of its ingredients; aggregates and binder. Kaplan [55] postulated following equation of effect of the modulus of elasticity aggregate and binder into modulus of elasticity of concrete.

$$E_c = V_a * E_a + (1 - V_a) * E_m \quad (16)$$

Where,  $E_c$ ,  $E_a$  and  $E_m$  are the moduli of elasticity of concrete, aggregate and binding paste respectively;  $V_a$  = volume concentration of aggregate.

The modulus of elasticity of concrete is the summation of modulus of elasticity of its ingredients; aggregates and binding paste with respect to their volume in concrete mix.

The average modulus of elasticity of greywacke aggregate rocks (used in this experiment) was 38.7 GPa [50], whereas modulus of elasticity of cement paste was measured around 24.0 GPa [56]. The binder content in super-workable concretes was around 35% higher (by weight) than in normal-workable concretes of same grade, thus higher volume of paste. This significant lower volume of coarse aggregates and higher volume of binder paste in super-workable concretes can contribute to lower the modulus of elasticity of super-workable concrete. Felekoğlu et al. [57] concluded that higher amount of binder was responsible to lower the modulus of elasticity of SCC.

The proportion of coarse and fine aggregates in the concrete mix is also a significant factor in modulus of elasticity of concrete. Nikbin, Beygi et al. [46] found a significant increase in modulus of elasticity with the increase in proportion of coarse aggregate in concrete mix. The average proportions of coarse aggregate in normal-workable and super-workable concretes of this study were 61% and 49% by weight of total aggregates respectively. The 12% difference in coarse aggregate may be responsible for the decrease in modulus of elasticity of super-workable concretes.

Lower density of super-workable concrete is also a major factor for the less modulus of elasticity according to Pauw [58]. In this study, average cylinder density of geopolymer super-workable concrete was around 2340 kg/m<sup>3</sup>, compared to the average density of 2430 kg/m<sup>3</sup> of geopolymer normal-workable concrete.

#### **4. Concluding remarks**

Normal-workable geopolymer Concrete required significantly less amount of water and binder for comparable 28 day compressive strength and workability level when compared to Portland cement concrete. Geopolymer concrete was produced without addition of any chemical admixture with sufficient workability.

Development of compressive strength in ambient cured medium grade geopolymer concrete was lower at early age (1 -3 days) when compared to OPC concrete. However, comparing with the early age strength results of OPC concrete having 20% to 40% of fly ash or slag, geopolymer concrete can attain same level of early age strength. Compressive strength development in high strength (65 and 80 MPa) geopolymer concrete was significantly higher at early age. The growth in compressive strength after 28 days was significantly higher in geopolymer concrete compared to OPC concrete of same grade which was ranged from 16 to 20% for 28 to 90 days period.

Normal-workable geopolymer concrete exhibited 15 to 20% higher indirect tensile strength than OPC concrete of same grade. Indirect tensile strength of normal-workable geopolymer concretes were higher than estimated value using Australian Standard 3600 [1] relationships. Therefore, a different relationship was proposed to estimate indirect tensile strength of geopolymer concrete. Indirect tensile strength of super-workable geopolymer concrete was relatively lower than normal workable concrete (around 15%) for the same strength grade. This was due to the small size of coarse aggregate, higher amount of binder and higher proportions of fine aggregates in the super workable concrete, therefore a separate equation has been proposed.

Normal-workable concretes from Geopolymer 1 and Geopolymer 2 binders exhibited similar values of modulus of elasticity to the OPC normal-workable concrete of same compressive strength. The measured moduli of elasticity of normal-workable concretes of this study can be close (within 10% error) estimated using Australian Standard 3600 [1] equations, hence, a different equation was not proposed.

Similar to tensile strength, geopolymer super workable concrete possessed relatively lower elastic modulus than normal-workable concrete of same grade. Previous investigations on OPC based self-compacting concretes also suggested lower elastic modulus. Higher proportion of sand, lower cylinder density and higher volume of binder paste in super-workable concrete are the major factors to decrease modulus of elasticity of super-workable concrete. Therefore, a different model has been proposed to estimate the modulus of elasticity of geopolymer super-workable concrete.

# Alkali-Activated Foamed Concrete

Elsabe Kearsley<sup>1</sup> and Maxim Kovtun<sup>2</sup>

<sup>1</sup>Professor of Civil Engineering, University of Pretoria, South Africa

<sup>2</sup>Researcher, University of Pretoria

**Abstract:** Foamed concrete has been used as isolating building material in many countries around the World. At the low densities required for high thermal resistance concrete strength is very low. Using alkali-activated cement as binder in foamed concrete instead of ordinary Portland cement does not only provide higher strength at low density but also results in reduction of associated CO<sub>2</sub> emissions. In this paper properties such as density, strength and abrasion resistance of Alkali-Activated Foamed Concrete (AAFC) is compared to that of traditional foamed concrete. The effect of manufacturing and curing techniques is compared. It is possible to manufacture alkali-activated foamed concrete using the same procedures and equipment than that developed to manufacture foamed concrete containing Portland cement. The density, strength and abrasion resistance of the AAFC is comparable to that of the normal foamed concrete and wet or dry heat curing does not seem to have a significant effect on the properties developed. At low density the heat curing does seem to result in crack formation indicating the heat developed during the chemical reaction stays in the concrete and cannot escape due to the high volume of voids acting as buffer.

**Keywords:** alkali-activated, fly ash, GGBFS, foamed concrete, heat curing.

## 1. Introduction

Foamed concrete has been manufactured for many years by replacing the aggregate in normal concrete with air voids. As larger volumes of aggregate are replaced with air voids both the density of the concrete and the strength of the concrete decreases. The compressive strength of foamed concrete is a function of density and foamed concrete is normally defined in terms of both density and strength requirements. The density of foamed concrete can vary between about 1800 kg/m<sup>3</sup> for foamed concrete that can be used for structural applications and 300 kg/m<sup>3</sup> for foamed concrete that is used for thermal insulation [1].

The air voids in foamed concrete can be generated through shear mixing, pre-foaming or pressure foaming. With both the shear mixing and pressure foaming the foaming agent can be added to the mixture in concentrated form, while pre-foaming requires that the foaming agent is diluted with water and foamed by forcing the diluted foaming agent and compressed air through baffles. Typically the pre-foamed foam has densities between 40 kg/m<sup>3</sup> and 100 kg/m<sup>3</sup> and the foam can then be blended into a cementitious paste to create foamed concrete. Both synthetic and protein based foaming agents are commercially available and the use of protein based foaming agents seem to produce smaller voids resulting in higher strength at any given density. High quality foam is stable for up to an hour and the viscosity of the paste should be such that the air voids created by the foam cannot escape once the foam starts breaking down.

The concrete mix composition of foamed concrete cannot be determined using the same procedures than that normally used for normal Portland cement concrete. The strength of normal Portland cement concrete is a function of the water/cement ratio and the water content is adjusted to ensure sufficient workability to make it possible to effectively place and compact the concrete. Foamed concrete on the other hand can only be manufactured with very limited variations in water contents. If too little water is added the foam breaks down too rapidly as the water in the foam is used in the hydration process. If too much water is used segregation takes place and the cement settles to the bottom and the foam start floating to the top thus resulting in significant variations in foamed concrete density.

The strength of foamed concrete is known to be a function of the porosity and the porosity is directly related to the volume of air entrained with the foaming agent [2]. It should be possible to manufacture foamed concrete with a given density containing a lower volume of air if the relative densities of the solids used in the foamed concrete can be reduced [3]. A reduction in porosity or air content should result in an increase in foamed concrete strength. As the relative density of both Ground Granulated Blast Furnace Slag (GGBFS) and Fly ash is significantly lower than that of pure Portland cement, Alkali-activated Foamed Concrete could yield higher strengths than traditional Foamed Concrete for constant densities.

Foamed concrete has been used as isolating building material in many countries around the World. At the low densities required for high thermal resistance concrete strength is very low. Using alkali-activated cement as binder in foamed concrete instead of ordinary Portland cement could not only provide higher strength at low density but also results in reduction of associated CO<sub>2</sub> emissions.

Alkali-activated Concrete has successfully been manufactured using both neutral and basic slag as well as low calcium fly ash [4, 5, 6]. The aim of current research is to determine whether it would be possible to manufacture alkali-activated foamed concrete by using existing foamed concrete technology and just replace the binder with alkali-activated fly ash and/or slag.

## 2. Background

### 2.1 Portland Cement based Foamed Concrete

Portland Cement based Foamed Concrete (PCFC) is normally classified in terms of density grade where the density is defined as the oven dry density of the foamed concrete [7]. The mix composition is determined based on the assumption that during cement hydration the cement will chemically bind some of the water resulting in the addition of 20% to the mass of the unhydrated cement. The design dry density can be established using equation 1:

$$D = 1.2 Cem + F \quad (1)$$

Where  $D$  is the design dry density of hardened foamed concrete (kg/m<sup>3</sup>),  $Cem$  is the cement content (kg/m<sup>3</sup>) and  $F$  is the sum of the weights of filler (kg/m<sup>3</sup>).

Besides the dry density formula, the sum of the volume of all the constituent materials should be one thousand litres for a cubic metre of materials as shown in equation 2 for mixtures containing cement, sand, fly ash and foam [3]:

$$1000 = \frac{x}{RD_c} + x (W/c) + \frac{x (a/c)}{RD_a} + \frac{x (s/c)}{RD_s} + V_f \quad (2)$$

Where  $x$  is the cement content (kg/m<sup>3</sup>),  $w/c$  is the water/cement mass ratio,  $a/c$  is the fly ash/cement mass ratio,  $s/c$  is the sand/cement mass ratio,  $V_f$  is the volume of foam,  $RD_c$  is the relative density of the cement,  $RD_a$  is the relative density of the fly ash and  $RD_s$  is the relative density of the sand.

The long-term strength of PCFC can be optimized by replacing significant percentages of the cement with fly ash. By reducing the relative density of the solids the volume of air than needs to be entrained into the matrix to obtain a given design density can be reduced, thus reducing the porosity of the foamed concrete and consequently increasing the strength of the PCFC [2].

The high heat-insulating capacity of low-density foamed concrete results in the conservation of the heat generated during the hydration of cement [7]. For constant cement content, there is an inverse relationship between the peak temperature recorded in foamed concrete samples and the foamed concrete density. The cement content of PCFC should be minimized to prevent temperatures developing in the matrix that could result in the collapse of the foam or the formation of cracks.

### 2.1 Alkali-Activated Cement

It has been established that South African fly ash can be efficiently activated using 9% Na<sub>2</sub>O and curing the samples in dry heat at 60°C for at least 12 hours [4]. Although basic ground granulated blast furnace slag (GGBFS) does not require heat curing to develop strength when more than 4% Na<sub>2</sub>O is used as activator, strength development of neutral slag can be accelerated through heat curing [8].

The strength of alkali-activated concrete is highly dependent on the water/binder ratio and this ratio should be minimized to optimize strength. The workability of mixtures can be significantly improved by adding Sodium Silicate as activator.

The combination of low water demand and resilience to thermal treatment indicates that it should be possible to manufacture A AFC.

### 3. Experimental setup

#### 3.1 Materials

The chemical composition and relative density of the fly ash, Portland cement, basic and neutral slag used in this investigation can be seen in Table 1. The Portland cement was only used to manufacture reference mixes for comparative purposes. Silica sand with a relative density of 2.65 was used as inert filler. Both sodium hydroxide and sodium silicate were used as activators. Sodium hydroxide flakes were dissolved in the mixing water and allowed to cool down before adding to the mixture. Liquid sodium silicate (water glass) consisted of 14.95% Na<sub>2</sub>O, 29.80% SiO<sub>2</sub>, and 55.25% H<sub>2</sub>O. A protein based foaming agent was used and for pre-foaming the foaming agent was diluted in water to a 2% concentration and then aerated to form foam with a density of 75 kg/m<sup>3</sup>.

**Table 1. Chemical composition of binder**

Material	Chemical composition, %										Physical characteristics
	SiO <sub>2</sub>	TiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	MgO	CaO	Na <sub>2</sub> O	K <sub>2</sub> O	SO <sub>3</sub>	LOI	Relative density
Neutral Slag	34.87	0.72	14.38	0.89	8.03	37.05	<0.01	0.72	1.96	0.16	2.90
Basic Slag	31.72	0.51	15.10	1.43	11.20	40.24	0.01	0.48	2.25	-	3.00
Cem I 52.5N	22.30	0.50	4.98	3.35	1.92	61.50	0.21	0.26	2.92	1.77	3.14
Fly ash	55.22	1.57	31.93	3.36	0.73	4.57	0.01	0.87	0.23	0.80	2.20

#### 3.2 Mixing and mix composition

Foamed concrete can be manufactured using three different mixing techniques (compressed air that is forced into the mixture under pressure, high speed shear mixing or pre-foaming) [9] and AAFC was cast using all three techniques. The lowest density foamed concrete can normally be manufactured by mixing the ingredients in a pressurized vessel thus forcing the entrained air into the mixture. For this method the foaming agent does not have to be diluted in water which means that the water content of mixes with extremely high foam volumes (in excess of 80% of total volume) can be limited. Although this method should be best suited for manufacturing AAFC for use as thermal isolation material, it has not yet been possible to manufacture stable mixtures using pressurization. Shear mixing can give the highest strength for foamed concrete mixes at relatively high densities (in excess of about 1100 kg/m<sup>3</sup>), while pre-foaming normally results in the most predictable and repeatable properties with the most uniform dispersion of air voids. This paper contains results of AAFC manufactured through either shear mixing or pre-foaming.

Fly ash was activated with approximately 9% Na<sub>2</sub>O, and slag with about 8% Na<sub>2</sub>O while different volumes of sand were replaced with foam to reduce the density of mixtures. The effect of combining fly ash and slag was investigated. Where combinations of ash and slag were used it was assumed that varying fractions of the ash would act as inert filler (varying between 100% binder to 100% filler).

The mix compositions for the AAFC results reported in this paper are listed in Table 2. For each mixture the "casting density" of the mixture was determined during the casting process. When the samples were demoulded 24 hours after casting a "demoulding density" was established as the average density of all the cubes cast from one mixture. From Table 2 it can clearly be seen that many of the densities increased significantly between casting and demoulding, indicating that the air entrained into the mixture escaped during the casting process.

#### 3.3 Curing and testing

Samples were cast in 100 mm steel cube moulds and all samples were left for 4 hours pre-curing, where after samples were placed in either a drying oven or a steam bath for 16 hours. Once the samples were placed in the oven or steam bath the elements were switched on and the temperature increased at a rate of approximately 20 °C per hour. After 16 hours all samples were removed from the heat curing environments and placed in a constant temperature room at 25 °C and 55% relative humidity. Sets of three cubes were tested 24 hours, 7 days and 28 days after casting.

**Table 2. Mix compositions**

Materials (kg/m <sup>3</sup> )	PCFC	AAFC 1	AAFC 2	AAFC 3	AAFC 4	AAFC 5	AAFC 6	AAFC 7	AAFC 8	AAFC 9
Cem I 52.5N	200									
Ash	400		330	321		285	233	252	285	381
Basic Slag								252	285	
Neutral Slag		261	330	321	250	285	233			
Sodium Hydroxide		15.3	19.4	18.9	14.7	16.8	13.7	14.8	16.7	44.3
Sodium Silicate		25.5	32.3	31.4	24.5	28.0	22.8	24.7	27.9	
Water	164	179	194	191	59	168	139	148	173	98
Silica Sand	200	573	396	385	20	342	279	303	342	22
Mixing method	Pre-foam	Pre-foam	Pre-foam	Shear	Pre-foam	Pre-foam	Shear	Pre-foam	Shear	Pre-foam
Casting density (kg/m <sup>3</sup> )	980	1100	1359	1295	400	1167	925	1025	1135	610
Demoulding density (kg/m <sup>3</sup> )	921	1437	1442	1372	831	1173	1095	1234	1382	542*

\*Density obtained by submerging wax sealed sample in water.

One of the main problems experienced with PCFC at low densities is the lack of abrasion resistance. The alumina-silicate reaction products that is formed in alkali-activated binder should result in an higher abrasion resistance than that of the calcium hydroxide products formed during Portland cement hydration. Abrasion resistance tests were therefore conducted on cube samples after 28 days. The abrasion testing was not conducted to any standard test method and the results only give an indication of the abrasion resistance of samples in comparison to other samples tested. A steel wire brush was attached to a small drill with a pre-set rotation speed as indicated in Figure 1. The time that it took for the brush to penetrate the foamed concrete to a depth of 5 mm was recorded. The result was taken as the average time obtained from conducting the test in four different positions on the face of a cube.

**Figure 1. Testing abrasion resistance of foamed concrete samples.**

## **4. Results**

### **4.1 Casting densities**

Visual observation indicate that sodium silicate affects the viscosity of mixtures to such an extent that the air entrained through the foaming agent can no longer remain entrapped by the paste and all the mixtures containing sodium silicates segregated with the solids migrating to the bottom of the cast samples while

the foam floated to the top. The mix compositions that segregated to the point that the cubes could not be demoulded are not provided in Table 2. The results in Table 2 do however indicate that the density of the majority of the mixtures containing sodium silicate increased significantly between the mixer and the mould. High quality foamed concrete should not experience this change in density.

Low density AAFC containing only fly ash activated with NaOH as binder was manufactured using pre-foaming (see AAFC 9 in Table 2). The casting density was  $610 \text{ kg/m}^3$  and after curing the top surface of the cubes showed no subsidence as indicated by the surface of the left-hand bottom cube in Figure 2. It was however impossible to demould these cubes as significant cracking took place below the surface. The cores of these cubes were also soft and powdery (as indicated in the two photos on the right of Figure 2) where the surfaces were hard with no obvious dust emission during handling.

**Figure 2. Damaged low density AAFC.**

The cores of the samples seem to be damaged and it seems possible that the heat generated during heat curing is trapped in the cores of samples with high air contents, resulting in cracking caused by excessive heat. Although these results indicate that it would be possible to manufacture AAFC using only fly ash and NaOH as binder, further research is required to investigate suitable curing regimes.

#### **4.2 Compressive strength**

The effect of density on the compressive strength of the AAFC samples can be seen in Figure 3 and it is clear that the strength increases exponentially as the density increases. There is only a slight increase in strength between 24 hours and 28 days, indicating that the duration of curing is sufficient for factory manufactured samples to be dispatched directly after curing. The variation in strength does seem to be less for the 28 day strengths than for the 24 hour strengths indicating that older samples may have more predictable strengths. It is interesting to note that the humidity of the curing environment does not seem to have a significant effect on the strength development of AAFC. This differs from observations made for alkali-activated fly ash concrete where curing at low humidity resulted in significantly higher compressive strengths.

The effect of manufacturing technique on strength development can be seen in Figure 4. Although the shear mixes seem to have marginally lower early age strengths, the 28-day test results indicate that there is no real difference in the density-strength relationships obtained for shear mixing and pre-foaming. It was also interesting to note that the strengths obtained from the basic slag was marginally lower than from the neutral slag for both early age and 28 day strength tests. For a testing density of approximately  $1350 \text{ kg/m}^3$  the neutral slag yielded 8.2 MPa after 24 hours and 11.5 MPa after 28 days while the use of basic slag only resulted in 6.4 MPa and 7.3 MPa at similar ages. As basic slag is significantly more expensive

than neutral slag it cannot be justified to use basic slag in AAFC. The binder/solid ratio, binder content, binder combination or activator combination do not seem to have a significant effect on the strength.

**Figure 3. Effect of density on compressive strength.**

**Figure 4. Effect of manufacturing technique on compressive strength.**

From the results obtained to date it has not been possible to determine an optimum mix composition. Further research is required to establish the most suitable mix compositions for different applications.

### 4.3 Abrasion resistance

The results of the abrasion resistance test can be seen in Figure 5. These results clearly indicate that the abrasion resistance rapidly decreases as the dry density of the foam concrete decreases. The abrasion resistance of the AAFC is only marginally higher than that of the PCFC tested and at this stage it cannot be claimed that the use of alkali-activated cement in foamed concrete would yield higher abrasion resistance.

**Figure 5. Testing abrasion resistance of foamed concrete samples.**

## 5. Conclusions

It is possible to manufacture Alkali-Activated Foamed Concrete. The density, strength and abrasion resistance of the AAFC is comparable to that of the normal foamed concrete and wet or dry heat curing does not seem to have a significant effect on the properties developed. AAFC can be manufactured with fly ash, neutral slag or basic slag or combinations of fly ash and slag. There does not seem to be any benefit in using basic slag in foamed concrete.

When sodium silicate is used as accelerator care should be taken to ensure that the viscosity of the mixture is not affected to the extent that the air voids can escape from the AAFC matrix, resulting in non-homogenous and unpredictable densities.

At low density the heat curing does seem to result in crack formation indicating the heat developed during the chemical reaction stays in the concrete and cannot escape due to the high volume of voids acting as buffer. Further research is required to determine an optimum curing regime that would yield sufficient strength without resulting in overheating and structural damage to samples containing high air contents.

# Alternative concrete materials from industrial waste

Valle Chozas<sup>1</sup>, Ignacio del Val<sup>1</sup>, José Vera<sup>1</sup>, Íñigo Larraza<sup>1</sup>  
<sup>1</sup>Concrete Group, Technology Innovation Division, ACCIONA Infrastructure

**Abstract:** The large consumption of natural resources, the global warming caused by the anthropogenic emissions of greenhouse gases and the massive generation of industrial waste have generated the need to develop technologies that can offer integrated solutions and at the same time generate industrial benefits. Geopolymers have revealed as a very solid alternative to traditional constructive materials. This paper describes the synthesis and characterization of two sets of geopolymer materials that represent an alternative to traditional foamed and lightweight concrete, respectively, including recycled materials in their composition. In both cases the mechanical and insulation performance of these materials have been measured both at laboratory scale and in the case of the foamed material, also at pilot scale, demonstrating their viability as alternatives to their traditional homologous.

**Keywords:** geopolymer, industrial waste, alkaline activation.

## 1. Introduction

In the production of traditional clinker, carbonates undergo a heating process, generating 900 Kg of CO<sub>2</sub> for every ton of cement produced. The cement industry generates about 10% of anthropogenic CO<sub>2</sub>, favoring the climatic change. [1] Also, the extraction of aggregates for concrete production generates environmental concerns, such as dust release, noise, ground vibration and landscape alteration.

Parallel, every year millions of different industrial residues that can replace cement or aggregates in concrete are generated. For instance fly ash, blast furnace slags and the combination of both are able to harden in the presence of alkali solutions, yielding solid matrixes with similar properties to those of cementitious materials. Also, end life tyre rubber aggregates can be used as lightweight aggregates with good insulating properties. In both cases, millions of tons of these residues are generated and landfilled, which is an environmental concern.

In this paper the preparation, characterization and viability of two types of alternative concrete materials as environmentally friendly constructive elements is reported:

- A foamed concrete type material made of alkali activated fly ash as an alternative to traditional autoclaved aerated concrete (AAC). In the synthesis of this material, a foaming agent is added into the mixture, producing a cellular structure that confers excellent insulating properties. A prototype was built with this material and its properties were compared to an identical one built with traditional AAC, showing a very similar performance in terms of mechanical properties and thermal and acoustic insulation. This material has been produced within the GREEN CAST project.
- A lightweight concrete type material where the matrix is composed by alkali activated industrial waste cured at room temperature. In this case behaved very similar or even higher mechanical properties than traditional lightweight concrete. When traditional aggregates were substituted by tyre rubber aggregates, an alternative concrete with low thermal conductivity was obtained. This material has been produced in the framework of the SUS-CON project.

## 2. Materials and methods

### 2.1 Foamed concrete

The fly ash used in this project has been supplied by Cencatra, a waste management company located in Spain. Sodium hydroxide (50%) and hydrogen peroxide (33%) were supplied by Panreac. A commercial bubble stabilizer was used as received. All materials were used as received without any further purification.

The fly ash composition was analyzed by X-ray fluorescence (XRF). This technique allows detecting chemical species and their content in a given sample. The particle size and distribution were analyzed by granulometry. A Malvern Mastersizer 2000 equipment was used. Measurements have been made after ultrasonic dispersion of samples by using water as dispersant.

The materials were homogeneously mixed with a mechanical stirrer in plastic recipients in the following way: first the sodium hydroxide solution was diluted and allowed to cool down at room temperature. Then, the bubble stabilizer (BS) was added to the solution and stirred. The fly ash was weighted and placed in

the corresponding recipient, then homogenized mechanically. In each case the aqueous solution was added and mixed until complete homogenization. Finally the hydrogen peroxide solution was added to the mixture and mixed. The liquid mixtures were then immediately poured into the corresponding mold and covered with plastic film in order to prevent evaporation. The foaming process was allowed to take place prior to the curing stage.

The blocks were fabricated in PTFE coated wood molds (25x63x7 cm) with capacity for 5 independent blocks. All the samples were cured in laboratory furnaces at 80°C for 16 hours.

The density ( $\rho$ ) of the GREEN CAST samples was analyzed according to the UNE-EN 772-13 standard. Six specimens were extracted from different parts of three blocks.

The compressive strength (MC) was determined by following the standard UNE-EN 772-1. A constant load was applied at a constant rate of  $0.1 \pm 0.05$  MPa/s. The specimens were kept at a constant humidity of  $6 \pm 2\%$  prior to the tests. The dry density value is obtained from drying the specimens to constant mass.

The thermal resistance and conductivity was measured in a NETZSCH HFM 463 Lambda Heat Flow Meter, according to the UNE-EN 12664:2001 standard. The heat flow meter was used according to the norm ISO 8301:1991. In order to do that, 3 specimens were introduced horizontally in a heat flow meter, being the hot plate in the upper side. Said specimens were conditioned in a ventilation oven at 105°C until constant mass is achieved, then coated with a waterproof cover which prevents them from moisture. The state temperature and the average temperature difference through the specimen were set at 10 and 15°C, respectively.

The free-thaw resistance was investigated by following the UNE-EN 15304:2010 standard. Six cubic specimens (7x7x7 cm) were extracted from different parts of two blocks, saturated and kept for 48 hours in a polyethylene bag for stabilization and preserve moisture. The samples were placed in a chamber and exposed to 15 cycles of freeze ( $-15 \pm 2^\circ\text{C}$ ) for 8 hours and thaw ( $20 \pm 5^\circ\text{C}$ ) and humidity 95% for 8 hours. Both the mass and compressive strength loss of the specimens after this test were determined and compared to that of references taken from adjacent parts of the blocks.

In order to demonstrate the viability of the developed technology as constructive element, two testing cells were built, one with the produced GREEN CAST blocks and an identical one built with commercial cement based AAC blocks. Both testing cells were built in ACCIONA's facilities in Alcobendas, Spain. The demo-scale buildings consisted of metallic structures anchored to onsite casted concrete ground slabs and the two types of blocks were used to build the walls of each of the testing cells. For the construction of the reference cells, Ytong blocks were used. The dimensions of the blocks were 25x63x7 cm and the density specified by the supplier 550 Kg/m<sup>3</sup>.

Both demo buildings possessed one window oriented to the east and one door oriented to the north. In both cases generic aluminum/polyurethane sandwich panels were used as ceilings. The blocks were glued together with insulating/waterproof mortar. Both testing cells were coated externally with such mortar, and finally, power supply was installed within them. The acoustic insulation of the developed material was studied by in situ measurements of the following parameters:

- Airborne sound insulation of façades, according to the standard ISO 140-5:1998. For this experiment, an omnipower sound source generating a sound field with a continuous spectrum was placed outside the prototype at 7 m from the analyzed façade. Then, the average sound pressure level is measured in a point at 2 m from the façade and 3 different points inside the prototype. The airborne sound insulation index was calculated as the difference between pressure levels, inside and outside, standardized by reverberation time. The airborne sound insulation index was calculated as the difference between pressure levels, inside and outside, standardized by reverberation time.

- Measurement of the sound reduction index. In this case, an omnipower sound source generating a sound field with a continuous spectrum was installed inside the prototype. The average sound pressure level was measured in a point at 1 m from the façade and 3 different points inside the prototype. Background noise reduction inside the prototype was recorded too. The sound measurements were carried out with the following equipment purchased to B&K: omnipower sound source 4292, audio power amplifier 2716, microphone 4189, hand held analyzer 2250 and sound level calibrator, **Figure 1**.

**Figure 1. Measurement of airborne sound insulation of façades.**

In order to study thermal behavior of the real scale demo-buildings, a data acquisition system was installed in both the reference and GREEN CAST testing cells. An Agilent 34972A Data Acquisition Unit with a built-in 20-bit resolution digital multimeter was selected as autonomous data logging system, combined with a pair of Type T thermocouples (Copper-Constantan) for internal temperature measurement (sensitivity  $40 \mu\text{V}/^\circ\text{C}$ , nominal accuracy  $\pm 0.5^\circ\text{C}$ ). A Davis Instruments Vantage Pro2 weather station was used for external temperature monitoring. Thermal sensors were previously calibrated using a FLUKE 724 Multi Function Calibrator, finding differences not higher than  $\pm 0.1^\circ\text{C}$ .

## **2.2 Lightweight GP concrete (GPC).**

Two recipes of lightweight geopolymer concrete (GPC) were designed with alkali activated wastes as binder. The first one was made from pulverized fly ash (PFA) and the second one was designed with a combination of PFA plus ground granulated blast slag (GGBS) as binder. This recipe was cured at room temperature. Expanded clay and natural sand were utilized as aggregates.

The GGBS utilized was supplied by Hanson, UK Company. The fineness is approximately  $500\text{m}^2/\text{Kg}$ . Commercially available chemicals were used as activators. Sodium hydroxide solution at 50% w/w was supplied by Panreac and a sodium silicate solution  $\text{SiO}_2:\text{Na}_2\text{O} = 2:1$  was supplied by Fisher Scientific. Expanded clay 3/8 mm was used as coarse aggregate and natural silica sand 0/4 mm as fine aggregate.

Mix parameters for activated waste binders developed by the geopolymer research group at the Queen's University Belfast, were used in order to design two lightweight GP concretes (GPC). The proportions set of recipe 1 and recipe two were the following:

-Recipe 1: 100% PFA in weight as binder. Alkali dosage were  $M+ = 7.5$  and  $AM = 1.25$ . For aggregates, 57% in volume was used, of which 50% in volume was expanded clay 3/8 mm and 50% in volume natural sand. The curing temperature was  $70^\circ\text{C}$  during 7 days. Then, they were kept in a wet room ( $20^\circ\text{C}$  and 90% humidity).

-Recipe 2: PFA/GGBS ratio = 30% / 70% in weight as binder. Alkali dosage were  $M+ = 7.5$  and  $AM = 1.25$ . For aggregates, 55% in volume was used, of which 50% in volume was expanded clay 3/8 mm and 50% natural sand. Regarding cured procedure, the specimens made were kept in a wet room ( $20^\circ\text{C}$  and 90% humidity).

A planetary concrete mixer was used and the sequence mix followed was the following: waste binders were placed in the mixer. Then, water plus sodium silicate solution plus sodium hydroxide solution premixed was added, stirred for 5 minutes. Expanded clay and natural sand were added and stirred for 5 minutes.

In order to characterize two different lightweight GPC formulations, mechanical and freeze/thaw tests were performed. The tests carried out in order to analyze mechanical properties were compressive strength according to Spanish standard UNE-EN-12390-3, tensile strength according to Spanish standard UNE-1239-6 and modulus of elasticity according to Spanish standard UNE-83-316-96. Regarding the freeze-thaw cycles analyses according to American standard ASTM C666 were carried out. For last, façade panels of  $62.5 \times 25 \times 7$  cm dimensions were made to analyze final surface finish and the occurrence of cracks.

### 3. Results and discussion

The ash was characterized by XRF and SEM. The ashes are mainly composed of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ , with a low content in  $\text{CaO}$ , which corresponds to an F-class type of ash, **Figure 2**. The X-ray pattern, shown in **Figure 3** reveals the mineralogical phases of this material: Quartz, Mullite, Hematite, magnetite.

Muestra N°		$\text{Al}_2\text{O}_3$	$\text{SiO}_2$	$\text{Fe}_2\text{O}_3$	$\text{TiO}_2$	$\text{CaO}$	$\text{MgO}$	$\text{Na}_2\text{O}$	$\text{K}_2\text{O}$	$\text{P}_2\text{O}_5$	$\text{Cl}^-$	$\text{SO}_3$	C	Ppc

Figure 3. Mineralogical phases of the used fly ash. Composition:  $\text{Al}_2\text{O}_3/27.5\%$ ,  $\text{SiO}_2/44.0\%$ ,  $\text{Fe}_2\text{O}_3/17.3\%$ ,  $\text{TiO}_2/0.9\%$ ,  $\text{CaO}/4.2\%$ ,  $\text{MgO}/0.9\%$

**Figure 4** shows the particle size distribution of the analyzed fly ashes, as it can be seen that the majority of the particles ranged between 1 and 100  $\mu\text{m}$ .

Figure 4. Fly ash particle size distribution

**Figure 5** shows the topology and internal microstructure of the fly ash. The particles are almost spherical and amorphous. Some spheres are hollow and others completely solid. The particles have a big range of sizes from 1.5 to 110  $\mu\text{m}$ . The media size is 33.5  $\mu\text{m}$ .

**Figure 5. SEM micrographs of fly ash.**

### 3.1 Foamed concrete

Previous research carried out showed that oxygen peroxide was the best performing foaming agent, and an optimization of the formulation proportions and the production process was carried out. Formulations with different proportions of the components were prepared and tested. Considering the heterogeneous properties of the fly ash due to its waste origin, the formulation was optimized in a range of proportions. **Table 1** shows a range of accepted formulations.

**Table 1. Range of weight percentages of each component in the mixture (wt.%)**

Fly ash	NaOH	Water	H <sub>2</sub> O <sub>2</sub>	BS
67-71	6-8	20-25	0.4-1	0-0.15

By following this procedure, 400 blocks were produced; some of them were kept for characterization. The material was prepared in form of blocks and their properties were measured. In **Figure 6** it is possible to appreciate a SEM micrograph of the porous structure of the material. The foaming agent added to the formulation generated a regular cellular structure that is the responsible for the low density of the material and its good insulating properties.

**Figure 6. SEM micrograph of the GREEN CAST material (scale bar is 1 mm).**

The main parameters of the samples were measured. The dry density was measured in 18 specimens extracted from 3 blocks. The average density was found to be  $790 \pm 21 \text{ Kg/m}^3$ .

Similarly, the compressive strength was measured by taking 6 specimens from 6 blocks. The average compressive strength for the tested samples was  $4.8 \pm 0.5 \text{ MPa}$ .

The thermal properties of the materials were studied through the measurement of the thermal resistance and the thermal conductivity. The average values for thermal resistance and conductivity, obtained after testing 3 specimens, were  $0.369 \pm 0.008 \text{ m}^2\text{K/W}$  and  $0.183 \pm 0.016 \text{ W/mK}$ , respectively.

In the case of a cellular material, such as AAC, the thermal conductivity is directly related to its density, since the air present in the structure, lightens the material and reduces the thermal conductivity, therefore improving the insulating behavior. Conventional AAC presents typical  $\lambda$  values of 0.1-0.2 W/mK). The reference AAC used in this work, with a density of  $550 \text{ Kg/m}^3$  presents a  $\lambda$  value of 0.16 W/mK according to the supplier. The slightly greater value of thermal conductivity obtained for the GREEN CAST material has been associated to its larger density.

Freeze/thaw cycles were carried out on the samples, measuring the mass and compressive resistance loss after said cycles. The temperature program consisted in cooling down to  $-15 \pm 2^\circ\text{C}$ , keeping at that temperature for 8 hours and heating up to  $20 \pm 5^\circ\text{C}$ , keeping at that temperature for 8 additional hours. After 15 cycles, for the tested samples, the average dry mass loss was  $0.6 \pm 0.4$  and the compressive strength loss was  $7.0 \pm 4.0$ .

In order to demonstrate the constructive viability of the developed material, as well as its insulating behavior, a testing cell was built with the GREEN CAST blocks and its performance was monitored. An identical testing cell built with reference AAC blocks was built and monitored in the same way. **Figure 7** shows pictures of the constructive process of both prototypes, as well as a picture of both finished ones.

**Figure 7. Testing cells being built with GREEN CAST blocks (left) and Ytong ones (center). Both testing cells finished (right).**

The acoustic insulation of the developed material was analyzed by in situ measurements. This method allows characterizing the developed technology as part of a constructive system. In order to enable the comparison with a reference, the same measurements were carried out for the reference testing cell. The sound insulation index ( $D_{2m,nT,Atr}$ ) is used to measure the level of sound insulation provided by a structure. This parameter can be expressed by a global value and by third octave bands. The results obtained for each of the façades of both testing cells are shown in **Table 2**.

In both prototypes the highest values for the sound insulation index were found in the West and South façades. This is because those walls do not contain elements with a low sound insulation such as windows. For this reason, these façades could be the most representative element of the prototype. The sound reduction index of a material characterizes the sound insulation properties of such material or the constructive system itself. It was obtained from a modeling of the acoustic field. The results obtained for each of the façades is collected in **Table 2**. Identically, West and South façades presented the best RW global values and in both cases both demonstrators showed very similar behavior.

**Table 2.** Airborne sound insulation for the measured façades. Sound reduction index ( $R_w$ ) obtained for the measured façades.

	$D_{2m,nT,Atr}$ (dB)		$R_w$ (dB)	
	GREEN CAST	Reference	GREEN CAST	Reference
North (door)	21.8	22.7	21	23
West	28.0	28.2	32	30
South	28.8	28.0	33	31
East (window)	25.1	26.4	25	25

**Figure 8** depicts testing cells internal temperature and external temperature from 7th August 2013 to 14th August 2013. Internal temperature for a given time is the result of averaging the output of two internal thermocouples placed at two different positions in the xy plane, keeping the height fixed at 1.5m

**Figure 8.** Testing cells internal and external temperatures measured in a period of one week.

For the analyzed period, the internal temperature inside the GREEN CAST testing cells showed a slightly attenuated thermal wave amplitude with respect to the reference case. This fact, in addition to the conservation of the observed frequency, confirms similar density and thermal conductivity values for both structures, corroborating GREEN CAST as an alternative to commercial solutions currently present in the market.

### 3.2 *Lightweight GP concrete (GPC).*

Two homogeneous lightweight concrete mixtures were obtained, and their fresh state presented good workability when concrete was placed compacted homogeneously without bleeding or segregation. In the case of recipe 2, it was decided to add a retarder additive after observing a fast setting of the fresh concrete in one test carried out without such additive. The consistency test was carried according to the Spanish standard UNE 83313:90 with the Abrams cone. In both cases a liquid consistency was obtained. **Figures 9** and **10** show Recipes 1 and 2, respectively.

Figure 9. GP fresh concrete Recipe 1 (cone 26 cm). Figure 10. GP fresh concrete Recipe 2 (cone 27 cm).

For the prepared samples, the mechanical performance was analyzed by measuring the compressive strength, the indirect tensile strength and the elasticity modulus. All specimens were tested at 28 days of age and the results have been collected in **Table 3**. The compressive strength was measured according to Spanish standard UNE-EN-12390-3, for cubic specimens (100x100x100 mm). The indirect tensile strength measurements were carried out according to Spanish standard UNE-1239-6 in cylindrical specimen (150 mm diameter and 300 mm length). The Young's modulus was measured on cylindrical specimens (150 mm diameter and 300 mm length) under standard UNE 83-316-96. **Figures 11** and **12** show pictures of the cubic specimens used for the mechanical characterization.

**Table 3. Mechanical performance of Recipes 1 and 2**

Sample	Density (Kg/m <sup>3</sup> )	Compressive strength		Indirect tensile		Elasticity modulus	
		Load (KN)	Stress (N/mm <sup>2</sup> )	Load (KN)	Stress (N/mm <sup>2</sup> )	Max stress (N/mm <sup>2</sup> )	Stress (N/mm <sup>2</sup> )
Recipe 1	1668	303.7	30.4	179.4	2.5	10.0	10959
Recipe 2	1741	549.4	54.0	220.7	3.1	18.1	13801

Compared to a conventional light-weight concrete with a density between 1600–1800 kg/m<sup>3</sup> and a compressive strength in the 20–35 N/mm<sup>2</sup> range, it can be pointed out that Recipe 1 is a light-weight GPC which properties are similar to its traditional homologous, however, it cures by action of the temperature. Recipe 2 reached better mechanical properties than conventional light-weight concrete and cures at room temperature. It can be highlighted that both materials represent an environmental alternative to cement based lightweight concrete.

Figure 11. Cubic specimen (Recipe 1)

Figure 12. Cubic specimen (Recipe 2). Prior to the test (left), after the test (right)

The freeze/thaw tests were carried out according to the American standard ASTM C666/666M “Standard Test Method for Resistance of Concrete to Rapid Freezing and Thawing”. This analysis method establishes a freeze/thaw cycle with the following thermal program: from 4°C to -18°C at 2.2 °C/min, 20 minutes at -18 °C, from -18 °C to 4 °C at 2.2 °C/min and an isothermal step of 90 minutes at 4 °C. The whole cycle is completed within 2 hours. The duration of the test is limited to 300 cycles, until the elastic dynamic modulus is reduced to a 60% of its initial value or until the longitudinal percentage variation achieves a value of 0.10%.

These tests provided values of height length change (%), diameter length change (%), weight change (%), relative dynamic modulus of elasticity and the durability factor. The length change is related to the deformations and is considered a valuable indicator of the internal microstructural damage. The weight loss is not considered as a main damage indicator; however it can be useful as indicator of the spalling. The durability factor is given by the relative dynamic modulus of elasticity multiplied by the number of completed cycles and divided by the total number of cycles, generally 300. All results have been collected in **Table 4**.

As it can be observed both materials presented very similar dimensional variation, however the weight change is slightly higher in Recipe 1. Both lightweight GPC recipes resisted well 320 freeze-thaw cycles. However, after 420 cycles the recipe designed with 100% PFA (Recipe 1) was observed deterioration on top of the specimen, **Figure 13**.

**Table 4.** Values of the different parameters of the durability tests

Sample	Height change (%)	Diameter length change (%)	Weight change (%)	Durability factor
Recipe 1	0.07	-0.02	5.5	110
Recipe 2	0.07	0.07	0.8	100

In order to compare lightweight GPC to commercial lightweight concrete, façade panels of 62.5x25x7 cm dimensions were manufactured. Regarding the surface finish, the pieces with the best surface finish were the façades made with Recipe 2, **Figure 14**. Neither segregation nor porosity was observed. The result was a very compact finish. Nevertheless, areas of different colors were observed.

**Figure 13.** Recipe 1 (100% PFA) after 420 freeze-thaw cycles.

**Figure 14.** Façade panel made of Recipe 2

### 3. Conclusions

The preparation of different geopolymer concrete formulations as well as their characterization has been reported in this paper. The first material consisted on a foamed geopolymer made of alkali activated coal fly ash which mechanical and insulation properties were analyzed at both laboratory and pilot scale, showing very similar density, compressive strength and thermal conductivity. This material was produced at large scale in form of blocks that were used in order to build a demo-building. An identical reference was built with commercially available AAC blocks. The thermal and acoustic performance of both demo-buildings was monitored, showing a very similar behavior in both cases. Two lightweight concrete

materials prepared with waste binder and aggregates were analyzed, revealing good workability, density, compressive strength and durability, compared to traditional lightweight concrete. In the second case, the material cured without a temperature program. Both sets of materials present feasible alternatives to non-structural traditional OP cement based materials.

**Abstract:** Our previous research conducted for the Cooperative Research Centre for Low Carbon Living identified several barriers to the widespread implementation of alternative, low CO<sub>2</sub> concrete such as geopolymers. It was found that the lack of standard specifications, lack of long-term performance data and non-compliance with AS 3600 were major obstacles to adoption. Therefore, current research is addressing these deficiencies through the preparation of a Handbook in association with Standards Australia. The primary purpose of the Handbook will be to assist engineers and end-users in specifying and constructing with geopolymer concrete. The Handbook will include background and properties of geopolymer concrete, a model performance-based specification, case histories and long-term durability studies, recommendations on testing and monitoring, and commentary on compliance with AS 3600. The objectives of this paper are to outline the proposed Handbook content, initiate discussion among stakeholders and seek input.

**Keywords:** Geopolymer, standards, specification, durability, test methods.

## 1. Introduction

Geopolymer concrete has been the subject of much research and offers a viable alternative to Portland cement concrete in a variety of applications. Potential benefits of geopolymer concrete include improved chemical resistance and reduced CO<sub>2</sub> impact. In 2013 a detailed study was performed to identify barriers to widespread adoption of geopolymer concrete (Berndt et al., 2013). Current practices with regard to concrete mix design and property requirements in Australian standards and state specifications were reviewed. Barriers to implementation of geopolymer concrete were analysed and case histories of how alternative can be successfully introduced into an established construction industry market were studied.

An industry survey was performed to better understand barriers particular to geopolymer concrete in Australia and to identify potential pathways to overcoming these barriers (Berndt et al., 2013). Based on review of prior studies and the industry survey, several actions and pathways were recognised. Highest priority activities identified were the development of a standard specification, development of new standards specific to geopolymer concrete that include performance requirements, provision for use of in state and local specifications and more independent research on engineering properties and long-term durability. Near-term research projects have subsequently been launched to address these needs. These were: (1) Development of a handbook (HB) through Standards Australia titled "Guide and Standard Specification for Construction with Geopolymer Concrete" and (2) Investigation of geopolymer concrete durability and field performance. It is intended that the handbook will be a platform for preparation of an Australian Standard on geopolymer concrete and will also build on the CIA Recommended Practice for Geopolymer Concrete (2011).

Geopolymer concrete is currently included in several VicRoads specifications and this is a major step forward in gaining acceptance and providing opportunities for use of geopolymers. National standardisation of geopolymer concrete, in conjunction with continued research, will give specifiers and end-users greater confidence with the material.

The proposed contents of the Handbook on geopolymer concrete are as follows:

1. Introduction
2. Constituent Materials

3. Properties and Applications of Geopolymer Concrete
4. Commentary on AS 1379 for Specification and Supply of Concrete
5. Commentary on AS 3600 for Design of Geopolymer Concrete Structures
6. Model Performance-Based Specification for Geopolymer Concrete
7. Recommended Performance Test Methods
8. Case Histories and Long-Term Durability
9. Summary

This paper describes current progress on Chapters 4, 5, 6, 7 and 8 listed above. Preparation of the Handbook contents commenced in mid-2014 and is a three year project.

## **2. Commentary on AS 1379**

AS 1379 (1997) covers specification and supply of concrete. The standard defines concrete as “a mixture of cement, aggregates, and water with or without the addition of chemical admixtures or other materials”. The cement type specified in AS 1379 is Portland cement complying with AS 3972. Geopolymer binders are not covered in the standard. Therefore, it is necessary to consider any deviations from AS 1379 that may be required for geopolymer concrete. The Handbook proposes to incorporate a commentary on AS 1379 to include such deviations and also provide explanation on assumptions with regard to aspects of materials, supply, testing and performance of geopolymer versus conventional concrete.

In general, specification and supply of geopolymer concrete can follow the majority of requirements given in AS 1379 for conventional concrete. The main deviation from AS 1379 is the description of binder materials. There are also aspects of supply and production of geopolymer concrete where further investigation is necessary to determine whether AS 1379 requirements and common practices for conventional concrete are applicable. Examples include the following:

- Alkali-aggregate reactivity and qualification testing of aggregates
- Temperature limits at point of delivery
- Hot and cold weather concreting precautions
- Curing practices

## **3. Commentary on AS 3600**

AS 3600 provides unified design and detailing rules (i.e., minimum requirements) for concrete structures and members with or without steel reinforcement and prestressing tendons. The standard also defines the performance criteria to assess the structural performance through its lifetime for concrete elements containing Ordinary Portland Cement (OPC) and blended cements. However, the material behavior and strength properties of geopolymer concrete show significant variability from the OPC concrete (OPCC) (e.g., Hardjito and Rangan, 2005; Ng and Foster, 2008; and Collins and Sanjayan, 1999) depending on the binder and method of curing etc. For example, geopolymer concrete has greater tensile and bond in comparison to OPCC.

Experimental studies have been undertaken to understand the shear and flexural behavior of geopolymer beam column members (e.g., Rahman and Sarker, 2011; Ambily et al, 2011; and Chang, 2009 etc). It was observed that AS 3600 estimates the flexural and shear capacities reasonably well. Due to high tensile and bond strength, the number of reinforcing bars and bond length of rebar may be reduced in geopolymer concrete. This eventually alters the detailing of design. Further, the serviceability limits set out in AS 3600 may not be adequate for geopolymer concrete members since the elastic modulus appears to be lower than OPCC. Therefore, it is necessary to make changes in AS 3600 in order to suit for geopolymer concrete. The proposed Handbook will provide a commentary on AS 3600 that includes modification to material strength, design equations and detailing. The focus will be devoted to following areas:

- Characterise the geopolymer concrete stress-strain behavior with and without confinements
- Determine the material properties including creep and shrinkage
- Assess the applicability of flexure and shear design rules in AS 3600 for geopolymer concrete member using experimental results and field performance data
- Assess the applicability of serviceability limit states provided in AS 3600
- Assess the applicability of fire design criteria provided in AS 3600
- Assess the applicability of strut and tie model provided in AS 3600

#### **4. Model Performance-Based Specification for Geopolymer Concrete**

A chapter of the proposed Handbook will present a model specification for geopolymer concrete. The specification has been designed to enable engineers to specify geopolymer concrete for projects in a manner similar to the current way in which conventional concrete is specified. The specification focuses on supply of geopolymer concrete and durability performance requirements. Existing Australian Standards and state transportation agency specifications relating to concrete have been used as a basis for this model specification on geopolymer concrete.

Given that geopolymer concrete does not have the same lengthy track record as Portland cement-based concrete, there are some uncertainties regarding long-term behaviour. Therefore, it has been necessary to make assumptions relating to properties and durability based on current knowledge. With ongoing research and practical experience with geopolymer concrete many uncertainties will be resolved. Hence, the specification will be subject to revision as more information becomes available.

The model specification sets out the requirements for the supply, testing and placement of geopolymer concrete. Currently, Australian standards such as AS 1379, AS 3600 or AS 4997 do not specifically cover geopolymer concrete. The only state specifications that include geopolymer concrete at the time of writing are VicRoads 701 (Underground Stormwater Drains), 703 (General Concrete Paving), 705 (Drainage Pits) and 711 (Wire Rope Safety Barrier). Further details are available in Andrews-Phaedonos (2014).

The specification is largely performance-based in that the required functional properties of the concrete are specified and limitations on concrete mix design or restrictions on binder type are not given. It has generally been assumed that the majority of requirements given in AS 1379 are applicable to geopolymer concrete. Therefore, areas where specification and supply of geopolymer concrete deviate from AS 1379 and the durability aspects of AS 3600 are covered.

Contents of the model specification are outlined below:

- Scope
- Definition of Geopolymer Concrete
- Existing Applicable Standard Clauses
- Material Requirements
- Geopolymer Concrete Classes, Mix Design and Property Requirements
- Sampling, Testing and Assessment of Compliance
- Placement, Finishing and Curing

A draft of the model specification has been prepared and comments from industry advisors and other interested parties are being invited so that the final document is practical, useable and achieves acceptance.

#### **5. Recommended Test Methods**

Existing testing protocols which are standardised worldwide have been developed specifically for Portland cement binder systems. However, chemical reactions characterising alkali-activated binder systems differ drastically from conventional hydration process of Portland cement. Thus, the mechanisms by which concrete achieves potential strength and durability are different between the two types of binders. As a result, existing testing methods are not necessarily suitable for geopolymer binders. This has been identified through the work of RILEM Technical Committee 224-AAM as being a key issue facing the widespread use of alkali-activated concretes in the industry (Provis and Van Deventer, 2014). Research

will be carried out combining laboratory work aiming to assess existing testing methods as well as field investigations required for the validation and the calibration of the new protocols. The project aims to determine:

- What are the best methods and protocols for testing a geopolymer concrete in laboratory?
- What are the performance requirements that should be specified?
- How do these correspond to in-service performance of real structure?

In addition to traditional standard tests related to the mechanical performance and the workability, the performance-based handbook will address the key issues surrounding the application of test methods to geopolymer concretes and mortars in the following areas:

- Creep and shrinkage
- Transport properties
- Atmospheric carbonation
- Concrete structures in marine environments
- Concrete structures in aggressive soils
- Sewer structures
- Alkali-aggregate reactivity

As an example, Table 1 shows the testing methods that will be assessed for chloride penetration in concrete structures. Laboratory experimentations will be carried out using different geopolymer concrete mix design. Results will be compared to the ones obtained in natural conditions for existing geopolymer concrete structures. The most suitable methods will be identified, protocols will be modified if necessary and performance based specifications will be calibrated for geopolymer concretes.

**Table 1. Test methods related to chloride penetration in concrete**

	Testing method	Standard protocol
1	Semi-natural chloride diffusion test	NT BUILD 443 / ASTM C1556
2	Rapid chloride permeability (RCP) test	ASTM C1202
3	Rapid chloride migration test	NT BUILD 492
4	Surface resistivity (SR) test	AASHTO TP95
5	Bulk electrical conductivity test	ASTM C1760

This work will be carried out in close collaboration with the RILEM Technical Committee 247-DTA: Durability testing of alkali-activated materials.

## **6. Case Histories and Long-Term Durability**

### **6.1 Laboratory Studies**

The majority of published durability research on geopolymer concrete has been laboratory-based. Table 2 compares broadly the laboratory tested durability properties of geopolymer and conventional Portland cement concrete. This is not a definitive list of research, but provides examples. Since properties of any concrete are highly dependent on mix proportions and constituent materials, only general comparisons have been made for concretes with similar compressive strengths.

**Table 2. Broad comparison between geopolymer and conventional concrete durability properties**

Property	Geopolymer versus Conventional Concrete	Examples of References
Carbonation Coefficient	Higher for accelerated tests	Bernal et al (2011, 2012a, b, 2014); Law et al (2012); Aperador et al (2009)
Chloride Diffusion Coefficient	Lower (migration test); lower (core test)	Bernal et al (2012a); Andrews-Phaedonos (2012); Kupwade-Patil and Allouche (2013a)
Rapid Chloride Permeability	Lower to similar depending on mix proportions	Bernal et al (2011, 2012a); Law et al (2012); Andrews-Phaedonos (2012); Kupwade-Patil and Allouche (2013a)
Corrosion Rate of Embedded Steel	Limited research, particularly field exposure, prevents conclusive comparison.	Aperador et al (2009); Aperador Chapparo et al (2012); Miranda et al (2005); Reddy et al (2013); Kupwade-Patil and Allouche (2013a)
Sorptivity	Higher	Law et al (2012); Bernal et al (2011)
Sulphate Resistance	Somewhat higher, depends on cation	Bakharev et al (2002)
Acid Resistance	More resistant to organic and inorganic acid attack	Literature reviewed by Pacheco-Torgal et al (2012); Bakharev et al (2003)
Alkali-Silica Reaction Susceptibility	Variable based on limited research, depends on composition	García-Lodeiro et al (2007); Fernández-Jiménez and Puertas (2002); Bakharev et al (2001); Literature reviewed by Pacheco-Torgal et al (2012); Kupwade-Patil and Allouche (2013b); Krivenko et al (2014)
Volume of Permeable Voids	Varies depending on mix proportions; higher	Bernal et al (2011); Andrews-Phaedonos (2012)
Water Absorption	Similar	Bernal et al (2011)
Gas permeability	Similar	Sagoe-Crentsil et al (2012)
Water Permeability	Higher	Sagoe-Crentsil et al (2012)

Table 2 indicates that the differences in properties and behaviour of geopolymer concrete compared with conventional Portland cement concrete are not always clear. This is frequently due to variation in materials, particularly activator concentrations and chemistry. Research between different organisations has not been coordinated, hence definitive comparisons are not always possible. The apparent variations and possible discrepancies highlight the need for greater understanding and verification of properties controlling service life in realistic exposure environments. It is also necessary to consider whether conventional test methods and procedures are applicable to geopolymer concrete and this is being investigated as part of the Handbook development.

## 6.2 Field Exposure Studies

Case histories and long-term durability data on geopolymer concrete in field exposure conditions are not as widely available as laboratory investigations. Recent reports on field performance of geopolymers and alkali-activated materials include work by Andrews-Phaedonos (2014), Shayan et al. (2013), Buchwald et al. (2015), Vanooteghem (2011) and Xu et al. (2008).

The research by Buchwald et al. (2015) and Vanooteghem (2011) is of particular interest as it refers to the long-term behaviour of alkali-activated slag cement concrete from buildings constructed in Belgium in the 1950s. The product used was known as "Purdocement". According to Buchwald et al. (2015) two types of Purdocement were produced. One was based on slag with a small proportion of Portland cement and the other was based on slag with a small proportion of calcium hydroxide. Both versions were activated by sodium sulphate.

Visual observations on the Purdocement buildings where the concrete was accessible showed variable performance (Buchwald et al., 2015; Vanooteghem, 2011). Some concrete was in sound condition and other concrete showed deterioration. Damage appeared to be due to water leakage or poor compaction and curing at the time of construction. Samples were extracted from damaged interior beams in a factory built in 1957 and analysed for composition, phases, microstructure, strength, carbonation and chloride ingress. Core samples from undamaged concrete in the factory were also taken for comparison. The compressive strength of cylindrical core samples from undamaged concrete was 52.2 to 54.8 MPa. The original strength was unknown. The cores were found to virtually be fully carbonated from both exposed

faces. Elevated acid-soluble chloride concentrations up to 0.49% by weight of binder were found in the damaged concrete whereas the concentrations in the undamaged cores were lower (up to 0.26% by weight of binder). The source of chloride ingress was attributed to fertiliser from leaking flower boxes. Sulphates from fertiliser may also have contributed to damage. Corrosion of reinforcement was observed in the damaged concrete and likely due to carbonation, chloride ingress or both. Corrosion was exacerbated by water leakage.

The carbonation data reported by Buchwald et al. (2015) and Vanooteghem (2011) showed that depths of carbonation for Purdocement located in an interior environment were 46 to 63 mm where measurable. In many cases carbonation of the concrete was complete and a depth of carbonation could therefore not be determined. Using the carbonation depths of 46 to 63 mm over a duration of 64 years gives carbonation rates of 5.7 to 7.9 mm/yr<sup>0.5</sup>. These values are relatively high even for an indoor environment, particularly considering that a coating had been applied to the concrete and that the calculated rates represent the lower range in the tested cores. Details on the coating and when it had been applied were unknown. However, it is possible that it may have provided some protection against carbonation. The carbonation rates can be compared with those reported for Portland cement-based concrete in indoor environments. Data is presented in Table 3 and shows the type of mixes with similar carbonation rates.

**Table 3. Indoor carbonation rates similar to “Purdocement” for conventional concrete mixes**

Mix	Curing (days)	Carbonation Rate (mm/yr <sup>0.5</sup> )	Reference
OPC, w/cm = 0.4	1	5.0	Burden (2006)
30% FA, w/cm = 0.4	1	8.0	Burden (2006)
20% FA, 46 MPa	1	8.5	Ho and Lewis (1987)
25% FA, w/cm = 0.5	28	5.9	Collepari et al (2004)
50% BFS, w/cm = 0.5	28	5.2	Collepari et al (2004)

Note: OPC = Ordinary Portland Cement, FA = Fly Ash, BFS = Blast Furnace Slag, w/cm = water/cementitious material ratio.

The data in Table 3 indicates that the measurable and, thus, lower range of indoor carbonation rates for Purdocement are similar to those for Portland cement and fly ash blends with water/cementitious material ratio of 0.4 and cured for only a short period of one day or for fly ash and slag blends with higher water/cementitious material ratio of 0.5 but cured for a longer period of 28 days. As noted above, the carbonation rates may actually have been higher, especially if the applied coating had given protection against CO<sub>2</sub> ingress.

The long-term performance of alkali-activated slag concrete in Ukraine has been reported by Xu et al. (2008). The slag was activated by carbonates or by carbonate/hydroxide mixtures and details of the original mix proportions were provided. The concrete was produced between 1964 and 1982 and had been exposed to freeze-thaw conditions typical of Kiev. The type of concrete elements included an underground drainage system, a high rise residential building, an outdoor precast slab and a silo. The age of the concrete elements at the time of testing ranged between 18 and 36 years. Chemical composition, phase analysis and microstructure of concrete samples were studied in addition to visual condition, compressive strength, depth of carbonation, surface pH and water absorption. The concrete appeared to be in good condition with no visible defects. Water absorption ranged between 4.76 and 8.04%. The compressive strengths of the samples ranged between 26 and 62 MPa. The pH of the surface was 9.08 to 11.57 and there appeared to be a correlation between surface pH and compressive strength. The depths of carbonation were 2 to 3 mm on the underground drainage system, 1 to 4 mm on the outdoor precast slab and 3 to 8 mm on the external surface of the silo. The depth of carbonation on the residential building was not reported but the concrete samples from this structure had the lowest surface pH of 9.08.

Based on the ages of the concrete and depths of carbonation for the Ukrainian alkali-activated slag concrete, the calculated carbonation rates were 0.3 to 0.5 mm/yr<sup>0.5</sup> for the drainage system, 0.2 to 0.8 mm/yr<sup>0.5</sup> for the precast slab and 0.7 to 1.9 mm/yr<sup>0.5</sup> for the silo. All of these carbonation rates are low. However, it is noted that the drainage system was likely to be wet and this would reduce carbonation. The

externally exposed concrete elements are also likely to have lower carbonation rates than might be experienced in Australia due to lower average temperatures.

The studies on Belgian and Ukrainian alkali-activated slag concrete that have been in service for decades offer insights to the long-term performance of such materials. Performance appears to depend on the type of activator and resultant chemistry of the concrete in addition to exposure conditions.

### **6.3 Proposed Field Testing**

As part of the development of a Handbook on geopolymer concrete, it is proposed to undertake detailed field testing of existing installations of geopolymers. Gourley (2014) summarised commercial use of geopolymers in Australia. Whilst the age of existing geopolymer concrete examples is relatively young, testing will provide an indication of performance to date and enable comparison with Portland cement concrete. One structure that will be tested as part of the research project is a slab constructed from geopolymer concrete at the former Zeobond batching plant in Campbellfield, Victoria. This slab was poured in 2006 and is exposed to an outdoor atmospheric environment.

The field testing programme will include non-destructive testing such as Schmidt hammer, resistivity, reinforcement corrosion activity and in-situ permeability. Extraction of core samples will also be performed and the cores will be tested for depth of carbonation, compressive strength, elastic modulus, density, sorptivity, volume of permeable voids and chloride diffusion coefficient. The microstructure of geopolymer concrete will also be examined to assist with understanding of microstructure-property relationships and identify any changes occurring with time. Comparisons will also be made with field studies on geopolymer concrete elements in Victoria reported by Shayan et al. (2013) and Andrews-Phaedonos (2014).

## **7. Conclusions**

Specific tasks are being undertaken towards preparation of a Handbook on geopolymer concrete to be published in cooperation with Standards Australia. The Handbook will assist development and adoption of geopolymer concrete in applications where an alternative to conventional concrete is sought. Widespread use of geopolymers requires engineering design and practical considerations to ensure successful construction, structural adequacy and durability. The current focus is on examination of existing standards such as AS 1379 and AS 3600, determination of how they can be applied to geopolymer concrete and identification of required deviations from the standards. A model specification suitable for use by engineers to specify geopolymer concrete for projects is being developed. Research is also investigating appropriate test methods and long-term durability investigations.

**Abstract:** It is desirable to have better thermal insulation materials to reduce energy consumption for regulating indoor temperature. Common thermal insulation materials such as expanded polystyrene and foamed polyurethane are available in the market. However, because of high flammability and low abrasion resistance of polymer-based insulator, it is not suitable for building envelope without extra protection and precautionary measures.

The fire and wear resistance can be improved by changing the material from polymer-based to inorganic. There is lots of research on foamed concrete by incorporating large volume of controlled air void. However, the application is restricted to component with limited size due to excessive drying shrinkage. On the one hand, when more air void is trapped in the matrix, the density is lower and it results in higher thermal resistance. On the other hand, with lower density, the matrix is weaker and the water permeability is significantly increased. The high water permeability allows fast penetration of water and causes leaching that may lead to disintegration in relatively short time especially for ultra-lightweight concrete.

In this paper, drying shrinkage of non-foamed mortar made of different blends among ordinary Portland cement, ground granulated blast-furnace slag, calcium sulfoaluminate cement, calcine magnesium oxide condensed silica fume, limestone powder and surface-treated hydrophobic clag will be investigated. The drying shrinkage of non-foamed mortar and foamed concrete with the same mix proportion will be performed to verify the methodology. Finally, the modification of the hydrophilic matrix of conventional cement mortar to hydrophobic by using surface treated hydrophobic clag is demonstrated.

**Keywords:** water repelling, foamed concrete, drying shrinkage, CSA, calcined magnesium oxide.

## 1. Introduction

Most energy consumed in building is spent on heating/cooling. However, significant energy is wasted through the heat transfer of the building envelope. It is desirable to increase the thermal resistance of external walls of buildings. For floor heating system, it is more efficient to provide thermal insulator below the heating pipes to minimise heat transfer to the ceiling of the lower floor [1]. Polymer-based thermal insulators, such as expanded polystyrene and foamed polyurethane, provide excellent thermal insulation that the thermal conductivity is close to air as well as satisfactory mechanical strength. However, they are not suitable to be used in buildings, for which fire safety is one of the major design concerns. When fire safety is the prime concern, inorganic thermal insulator is preferable. Foamed concrete is one of the candidates. Foamed concrete consists of cementitious paste with macroscopic entrapped air void [2,3]. By reducing the density of the cementitious matrix, the thermal conductivity can be greatly reduced. One of the major problems of conventional foamed concrete is the excessive dry shrinkage because there is no coarse aggregates in the matrix. Also, by reducing the density, the matrix becomes more water permeable. In the presentation, different approaches of reducing the drying shrinkage as well as modifying the hydrophilic matrix to hydrophobic will be discussed.

## 2. Materials and methods

### 2.1 Materials

The studied lightweight foamed concrete consists of ordinary Portland cement (OPC), calcium sulfoaluminate (CSA) cement, ground granulated blast-furnace slag (GGBS), calcined magnesium oxide, limestone powder, uncondensed silica fume and surface-treated hydrophobic clag. The results of elemental analysis from X-ray fluorescence spectroscopy are shown in Table 1. To improve the

workability of the mix in fresh state, high performance polycarboxylate based superplasticizer (SP) is used. Boric acid is used to control the setting time of the mix with CSA cement. The particle size of OPC, GGBS, CSA, limestone powder and surface treated hydrophobic clag is in similar range (in 10-100  $\mu\text{m}$ ). Since the mix contains all fine powder, hydroxypropyl methylcellulose (HPMC) and uncondensed silica fume is added as a viscosity modifying agent to improve the cohesiveness of the mix. All CSA cement is blended with 15% wt of industrial grade gypsum dihydrate ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) in powder form before mixing with other types of powder. [5] discusses the hydration process of CSA. Magnesium oxide is a common admixture for shrinkage compensation of cement based repair mortar. The magnesium oxide used in this study is the industrial grade lightly calcined from magnesium hydroxide. The as-received magnesium oxide is further calcined in an in-house furnace for 1 hour at 800°C, 900°C and 1000°C, respectively under normal atmospheric condition. The purpose of calcination of magnesium oxide is to increase the crystallinity and hence reduce the reactivity so that it can compensate the drying shrinkage in longer period. The foaming agent used for the foamed concrete is fatty alcohol-based liquid form (BASF Rheocell 30). To modify the surface of the matrix from hydrophilic to hydrophobic, a surface treated clag is used.

**Table 1. Elemental analysis of the raw materials of foamed concrete.**

	OPC	GGBS	CSA	Limestone	Silica fume	Clag
CaO	67.0%	46.5%	41.3%	96.9%	0.4%	4.5%

## 2.2 Specimens preparation and test

In this study, the drying shrinkage of the binder is investigated with different combination of binder and filler instead of making foamed concrete. The reason is to minimise the variation caused by adding air void. Also, the strength of foamed concrete is significantly reduced and it is damaged easily during continuous measurement of drying shrinkage. Foamed concrete specimens were made in three different sets of mix proportion to verify whether the trend and magnitude of drying shrinkage of foamed concrete is similar to the binder with the same mix proportion. To investigate the drying shrinkage of the non-foamed mortar, the specimens are divided into 3 groups as summarised in Table 2. All samples consist of the same content of uncondensed silica fume, SP and HPMC. Since the bubble stability of foamed concrete depends on the workability of the fresh state, the water content is kept the same. When boric acid is added, the workability of the fresh state of the mix may change significantly and hence the water content is adjusted to maintain similar workability. The first group consists of OPC, GGBS, uncondensed silica fume and limestone powder. The purpose of the first group is to investigate the conventional composition of foamed concrete. Conventional foamed concrete is made of OPC. To improve the greenness of foamed concrete, one traditional way is to replace OPC by GGBS. To reduce the cost of foamed concrete, part of OPC is replaced by limestone powder as well. The second group consists of fixed OPC-to-GGBS ratio and with addition of 4% mass of magnesium oxide with different calcination temperature. The reaction between the magnesium oxide and water to form magnesium hydroxide is expansive and it is conventionally used for shrinkage compensation in cement-based repair mortar. In this study, magnesium oxide with different crystallinity and reactivity is added to the mix for investigation of the effectiveness of using magnesium oxide to reduce the drying shrinkage in foamed concrete. The third group consists of more complicated blend among OPC, GGBS, CSA, uncondensed silica fume and limestone powder. Since the setting time of CSA cement with gypsum dihydrate can be as fast as 15 minutes, boric acid powder is added to retard the setting time to 60-75 minutes. While there is neutralisation reaction between boric acid and the alkaline in other powder and form water, the total water content is adjusted so that the mix in fresh state maintains similar workability.

**Table 2. Mix Proportion, compressive strength and dry shrinkage of non-foamed mortar.**

To compare the drying shrinkage between non-foamed mortar and foamed concrete, three sets of mix proportion is selected as shown in Table 3. Since it is too fragile to produce ultra-lightweight foamed concrete and it is broken easily during the measurement drying shrinkage manually, the wet density of foamed concrete is set at around 1600 kg/m<sup>3</sup>. For each mix proportion, three cubic samples for compression test and three prism samples for drying shrinkage measurement will be prepared for each binder and foamed concrete.

**Table 3. Mix proportion, wet density and compressive strength of non-foamed mortar and foamed concrete.**

	OPC	GGBS	Silica fume	Lime-stone	Water	Foaming agent (Liquid)	Wet density (kg/m <sup>3</sup> )	Compressive strength (MPa)

To transform the hydrophilic surface of conventional mortar matrix to hydrophobic, the limestone powder is replaced by surface-treated hydrophobic clag. Since the particle shape of clag is clay-like, the water requirement is higher compared to limestone powder [4]. The hydrophobic property of clag affects the foam volume with the same amount of foaming agent. The detail mix proportion is still undergoing. Hence, only 70 mm x 70 mm x 140 mm cubes are fabricate to demonstrate the hydrophobicity of the matrix by using clag.

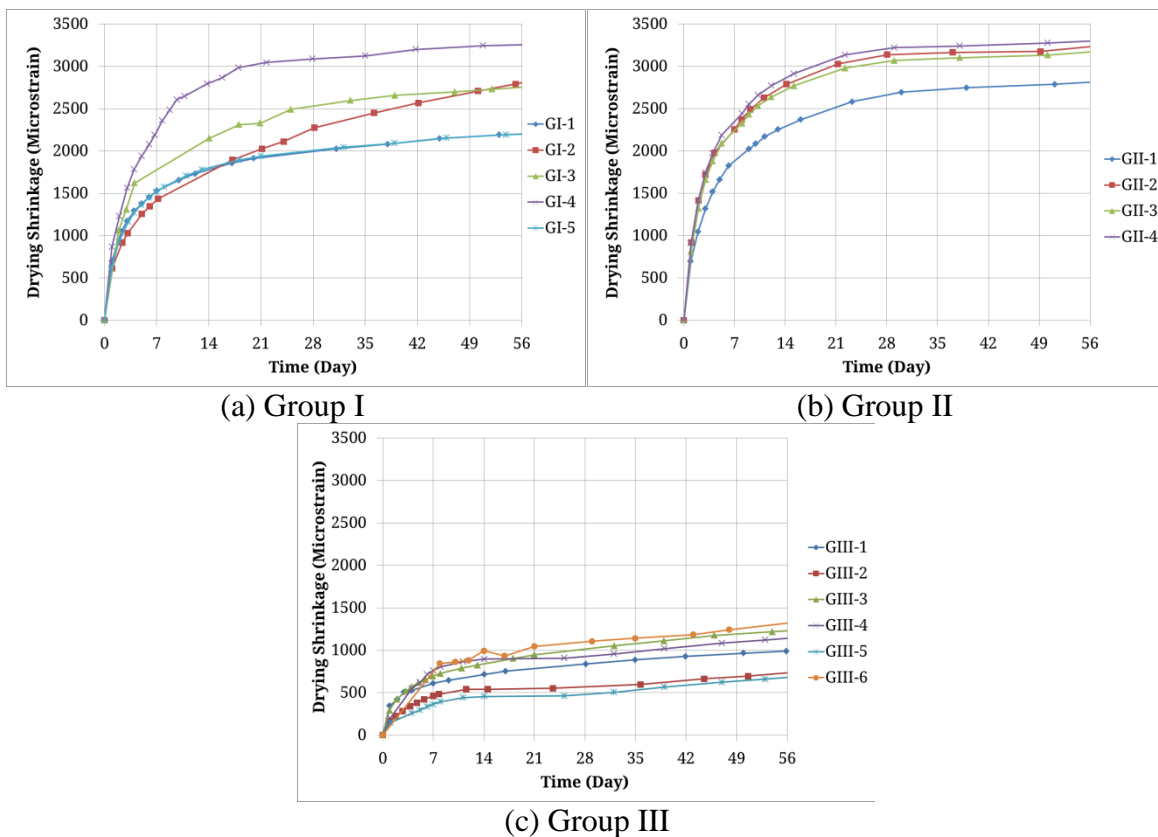

To fabricate non-foamed mortar, all dry powder including OPC, GGBS, CSA, uncondensed silica fume, limestone powder, calcined magnesium oxide, surface treated hydrophobic clag, boric acid and HPMC are mixed in the mixer. SP is mixed with water before adding to the mixed dry powder. The dosage of boric acid in Table 2 is the ratio to the total weight of OPC and CSA cement only. To fabricate foamed mortar, SP is mixed with 80% of the total water content while liquid form foaming agent is mixed with the remaining 20% water separately. The 80% water + 100% SP is thoroughly mixed with the dry powder mix. After the SP is effective, 20% water + 100% foaming agent is mixed to the wet mix to produce lightweight concrete. The amount of foaming agent added to achieve the desired wet density is based on trial-and-error process.

The wet density of the sample is measured in 100 mm x 100 mm x 100 mm cubes. The sample is cured at room temperature in the laboratory for 24 hours then the samples are demoulded. After demoulding, the cubic samples are put in a 60°C water bath for 7 days. Before the compression test, all samples are air dried for another 7 days. For each mix, three cubic samples are prepared. In the same batch of wet mixture, three 40 mm x 40 mm x 300 mm prisms are prepared for drying shrinkage measurement. A bolt is embedded at each end of the prism. A dial guage is used to measure the length of the sample. The wet sample is cured in normal laboratory for 24 hours then the samples are demoulded. After demoulding, the length of the sample is measured and then those samples are immersed in water bath in room temperature of the laboratory for 2 days. After 2 days of immersion in water, the length of the sample is measured and it is the initial length of the drying shrinkage measurement. The samples are put in a room with 23°C and 55% R.H. and the length change with time is measured by the dial gauge in the room manually. The frequency of measurement depends on the age of the sample since most drying shrinkage happens in the first week of test.

### 3. Results and discussions

The compressive strength of different mix is shown in Table 2. For group I, compressive strength of those mixes with OPC is similar. For GI-5, which contains 20% replacement of OPC by limestone powder, the

compressive strength is similar to those with high replacement proportion of OPC by GGBS. It is because there is no change in water content in the mix when binder is replaced by limestone powder and hence, the water-to-binder ratio increases. However, the strength development of GI-2, for which contains no OPC, is much lower comparing with other mixes in the group. It can be explained by the slow hydraulic reaction rate of GGBS. The drying shrinkage results of group I are shown in Figure 1a. The drying shrinkage at the 28<sup>th</sup> day is shown in the last column of Table 2. If there is no data at the 28<sup>th</sup> day, linear interpolation is used to deduce the drying shrinkage. In general, all drying shrinkage at the 28<sup>th</sup> day beyond 2,000 microstrain which is several times higher than normal concrete. The trends of drying shrinkage of GI-1 and GI-5 are identical. For GI-5, 20% of OPC is replaced by limestone powder. That means from the drying shrinkage reduction depends on water content instead of binder content. The drying shrinkage of those mixes with GGBS is generally with higher drying shrinkage (GI-2, GI-3 and GI-4). For GI-4, by replacing 75% of OPC by GGBS, the drying shrinkage at the 28<sup>th</sup> day is increased by 50% compared with GI-1 which contains no GGBS. For GI-2, for which contains no OPC, the drying shrinkage seems to be low compared to other mixed with blended OPC and GGBS. However, the low drying shrinkage is because of slow strength development. The trend of drying shrinkage of GI-2 keeps at much faster rate even after 28<sup>th</sup> day of measurement. Hence, the expected ultimate drying shrinkage of GI-2 is higher than the current value.

**Figure 1. Drying shrinkage of the specimens.**

In group II, in general, the calcined magnesium oxide does not reduce drying shrinkage of the mix GI-4 as shown in Figure 1b. For GII-1, which contains 4% as-received lightly calcined magnesium oxide, shows less drying shrinkage compared with other mixes in the same group. However, the compressive strength of the mixes with extra in-house calcination demonstrates higher strength. For higher the calcination temperature, that means higher degree of crystallisation, the higher the compressive strength. However, for lightly calcined magnesium oxide, the expansions reaction starts earlier compared with other cases in Group II. When the reactivity of magnesium is reduced by extra-calcination, the expansion reaction cannot compensate the drying shrinkage because the strength of the matrix has been developed.

In group III, in general, the CSA cement can reduce drying shrinkage significantly as shown in Figure 1b. From the compression data from Table 2, the compressive strength of CSA mortar is significantly reduced when the ratio between CSA and OPC is less than 2. When CSA is blended with GGBS without OPC, the compressive strength is about one-third of pure CSA (Mix GIII-5). The minimum drying shrinkage is obtained when half of binder is GGBS and CSA-to-OPC ratio is 2 with 20% of limestone powder. The drying shrinkage is less than 500 microstrain at the 28<sup>th</sup> day which is comparable to conventional concrete with coarse aggregate. The compressive strength of GIII-5 is reduced by 16% compared with the GIII-1 with pure CSA.

The compressive strength of the three selected mix proportion of non-foamed mortar and foamed concrete is shown in Table 3. The compressive strength of the three non-foamed mortars is similar. With the same wet density of foamed concrete, the compressive strength is similar as well. Figure 2 shows the drying shrinkage of the non-foamed mortar and foamed concrete. Although the three selected non-foamed mortars achieve similar compressive strength, the magnitude of drying shrinkage is significantly different (varies from 2000 microstrain to more than 3000 microstrain). In Figure 2, the trend and magnitude of drying shrinkage of foamed concrete is very close to the non-foamed mortar. Hence, it is justifiable to investigate the drying shrinkage of foamed concrete by measuring the drying shrinkage of non-foamed mortar with the same mix proportion. When foaming agent is added, the viscosity of the wet mix becomes much higher. If the workability of the mix is too low, the shear stress in the wet mix may force merging of bubbles and the compressive strength of foamed concrete is significantly reduced. It is the major reason to keep the water content of the mix identical even through it increases the water-to-binder ratio when binder is replaced by inert filler (limestone powder or surface treated hydrophobic clag).

**Figure 2. Drying shrinkage of the specimens of non-foamed binder and foamed binder.**

Figure 3 shows water droplets on top of foamed concrete with replacement of limestone powder by surface treated hydrophobic clag. Figure 4 shows the contact angles of 2 randomly selected location. The contact angles of both locations are greater than 90° that means the matrix is modified from hydrophilic to hydrophobic. The drying shrinkage measurement and compressive strength test is still ongoing.

**Figure 3. Water droplets on hydrophobic foamed concrete.**

**Figure 4. Contact angle measurement of 2 randomly selected locations of foamed concrete with surface treated hydrophobic clag.**

#### 4. Conclusions

In this paper, the drying shrinkage of foamed mortar was investigated by measuring the drying shrinkage of non-foamed mortar blended with OPC, GGBS, CSA, calcined magnesium oxide, condensed silica fume and limestone powder. This methodology was verified by selecting 3 sets of mix to compare the drying shrinkage of foamed and non-foamed mortar with identical constituents with different densities. The optimal drying shrinkage of non-foamed mortar could be reduced to comparable to normal concrete. Finally, the modification of hydrophilic cement mortar to water-repelling matrix by using surface treated hydrophobic clag was demonstrated.

**Abstract:** Chloride ion penetration in concrete is one of the major causes of deterioration of reinforced concrete structures by depassivation of reinforcing bars. Since testing of the natural chloride penetration is time consuming, utilising an accelerated test method is more desirable. Surface resistivity (SR) test is increasingly being used, due to its relative speed and ease of performing combined with the non-destructive nature, to assess the permeability of concrete and its resistance to chloride ion penetration. The test has been standardised as AASHTO TP 95 which consists of measuring the resistivity of water-saturated concrete cylinders using a four-pin Wenner probe array. This paper presents the results of an experimental investigation on the surface resistivity (SR) of a low-calcium fly ash-based geopolymer concrete (GPC). SR test results show that the resistivity of GPC samples are very low, this does not necessarily mean that they are having a high level of chloride penetrability since the AASHTO TP 95 limits are only applicable for conventional OPC concrete and not for the GPC. In case of geopolymer concrete, there are a large amount of mobile metallic ions such as Na<sup>+</sup> in the pore solution which could probably affect the resistivity test measurements. A further study is required to directly measure the chloride permeability of the GPC such as natural diffusion or ponding test to be able to properly correlate the surface resistivity measurements of GPC to its actual chloride permeability level.

**Keywords:** geopolymer concrete, surface resistivity (SR) test, chloride diffusion, permeability.

## 1. Introduction

Chloride ion penetration in concrete is one of the major causes of deterioration of reinforced concrete structures by depassivation of reinforcing bars [1]. The time taken by the chloride ions to reach the rebar and initiate corrosion depends on factors such as; mechanism of intrusion, external concentration of the chlorides, the transport rate of Cl<sup>-</sup> ions into concrete, the microstructure of the material and the matrix chloride binding capacity [1], [2].

Ion transport can take place by diffusion or by capillary suction [2]. In a completely water-saturated concrete, chlorides penetrate by pure diffusion mechanism due to the concentration gradients. However, in the case of partially saturated concrete, chloride ions penetrate by absorption, capillary forces or dissolving in the maritime fogs micro drops [1].

Since testing of the natural chloride penetration is time consuming, utilising an accelerated test method is more desirable. Rapid chloride permeability (RCP) test which has been first developed by Whiting (1981) and standardised as ASTM C1202, is an eminent test method using an electrical field. A potential difference of 60 V dc is applied to a 50 mm thick concrete disc over a 6 h period and the total charge passed, in coulombs, is used as an indication of chloride permeability of concrete. Although the RCP test is relatively simple and quick, the high voltage used causes heating and microcracking of the test specimen and the total current passed corresponds to the movement of all the ions (not only the Cl<sup>-</sup> ions) in the pore solution of the concrete. Considering the above mentioned uncertainties, the RCP test method may only be used as an approximate indication of concrete permeability.

Surface resistivity (SR) test is another accelerated test method which is increasingly being used, due to its relative speed and ease of performing combined with the non-destructive nature, to assess the permeability of concrete and its resistance to chloride ion penetration. The test has been standardised as AASHTO TP 95 which consists of measuring the resistivity of water-saturated concrete cylinders using a 4-pin Wenner probe array.

**Table 1. SR values to determine chloride ion penetrability in accordance with AASHTO TP 95-11 criteria**

Chloride ion penetrability	Surface resistivity [ $k\Omega\text{-cm}$ ] SR test - AASHTO TP 95
High	< 12
Moderate	12 – 21
Low	21 – 37
Very low	37 – 254
Negligible	> 254

Previous research works [4]–[6] have demonstrated that SR test results can be related to chloride diffusivity and also to chloride ion penetrability (RCP test results) of conventional Portland cement and blended cement concrete. Furthermore, since SR test is non-destructive and can be applied to the same specimen at different ages, changes in resistivity over time can be used to evaluate the rate of microstructure development, pore refinement and strength development.

Resistivity is an intrinsic property of a material that indicates how resistant the material is to the flow of electric current. The factors that mainly influence the resistivity of concrete are similar to those that affect its permeability [7]. When a voltage is applied to concrete, it creates an electric potential gradient which drives the flow of electrons through the concrete (**Figure 1**). The electrons flow mainly through the saturated complex and multi-scale porosity in the concrete matrix structure. Although the flow of electrons through the aggregate and hardened binders is also possible, it plays a smaller role due to the higher resistivity of these materials [7].

As it is graphically illustrated in **Figure 1**, the concrete containing less interconnected pores with a more tortuous path will have a higher electrical resistivity as it would be more difficult for electrons to pass through these kinds of pore network. Accordingly, the measurements of concrete electrical resistivity can provide a good indicator of its permeability since both properties are mainly controlled by the tortuosity of the pore network. More compacted microstructures which tend to have more complex and refined pore networks result in a higher tortuosity and a lower permeability, whereas, less-dense microstructures (resulting for instance from a higher water to binder (w/b) ratio) would have greater porosity, lower tortuosity and higher permeability [7].

It worth mentioning that, to some extent, other factors including pore solution chemistry, curing conditions, temperature and moisture content could also affect the concrete's resistivity [8].

**Figure 1. Schematic representation of electron flow through saturated concrete mixtures: (left) highly porous microstructure; (right) dense microstructure [7].**

In this paper, the resistivity of a low-calcium fly ash-based geopolymer concrete (GPC) is investigated. Twelve different heat-cured GPC samples are studied for their surface resistivity after 28 days of age. The curing regimes include 3 temperatures of 60, 75 and 90 degree Celsius as well as 4 different curing durations of 8, 12, 18 and 24 hours. An ordinary Portland cement concrete (OPCC) having the same amount of binder and aggregate and being cured under the same conditions as the GPCs is also included

in the experiments as the reference point for comparisons. The surface resistivity results are compared to the ones obtained using the ultrasonic pulse velocity test which is another test method to assess the concrete microstructure and compactness.

## 2. Materials and mixing

Geopolymer concrete is produced by the alkali activation of aluminosilicate raw material, which is transformed into a reaction product by polymerization in a high pH environment under hydrothermal conditions at relatively low temperatures [9]. With regard to matrix formation, geopolymer paste differs substantially from ordinary Portland cement paste. While Portland cement relies on the presence of calcium, geopolymer does not utilize the formation of calcium silicate hydrates (C-S-H) for matrix formation and strength. Geopolymer contains aluminium and silicon species that are soluble in highly alkaline solutions. The dissolved species then undergo polycondensation to attain matrix structural integrity [10].

Three different sources of aluminosilicate materials have been used in this study in order to prepare the GPC mixes. A low-calcium type (ASTM C 618 Class F) fly ash (FA), sourced from Eraring Power Station in New South Wales, Australia, has been used. The fineness of FA by 45  $\mu\text{m}$  sieve was determined to be 87% passing (tested in accordance with AS 3583.1-1998). A special grade (ultra-fine) fly ash branded as Kaolite High Performance Ash (HPA) by Cement Australia has also been used as the second aluminosilicate source. The Kaolite HPA was obtained from Callide Power Station in Queensland, Australia. And finally, ground granulated blast furnace slag (GGBFS) supplied by Blue Circle Southern Cement Australia was used as the third aluminosilicate source of the geopolymer binding system.

The alkaline activator used is a mixture of sodium hydroxide (NaOH) solution and sodium silicate ( $\text{Na}_2\text{SiO}_3$ ) solution. The ratio of sodium silicate to sodium hydroxide solution used was 2.5:1 (by mass), according to the study conducted by Hardjito and Rangan [11] showing that more consistent test results could be achieved by using this ratio.

The sodium hydroxide solution used was prepared by dissolving the technical grade NaOH pellets in water. The sodium hydroxide white pellets with a purity of at least 98% were supplied by Ajax Finechem under the commercial brand of UNIVAR A-302. These pellets have a molecular weight of 40, a specific gravity of 2.1 and a pH of approximately 14. The concentration of sodium hydroxide solution used is 12 molar (M) consisted of 480 grams (g) of NaOH pellets per litre of NaOH solution or 361 g of NaOH pellets per kg of NaOH solution. The Sydney tap water was used in this study as the solvent to produce the NaOH solution.

The sodium silicate solution used, which was manufactured by PQ Australia under the commercial name of Vistrol D-A53 or grade D, has a chemical composition of  $\text{Na}_2\text{O}=14.7\%$ ,  $\text{SiO}_2=29.4\%$ , and  $\text{H}_2\text{O}=55.9\%$  (by mass). The  $\text{Na}_2\text{SiO}_3$  solution used, also known as waterglass, is a thick adhesive liquid with a viscosity of 400 cps at 20 °C, has a specific gravity of 1.53 and a pH of 12.9 (values provided by supplier, PQ Australia). Both alkaline solutions were prepared and mixed together 1 day prior to usage.

A maximum nominal size of 10 mm aggregate was used in this study. Sydney sand with specific gravity of 2.65 and water absorption of 3.5% was used as fine aggregate and 10 mm crushed basalt gravel, also known as blue metal, with specific gravity of 2.8 and water absorption of 1.6% was used as coarse aggregate. All aggregate was kiln dried at 105 °C for a period of 48 hours prior to batching. The drying procedure which removes all the moisture content of the aggregate and also the organic particles in sand could help to more accurately adjust the mix water and consequently enhance the consistency of the GPC.

Mix proportioning of the raw material ingredients, as shown in **Table 2**, was carried out by mass. For OPCC, mixing was performed in accordance with AS 1012.2 [12]. for GPC the below mixing sequence was followed. Using a vertical pan mixer, the solid constituents except for GGBFS were firstly dry mixed for 5 minutes to achieve a uniform dispersion. The alkaline activator solution and water were then gradually added and further mixed for 15 minutes. The longer mixing time could help to increase the rate of leaching and transportation of Al and Si atoms in the geopolymer mixture which leads to enhanced strength of the GPC [13]. Lastly, the GGBFS was introduced and mixing continued for another 5 minutes.

The reason for adding slag at the end of the mixing procedure is to prevent rapid hardening of the mixture due to high calcium content of GGBFS and to allow for sufficient workable time to complete casting.

Slump was measured to check the workability and, thereafter, freshly mixed concrete was placed into moulds and compacted using an external vibrating table to achieve proper consolidation and to minimise the amount of the entrapped air arising within the mix. Meanwhile, the mass per unit volume (density) and air content (AC) tests were also performed.

**Table 2: OPCC and GPC mix proportions (kg per cubic meter)**

Materials	GPC	OPCC
Coarse Aggregate	1221	1221
Fine Aggregate	621	621
FA	272	0
Kaolite HPA	77	0
GGBFS	39	0
Portland cement	0	388
Activator Solution (Na <sub>2</sub> SiO <sub>3</sub> :NaOH = 2.5:1)	194	0
Free Water	13	175
High-range water reducer (HWR)	0	1
Activator to geopolymer binder (SCMs) ratio	0.5	N.A.

Once casting and finishing the surface of all specimens completed, moulds were sealed with the lids and the plastic sheets to prevent excessive loss of moisture. One hour after finishing of the casting, sealed specimens were moved to the oven. 12 different curing conditions applied to the identical concrete samples consists of 3 different temperatures of 60, 75 and 90°C and four curing periods of 8, 12, 18 and 24 hours. After finishing of the heat curing period, samples were demoulded and stored in the controlled room at a temperature of 23 ± 2°C until the testing date.

### 3. Testing methods

#### 3.1 Static mechanical tests

Compressive strength and modulus of elasticity of hardened GPC and OPCCs are measured in accordance with ASTM C39-12 and ASTM C469-14, respectively. Cylindrical specimens of 100 mm diameter by 200 mm height were tested under a load rate control condition in a universal testing machine. The load rate was adjusted to apply a stress rate on the specimen of 0.25 ± 0.05 MPa per second. In order to measure the static chord modulus of elasticity of concrete samples, the axial and circumferential strain has been recorded by means of extensometers/strain gauges mounted on the specimen recording data up to the point equivalent to 40% of the measured maximum compressive strength.

#### 3.2 Surface resistivity (SR) test

The SR test has been performed in accordance with the standard procedure AASHTO TP 95-11. The test consists of measuring the resistivity of vacuum-saturated 100 × 200 mm cylinders by use of a 4-pin Wenner probe array (**Figure 3-right**). An alternative current potential difference is applied at the outer pins of the Wenner array resulting in current flow in the concrete (**Figure 2**). The resultant potential difference between the two inner pins is measured and used to calculate the resistivity of the concrete specimen. Resistivity ( $\rho$ ) can be obtained using Eq. 1.

$$\rho = R \frac{A}{L} = 2\pi a R = 2\pi a \frac{V}{I} \quad (1)$$

where  $\rho$  is resistivity,  $R$  is resistance,  $A$  is area of the element and  $L$  is the length of element and  $a$  is the spacing between the probs.

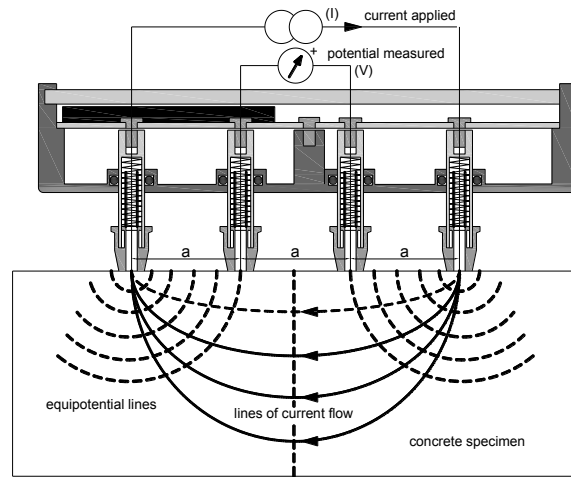

Figure 2. Four-point Wenner array probe setup (AASHTO TP 95-11)

### 3.3 Ultrasonic pulse velocity test

Ultrasonic pulse velocity (UPV) of concrete specimens is measured using PUNDIT (Portable Ultrasonic Non-destructive Digital Indicating Tester) equipment (Figure 3-left). UPV test is conducted on 100 mm diameter concrete cylinders based on the ASTM C597-09 test method. UPV method is based on measuring the velocity of compression stress waves (P-waves) to determine the material characteristics. PUNDIT generates low-frequency ultrasonic waves and measures the time taken for them to pass from one transducer to the other. The velocity of these waves traveling in a solid material depends on the density and elastic properties of material.

Figure 3. Pulse velocity (left) and surface resistivity (right) tests

## 4. Results and discussions

Compressive strength and modulus of elasticity test results of GPC and OPCC specimens are presented in **Table 3**. All the GPCs achieved 68% to 100% of their 28-day strength after 1 day, while this ratio ranges between 55% to 71% for the OPCCs. All the GPCs cured at 75°C and 90°C for 8 to 24 hours reached more than 90% of their 28-day compressive strength after 1 day which is a significant advantage for applications required high early-age strength such as precast industry.

The compressive strength of the geopolymer concretes cured for a short period of time (8 hours and 12 hours), increases with increase in the curing temperature from 60°C to 90°C. However, for a longer period of heat curing (18 hours and 24 hours) the optimum strength is achieved at 75°C. Heat curing at 90°C

leads to a strength reduction. Other researchers [14], [15] observed that curing geopolymer concrete for longer periods of time at elevated temperatures weakens its microstructure resulting in a lower compressive strength.

Among all the different curing durations and temperatures, the GPC cured at 75°C for a period of 24 hours shows the highest compressive strength at 28 days of 62.3 MPa. However, reducing the heat curing duration from 24 hours to 18 hours does not lead to a significant reduction in strength (around 4% reduction). As a result, 18 hours heat curing at 75°C could be considered as the optimum economical heat curing condition for low-calcium FA-based geopolymer concrete. Heat curing at 60°C for a period of less than 18 hours appears not to be a suitable option for the GPC in terms of strength.

Furthermore, at any age, the compressive strength of GPC properly heat cured (i.e. temperature  $\geq 75^\circ\text{C}$  and duration  $\geq 12$  hours) is higher than that of their counterpart OPC concrete subjected to identical curing condition. The GPC cured at 75°C for 18 hours obtained a similar strength grade (only 7% lower) of the lime-water cured (WC) OPC concrete which is known as the ideal curing condition for the OPC concrete. As a result, for applications which require high early-age strength (e.g. precast industry), low calcium FA-based GPC appears to perform better than OPC concrete in term of both early and long term compressive strength.

**Table 3: Properties of GPC and OPCC at the age of 28 days**

Mix Designation	1-d Compressive Strength [MPa $\pm$ SD]	28-d Compressive Strength [MPa $\pm$ SD]	28-d Modulus of Elasticity [GPa]
GPC-60D-8h	18.6 $\pm$ 0.9	27.4 $\pm$ 0.9	13.5
GPC-60D-12h	29.7 $\pm$ 1.4	37.8 $\pm$ 0.3	16.6

GPC-60D-24h	43.6 $\pm$ 1.6	50.0 $\pm$ 0.8	22.9
GPC-75D-8h	45.2 $\pm$ 1.9	44.8 $\pm$ 0.2	20.4
GPC-75D-12h	50.5 $\pm$ 0.8	53.9 $\pm$ 0.5	22.8
GPC-75D-18h	55.9 $\pm$ 1.1	60.0 $\pm$ 0.1	24.4
GPC-75D-24h	60.2 $\pm$ 0.3	62.3 $\pm$ 0.2	25.9
GPC-90D-8h	51.1 $\pm$ 0.1	52.2 $\pm$ 0.7	23.5
GPC-90D-12h	54.1 $\pm$ 1.9	58.6 $\pm$ 0.9	23.9
GPC-90D-18h	56.0 $\pm$ 0.6	59.8 $\pm$ 0.2	25.1
GPC-90D-24h	60.5 $\pm$ 1.3	60.7 $\pm$ 1.2	25.8
OPPC-60D-8h	23.6 $\pm$ 0.1	42.6 $\pm$ 0.1	28.9
OPPC-60D-12h	27.1 $\pm$ 0.3	47.6 $\pm$ 0.7	30.5
OPPC-60D-18h	27.8 $\pm$ 0.2	47.6 $\pm$ 1.9	30.7
OPPC-60D-24h	28.7 $\pm$ 0.3	49.4 $\pm$ 0.9	31.2
OPPC-75D-8h	26.0 $\pm$ 1.1	45.2 $\pm$ 1.5	30.8
OPPC-75D-12h	29.0 $\pm$ 1.1	45.4 $\pm$ 0.4	30.0
OPPC-75D-18h	28.2 $\pm$ 0.4	46.0 $\pm$ 0.5	29.3
OPPC-75D-24h	31.4 $\pm$ 0.2	48.9 $\pm$ 0.1	29.4
OPPC-90D-8h	26.1 $\pm$ 0.6	46.1 $\pm$ 1.7	29.2
OPPC-90D-12h	28.5 $\pm$ 0.4	43.1 $\pm$ 0.4	29.8
OPPC-90D-18h	29.5 $\pm$ 0.6	43.7 $\pm$ 0.5	29.0
OPPC-90D-24h	31.3 $\pm$ 0.5	43.8 $\pm$ 0.9	28.7

From the results listed in **Table 3**, it could be noticed that the modulus of elasticity of GPCs are significantly lower than that of OPCCs for all the curing condition. GPCs are having a modulus of elasticity ranging between 13.5 GPa to 25.9 GPa which is equal to 47% to 90% of the modulus of elasticity of their counterpart OPCC cured in the same condition. The low modulus of elasticity of the GPC is attributed to the lower modulus of elasticity of the geopolymer paste compared to the OPC paste [16]. In **Figure 4**, the modulus of elasticity of GPCs and OPCCs are plotted against the compressive strength together with the recommended models of the AS 3600 [18] and CEB-FIP-90 [19]. As expected, both the fib model code and the AS model significantly over-estimate the elastic modulus of the GPCs while providing an acceptable prediction for the OPC concrete.

**Figure 4. Relationship between modulus of elasticity of GPC and OPCC**

The pulse velocity test results of GPCs and OPCCs are shown in **Figure 5**. It could be observed that the pulse velocity of geopolymers increases with the increase in the curing temperature and duration. Since the speed of the wave varies as a function of the density of material, the increased pulse velocity for GPC shows that increasing the curing temperature up to 75°C and the curing duration to 18 and 24 hours lead to a more integrated matrix with higher density. The UPV results indicating that the appropriate heat-cured GPCs are having a similar or denser microstructure than their counterpart OPCCs.

**Figure 5. Pulse velocity of GPC and OPC concrete specimens after 28 days of age**

Both GPC and OPCC samples were tested for their surface resistivity after 28 days of age and results are presented in **Figure 6**. Four separate readings were taken around the circumference of the cylinder at 90-degree increments (0°, 90°, 180° and 270°). This process was repeated once again, in order to get a total of eight readings which were then averaged. An in-depth view of the test results show that the resistivity of the GPC samples increases by increasing the curing temperature and duration. This ongoing increase in resistivity is due to a continued geopolymerisation reaction following gelation. As the gel structure develops and becomes more cross-linked, the pore structure would be more disconnected leading to a reduction in the ions/electrons flow. This again confirms the fact that heat curing at 75°C for a

period of 18 to 24 hours could be considered as the optimum curing condition for geopolymer concrete since it leads to the highest achieved resistivity.

**Figure 6. SR test results of GPC and OPCC specimens at the age of 28 days**

As shown in **Figure 7**, there is strong correlation between the pulse velocity and compressive strength of GPC. Although both surface resistivity and pulse velocity of GPC are increasing with the increase in compressive strength, however, the correlation between the surface resistivity and compressive strength seems not to be as good as the UPV. Yet, it could be stated that heat curing improves the microstructure of the GPC and results in a higher strength, performance and density.

**Figure 7. Pulse velocity and surface resistivity of GPCs versus 28-d compressive strength**

However, SR test results show that resistivity of GPCs are much lower than that of their counterpart OPCC which is in contradiction with the UPV test results. From all the results obtained in this study, it could be stated that the surface resistivity test could properly reflect the mechanical and microstructural characteristics of GPC. Although the resistivity of GPC samples are observed to be very low according to the AASHTO TP 95 criteria, this does not necessarily mean that they are having a high level of chloride penetrability since the AASHTO TP 95 is only applicable to conventional OPC concrete and not to the GPC. Basically, the high level of chloride permeability is supposed to be the result of high porosity and high volume of permeable voids in the structure of a material, however, the UPV results indicating that GPCs are having a similar or denser microstructure than their counterpart OPCCs. Thus, there should be

other factors rather than the permeability and porosity (open pore network) which could affect the resistivity of a material and result in the significant reduction in surface resistivity of GPC samples compared to their counterpart OPCC. Conductivity of the pore solution is most probably an important contributor to the conductivity of the final material network structure. In case of geopolymer concrete, there are a large amount of mobile metallic ions such as  $\text{Na}^+$  in the pore solution which may affect the resistivity test measurements.

A further study is required to directly measure the chloride permeability of the GPC such as natural diffusion or ponding test. Identical GPC specimens should be tested for both surface resistivity and chloride permeability in order to set out new criteria against which the chloride penetrability of GPC could be judged.

## 5. Conclusions

Based on the AASHTO TP 95 limits, the low-calcium fly ash-based GPC investigated in this research work is prone to have high level of chloride penetrability since they were showing a very low resistivity. However, the UPV results showed that the GPCs are having a similar or even denser matrix than their counterpart OPCC which should basically results in higher resistivity. The reason for the observed contradiction might be the higher conductivity of the GPC's pore solution compared to OPCC which has nothing to do with chloride penetrability but could significantly affect the SR test measurements.

Hence, the true justification for the use of this accelerated test method (SR test) has to be based on how well the results correlate to long term diffusion test. Therefore, a further study is required to directly measure the chloride permeability of the GPC such as natural diffusion or ponding test. A more comprehensive research on the long term diffusion of the material is currently under process by the authors, following ASTM C1543 and NT BUILD 443 standard test methods, and results will be published in due course.

**Abstract:** Geopolymer concrete (GPC) is considered as a very interesting alternative for ordinary Portland cement (OPC) concrete, because it needs less energy and emits a lot less carbon dioxide during the production process; which comes from employing industrial by-product precursors such as fly ash and Ground Granulated Blast Furnace Slag (GGBS). Reaction of these materials which are rich in aluminium and silicate with alkalis will form a highly cross-linked aluminosilicate binder which can develop high early-age mechanical strength and has a good performance in elevated temperatures, freezing-thawing cycles and against chemical attacks. However; there are some concerns over the durability aspects of these types of concretes and their long-term performance have yet to be assessed; particularly when it comes to the corrosion of reinforcing bars in GPC. In the current paper, the results of corrosion experiments on a number of chloride contaminated reinforced GPC samples which are manufacture using a blended low calcium (class F) fly ash and slag cement are reported. The initiation phase of corrosion is accelerated to study the propagation phase. Corrosion parameters such as free corrosion potential, polarization resistance and Tafel constants are investigated and compared to the reported values for OPC concrete. Direct mass loss measurement is carried out as well. Results show that the conventional test protocols which are used for OPC concrete can be applied to GPC. Besides, GPC can perform as well as a similar strength OPC concrete during the propagation phase of corrosion in marine environments.

**Keywords:** Geopolymer Concrete, Low-Calcium Fly Ash, Durability, Corrosion

## 1. Introduction

Over the last two decades, geopolymer concretes (GPC) have emerged as novel engineering materials with the potential to become a substantial element in an environmentally sustainable construction and building products industry [1–4]. GPC is the result of the reaction of materials containing aluminosilicate with an alkali solution to produce an inorganic polymer binder. Industrial waste materials such as fly ash and blast furnace slag are commonly used as the source of aluminosilicate for the manufacture of GPC due to the low cost and wide availability of these materials. Geopolymer binders can provide reduction of embodied CO<sub>2</sub> of up to 80% compared to OPC binders. Despite the very different chemical composition and reactions of geopolymer binders they exhibit many of the characteristics of traditional concretes [5,6]. The workability of freshly mixed geopolymer concretes and the mechanical characteristics of the hardened material appear to be similar to those for traditional OPC concretes. However, the quantity of available durability data such as chloride ingress properties or corrosion rate of embedded reinforcing steels, is limited and the long-term performance of GPC structures is yet to be determined [4]. Low calcium fly ash (Class F) GPC has been reported by some researchers to have lower chloride diffusion coefficients, chloride content and porosity compared to high calcium (Class C) fly ash GPC and OPC concrete [9], while others have found that the exact raw materials and mixture design can result in varying performance [10]. Previous studies reveal that due to the high alkalinity of the pore system, fly ash based geopolymeric binders can passivate the reinforcement steel as effectively as Portland cement binders [11–15]. Type and concentration of the alkaline activators have also been found to play a very important role in the stability of passive film [16,11,15]. While performance of fly ash GPC is observed to be similar to OPC concrete in passive state [12,15], There is not a consensus among researchers regarding the performance of low-calcium fly ash GPC compared to OPC concrete in severe marine environments during the propagation phase of corrosion [15,17,18].

In this paper, tests carried out using a blended class F fly ash and slag reinforced GPC are reported. Corrosion experiments were performed in order to assess the evolution of the steel corrosion potential and the linear polarization resistance with the chloride contamination. The Tafel constants are evaluated as well. The work aims to assess if existing testing methods and recommendations commonly used for OPC based concrete are suitable for GPC.

## 2. Experimental program

### 2.1 Geopolymer concrete mix and batching

The mix proportioning of the raw material as well as the stockpile/supplier details are provided in Table 1. The aggregate's mass shown in Table 1 is in the saturated surface dry (SSD) condition. The alkaline solution used was a mixture of 12 molar sodium hydroxide (NaOH) solution and sodium silicate ( $\text{Na}_2\text{SiO}_3$ ) solution with a ratio of 1:2.5 (by mass).

**Table 1: GPC mix proportions**

Material	Kg/m <sup>3</sup>
Coarse aggregate (10 mm nominal size crushed basalt)	1135
Fine aggregate (Sydney sand)	705
FA (Eraring Power Station, New South Wales, Australia)	200
Kaolite HPA (Callide Power Station, Queensland, Australia)	55
GGBFS (Blue Circle Southern Cement Australia)	45
Sodium hydroxide solution (NaOH)	45.7
Sodium silicate solution ( $\text{Na}_2\text{SiO}_3$ )	114.3
Free water	60

After casting, moulds were sealed and stored in a humidity chamber at 40°C for 24, followed by another 24 hours of curing at 80°C in hot water bath. Thereafter, samples were stored in a controlled room with a fixed temperature of  $23 \pm 2$  °C and relative humidity (RH) of 50% until the testing dates. The average compressive strength and elastic modulus of the concrete at 28 days were 54.5 MPa and 23.8 GPa respectively.

### 2.2 Corrosion experiments

To prohibit any external corrosion, normal ductility grade, 12 mm deformed bars with 500 MPa yield strength were embedded in the concrete. The deformed bars were cut and machined at both ends and then glued together with acrylic tubes. An electrical wire was welded on each steel bar to perform electrochemical measurements (**Figure 1**). The initiation period of the chloride-induced corrosion process (i.e. chloride diffusion through the concrete cover) was accelerated by drying samples in the oven, followed by alternative wetting/drying cycles in 35 gr/l NaCl solution and in controlled room respectively. This method has been already used for traditional OPC concrete [19] and allows obtaining a total chloride content of around 0.6% of binder mass after only 24 hours of immersion, which is beyond the suggested threshold chloride concentration values required to destroy the passive layer around the bars [20,21].

**Figure 1: GPC Specimen configuration**

Alongside with the 9 active samples whose initiation phase of corrosion was accelerated, 6 samples were submerged in tap water for 6 weeks to be saturated and used for passive condition corrosion assessment. Electrochemical measurements are performed using a potentiostat. Free corrosion potential ( $E_{corr}$ ) was determined by open circuit measuring of the potential difference between the reinforcing bar and a saturated calomel reference electrode (SCE) while the stability of the half-cell potential was controlled beforehand. In order to monitor the time-dependent corrosion activity, the linear polarization resistance technique (LPR) was carried out in a limited range of over-potentials ( $E-E_{corr}= -20$  to  $+20$  mV) to avoid introducing any irreversible change into the system. To measure the corrosion current density and consequently the electrochemical mass loss by means of Faraday law, the destructive Tafel tests were conducted over a large range of overpotentials ( $E-E_{corr}= -200$  to  $+200$  mV) at 5 different time steps for active samples within the whole period of experimental program. The Tafel constants were measured to calculate the “B” parameter in the Stern-Geary equation [22,23]:

$$I_{corr} = \frac{\beta_a \beta_c}{2.3 R_p (\beta_a + \beta_c)} = \frac{B}{R_p} \quad \text{(Equation 1)}$$

Where  $I_{corr}$  is the corrosion current,  $R_p$  is the polarization resistance measured by conducting a LPR test and  $\beta_a$  and  $\beta_c$  are anodic and cathodic Tafel constants, respectively. A sweep rate of 10 mV/min is used for both LPR and Tafel tests [24]. To verify the results of LPR tests, Gravimetric mass loss measurements were conducted on samples which had been already used for Tafel tests based on the ASTM G1-03 protocols [25].

### 3. Experimental results

**Figure 2** shows variation of the corrosion potential ( $E_{corr}$ ) values and compares them to the reference values [26] which are commonly used to assess the corrosion state of OPC concrete structures. Since the active samples were also used to carry out the destructive Tafel test throughout the monitoring period, the average values are representative of only 4 data points at the end of the testing period.

**Figure 2: Evolution of the average free corrosion potential ( $E_{corr}$ ) and the suggested reference values for OPC concrete (the initiation phase is accelerated)**

After only 7 days in the chloride solution, the measured corrosion potentials fall into the severe corrosion zone which can be attributed to the initial very low corrosion potential and the high chloride content of

samples due to the oven drying (accelerating the initiation phase). The corrosion potential reduction is about -200 mV in average which is comparable to the potential drop criterion which is used to distinguish between the passive and active steel reinforcements in OPC concrete [27,28]. Thus, the corrosion potential method seems to be suitable to assess qualitatively steel corrosion in GPC. However, the absolute value of the average corrosion potential of passive specimens (before chloride contamination) is more negative than the range in which reinforced Portland cement concretes are considered passive (i.e.  $E_{corr} > -140$  mV vs SCE). The more negative values are not necessarily indicative of a higher risk of corrosion; this can be attributed to a high concrete moisture content and lack of oxygen at the steel-concrete interface [29]. After 28 days, all the values have remained in the severe corrosion zone throughout the testing period; although, The absolute values of corrosion potentials are more negative than the reported figures for OPC concrete in active phase of corrosion, ranging between -550 and -650 mV vs SCE. These experimental results highlights the need for carefully interpretation of the measured corrosion potential values when assessing corrosion in reinforced GPC by using the reference values of corrosion potential commonly used for OPC concrete.

**Figure 3** shows the measured  $R_p$  values of GPC samples compared to Andrade and Alonso [23] recommendations for OPC concretes. Also, results of a set of similar tests on OPC concrete samples from Zhang et al. [19] with a similar fabrication method and almost the same exposure condition as the current study is presented in **Figure 3**. The presented OPC concrete results are the average of four data points. The  $R_p$  trend is consistent with the corrosion potential trend and the polarization resistance values fall into the high corrosion rate range after just two cycles of exposure to NaCl solution which means the initiation phase is successfully accelerated. The measured polarization resistance of passive specimens (the data point at day 0) are lower than expected according to Andrade and Alonso [23] recommendations (i.e.  $R_p > 250$  k $\Omega$ .cm $^2$  for passive samples). This suggests that the OPC concrete classifications might not be suitable for GPC samples in passive state. Moreover, the average polarization resistance trends for GPC and OPC concrete samples exhibit a remarkably good match and as a result, a similar performance of Portland cement binders and geopolymer binders in chloride contaminated environments during the propagation phase of corrosion (after depassivation of reinforcing bars) can be concluded.

**Figure 3: Polarization resistance for GPC and OPC concrete specimens before and after immersion in the chloride solution along with the suggested reference values for OPC concrete (the initiation phase is accelerated)**

By polarizing samples over a large range of over-potentials and using the Tafel plot method, parameters such as Tafel constants (and hence the B coefficient in Stern & Geary equation [22]) and corrosion current densities (and consequently electrochemical mass loss by means of Faraday law [23]) are calculated and presented in Table 2. It can be implied that using the conventional value of  $B=26$  [30] which is commonly used to calculate the corrosion current density of corroding OPC concrete systems instead of the actual values of B coefficient can lead to erroneous results when applied to GPC samples. Moreover, the recorded

values of predicted mass loss to actual mass loss ratios are similar to the reported values for corroding OPC concrete systems [30] which suggests that the employed electrochemical techniques have predicted the mass loss within a reasonable level of accuracy.

**Table 2: Stern-Geary “B” coefficient, predicted and actual mass losses**

Time after the first Immersion (day)	B (mV)	Electrochemical mass loss (mg/cm <sup>2</sup> )	Gravimetric mass loss (mg/cm <sup>2</sup> )
49	57	4.28	13.66
112	52	12.01	20.35
288	55	62	26.14
336	46	82.93	61.46

### 3. Conclusion

The work aimed to assess the performance of reinforced GPC in chloride contaminated environment during the propagation phase of corrosion and examine if existing testing methods and recommendations commonly used for OPC based concrete to assess steel corrosion are suitable for low calcium GPC. The half-cell potential measurements and the polarization resistance techniques as well as gravimetric mass loss measurements were used. Results show that both corrosion potential and polarization resistance reduce significantly with chloride contamination with a similar magnitude as the ones usually observed for reinforced OPC concrete. Indeed, both  $E_{corr}$  and  $R_p$  are lower than the reported values for reinforced OPC concrete, particularly in passive state and hence recalibration of the reference values traditionally used for OPC concrete might be required. The electrochemical mass losses compare rather well with the gravimetric mass losses; thus, the employed electrochemical techniques appear to be usable to assess steel corrosion in low calcium fly ash based GPC. However, special consideration should be given to analysing the results of electrochemical tests carried out on reinforced GPC in passive condition. The observed strong similarity between the measured trends of polarization resistance of reinforced GPC samples and their OPC counterparts along with the results of mass loss measurements can be interpreted as the equal performance of GPC and OPC concrete during the propagation phase of corrosion (after depassivation of reinforcing steel) in marine environments.

### 4. Acknowledgement

This research is funded by the CRC for Low Carbon Living Ltd supported by the Cooperative Research Centres program, an Australian Government initiative. The experimental work was carried in the concrete Laboratory of the School of Civil and Environmental Engineering at the University of New South Wales. The assistance of the laboratory staff is also acknowledged.

**Abstract:** Geopolymer is regarded as a green alternative to the current ordinary Portland cement. It uses industry wastes, such as fly ash, as source materials. Variations between fly ash lead to large differences in the performance of the geopolymer derived from them. This study aims to address the effects of physical, crystallographic and chemical characteristics of fly ash on geopolymerisation performances and the strength of deriving materials. Physical and glass chemistry are combined all these factors together to develop a single parameter, a fly ash reactivity index. This comprehensive index can be a powerful tool in evaluating the suitability of fly ash for the formation of high strength geopolymer, and can be further used to predict the performance of the resulting fly ash-based geopolymer materials. A reliable and predictable geopolymer will be a big step moving the new and greener cement towards the acceptance by industries.

**Keywords:** fly ash, geopolymer, reactivity index, glass, crystalline, particle size.

## 1. The problem of using fly ash as feedstock

Geopolymer is increasingly regarded as greener alternative cement-like binder [1-3]. It is a synthetic inorganic polymer produced by the alkali activation of aluminosilicates. This reaction takes place at room temperature or slightly elevated temperatures, totally bypassing the high temperature calcination process with significantly less energy consumption. By not using limestone, it also eliminates the chemical CO<sub>2</sub> emission during calcium carbonate decomposition, resulting in a binder with low CO<sub>2</sub> emissions [4,5]. Furthermore many industry waste materials, such as power station fly ash [6,7], blast furnace slag [8,9], alumina refinery red mud [10] and reservoir sludge [11], can be used as the aluminosilicate raw materials for geopolymer manufacture. While researchers still debate the reaction mechanism taking place during geopolymerisation, many agree the reaction can be divided into three main stages: (1) dissolution of the source material to form aluminate and silicate species; (2) aluminosilicate gel formation; and (3) condensation forming the 3D network [12], which gives geopolymer a set of properties that are equivalent, or even superior, to those of ordinary Portland cement (OPC).

Fly ash, a waste material from coal fired power stations, is commonly used for geopolymer manufacturing. However, inconsistent mineral compositions of source coal and variations in the combustion process can result in large variations of resulting fly ashes, in terms of the chemical and physical characteristics, varying from one source to another, and sometimes from one batch to another from a single power station. These variations could lead to varying properties of the deriving geopolymer [13-15], which will hinder its acceptance by civil and construction industries [16].

Chemical composition, particle size and morphology of fly ash are commonly used to characterise fly ash. In our previous research [17], five fly ashes with varied compositions were used to study the geopolymer synthesis. The results showed that there was no single correlation between the bulk composition, Si/Al molar ratio, reactive SiO<sub>2</sub> or fly ash particle size and the compressive strength of the derived geopolymers, as shown in Figure 1. Despite the use of many techniques to characterise and classify fly ash for geopolymer synthesis [18-20], the absence of a comprehensive method to effectively evaluate the raw fly ash and its variables has become one of the biggest barriers for geopolymer being fully adopted by the industries, especially in civil and construction industries, where predictable and consistent performance is critical.

In this paper we will present our new understanding on the behavior of fly ash during geopolymerisation, and the effects of physical, chemical and crystallographic factors of fly ash. We introduce the concept of a reactivity index to find a correlation between the fly ash characteristics and the properties of the resulting geopolymer. This proposed reactivity index can be used to assess the suitability of fly ash as the source material for geopolymer; it can also be used in the design of the activator system to match the fly ash

reactivity, which will achieve the maximum geopolymerisation with the minimal residual alkali solution. Knowing the extent of geopolymerisation will make the prediction of the properties of the resulting materials possible.

Figure 1. Compressive strength of geopolymers produced from different fly ashes. The inserted table shows the compositions and particle sizes of the ashes [17].

## 2. How the properties of fly ash affect the strength of geopolymer

### 2.1 Physical characteristics

Fly ash typically has a spherical morphology. Figure 2 shows the fly ash particles from fly ash A, B and E. Such a spherical shape is beneficial to the geopolymer formation as it results in good workability at low liquid/solid ratios [21]. The medium particle size for each of the fly ashes is given in Figure 1. Fly ash A has the smallest particle size, with medium size 7.6 µm. Fly ash B and D are in the middle with a particle size of about 20 µm, while fly ash C and E are the largest at about 30 µm. With the assumption that fly ash particles are perfectly spherical, the specific surface area (SSA) can be estimated from the particle size data from a particle size analyser (PSA). The results are listed in Table 1.

Figure 2. SEM images of fly ashes showing fly ash A (a) has much finer and fewer irregular particles than fly ash B (b) and E (c).

Table 1. Physical characteristics of fly ash particles. Residual carbon is determined by thermogravimetric analysis.

Sample	Geometric SSA by PSA, m <sup>2</sup> /g	Accessible SSA by BET, m <sup>2</sup> /g	Carbonaceous, mass%	Particle density, g/cm <sup>3</sup>	Packing density, g/cm <sup>3</sup>
A	2.1	1.9	0.6	2.3	1.4
B	2.4	2.5	0.5	2.0	1.2
C	0.9	1.2	0.9	2.1	1.4
D	1.0	1.1	0.9	2.0	1.3
E	0.6	0.8	0.7	1.8	0.9

Fly ash B has the highest SSA of 2.4 m<sup>2</sup>/g, followed by fly ash A 2.1 m<sup>2</sup>/g; while fly ash E has the lowest surface area 0.6 m<sup>2</sup>/g. We also used the Brunauer-Emmett-Teller (BET) method [22] to measure the SSA directly. The two sets of SSA have the similar order, however there are differences in the absolute value for a particular fly ash, which is caused by the particle shape and residual carbon. The shape of particles affects the surface wetting [21]. The fly ashes B and E contain many irregular particles (Figure 2), which may require a thicker liquid layer on the surface to overcome the friction for particle sliding. In addition to the particle shape, the residual carbon affects their SSAs and then liquid requirement as well. Table 1 lists the residual carbon as determined by thermogravimetric analysis. In combination with the BET surface areas, it is able to estimate the SSA of carbon particles in each fly ash, in a range of 25 - 60 m<sup>2</sup>/g, which is in agreement with the reported value [23]. The high SSA of the carbon particles leads to a high liquid requirement. In this study, as the residual carbon has not been removed from the samples, we assume that the SSA estimated by PSA is more accurate to describe the fly ash particle characteristic, therefore it is chosen for the evaluation of reactivity of fly ash.

Particle surface area is where the fly ash contacts with the alkaline activator solution and makes the dissolution occur. In the geopolymer formation process, the activator solution wets the fly ash particles, forming a layer of liquid around the surface. We describe this liquid requirement as 'surface layer volume (SLV)', as shown in Figure 3. It is one of the most important physical properties affecting the reactivity of fly ash in geopolymer formation. It has been reported that the SSA of fly ash has a direct correlation to the compressive strength of the derived geopolymers [24]. Our measurement shows that fly ash B has the highest SSA. It would be expected that this fly ash will have the fastest and largest dissolution and geopolymerisation, which will lead to the highest strength. But our strength results show that fly ash A has the highest strength. There must be other factors that contribute to the strength development in geopolymer system.

**Figure 3. A sketch of fly ash particles mixed with liquid activator.**

Here we introduce an additional geometric parameter, the inter-particle volume (denoted IPV), as a physical characteristic of fly ash to be incorporated into the ash activity index calculation. As indicated in Figure 3, when polydisperse particles are randomly packed up, small particles fill in the empty spaces between large particles to increase the packing density. However, there are still gaps between particles, forming the IPV. When a liquid activator is mixed with a dry fly ash powder, the SLV contributes to wetting the fly ash particles, while at the same time, additional liquid is required to fill the IPV to reduce the surface tension of activator (to air), lubricating the system to provide a necessary workability to the paste by enabling it to become a coherent fluid rather than a partially-cohesive granular system. For a given volume of fly ash, we are able to calculate the IPV by subtracting the particle volume from the total volume. When a liquid activator is mixed with dry fly ash powder, the SLV contributes to the wetting the fly ash particles. Additional liquid is required to fulfill the IPV to provide a necessary flowability (140-170 mm in this study) for paste. In general, the smaller the IPV, the less liquid required. The total liquid

requirement for a geopolymer system is the sum of the SLV and the IPV, which are determined by particle surface area and packing density, respectively.

After geopolymerization, the excess liquid which is introduced into the system to provide the workability will eventually evaporate, leaving a certain volume of pores, if the space is not able to be filled by geopolymeric gels. It is well known in conventional cement and concrete systems that a smaller IPV will generate a more compact binder with lower porosity [25]. A lower porosity usually means a higher strength [26]. In Figure 4 we plot the SLV (using SSA) and IPV of the 5 fly ashes together with the compressive strength of the resulting geopolymers. Some kind of correlation is starting to show between the strength and these two physical characteristic parameters. In the 5 fly ashes, SLV is generally proportional to the strength while IPV is inversely proportional to the strength.

**Figure 4.** The relationship between specific surface area and inter-particle volume ratio of fly ash and the compressive strength of deriving geopolymer.

## 2.2 Crystallographic characteristics

Fly ash is the fine particle residue of coal after combustion. During coal combustion (temperatures may exceed 1600°C), most inorganic matters (except quartz) presented in coal particle melt. Molten aluminosilicate droplets cool rapidly and form amorphous, and some as crystalline, phases. The amorphous phase is described as aluminosilicate glass. Quartz and mullite, which are unmelted or crystallised during the melt droplet solidification, are generally presented as crystals in fly ash. Different phases in fly ash have substantially different dissolution rates and extents in alkaline solution [17].

**Figure 5.** SEM images of dissolved fly ashes by sodium silicate solution (4 M NaOH+1.3 M SiO<sub>2</sub>) at a liquid to solid ratio of 35 g/g, 80°C for 6 hours and the residual particles in geopolymer binders after 28 days: (a) dissolved fly ash A; (b) geopolymer A; (c) dissolved fly ash B; (d) geopolymer B.

Figure 5 shows the images of fly ash particles after dissolution in alkaline solution and after geopolymerisation. The crystals in fly ash particles remain unattacked or much less dissolved under the two conditions. The glassy phases are dissolved and participated in the geopolymerisation. This fact suggests that the molar ratio based on the bulk chemical compositions, which is used in most literatures for geopolymer design, is actually giving inaccurate information, if not misleading. We need to use the glassy phases and their compositions, rather than the overall composition, to calculate fly ash dissolution and geopolymerisation.

**Table 2. The mineralogical compositions (wt.%) of fly ashes as determined by Rietveld quantitative XRD method with 20 wt.% of internal reference material (corundum).**

Components (ICSD no.)	A	B	C	D	E
Mullite (66448)	18.7			15.7	24.1
Mullite (43289)		13.6	15.3		
Quartz (89280)	3.1	2.6	6.5	5.0	13.1
Magnetite (43001)	2.5	1.3	2.4	0.9	
Hematite (15840)	1.5	0.8			
Glassy phases	74.2	81.7	75.8	78.4	62.8
$W_{RP}$ , %	3.0	6.0	3.9	3.3	5.0

We used the RQXRD method [19] to determine the mineral components in the 5 fly ash samples, with the results listed in Table 2. RQXRD is better suited for quantitative analysis of fly ash as a complex material than other methods of analysis of XRD data, such as the reference intensity ratio method [27], because it uses the full profile of the diffraction patterns, which minimises the inaccuracies in the raw data raised from the systematic errors, such as peak overlap, preferred orientation, sample broadening and the lack of a pure standard [28]. This is particularly suitable when the fly particles in this study were sampled without any classification and grinding to avoid phase changing or separation. The results show that the fly ash E has the lowest amount of glassy phases. If it is assumed that glassy phases are the reactive components in geopolymerisation [29], fly ash E will certainly generate a weaker binder. However, the amounts of glassy phases in the other four fly ashes are not significantly different compared to their strength variations. This implies that the quantity of glassy phases is insignificant. The composition of glass phases is more likely another key factor that affects the 'apparent' reactivity of fly ash in geopolymerisation, through controlling its reaction rate and extent.

Table 3 shows the compositions of glassy phases in each fly ash. It is calculated by subtracting the mineral compositions (assuming all of the crystalline phases are 'pure') from the bulk composition determined by XRF analysis. This is an important correction to the use of bulk composition only (Figure 1).

**Table 3. Chemical compositions in the glassy parts of fly ashes as calculated from the bulk composition and mineral compositions. 'Others' includes  $P_2O_5$ ,  $SO_3$ , trace components and LOI, wt.%.**

Fly ash	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	CaO	MgO	K <sub>2</sub> O	Na <sub>2</sub> O	Fe <sub>2</sub> O <sub>3</sub>	TiO <sub>2</sub>	Others
A	40.0	13.0	4.2	1.5	0.5	0.7	10.2	1.5	2.5
B	46.2	23.5	6.9	0.9	0.6	0.3	1.0	1.6	0.8
C	41.7	23.1	1.1	0.8	0.2	0.1	5.0	2.1	1.7
D	58.6	10.5	1.0	0.5	2.1	0.5	2.7	0.9	1.5
E	52.4	6.3	0.1	0.1	0.5	0.0	1.2	1.4	0.9

### 2.3 Chemical composition of glassy phases

During the geopolymerisation, the dissolved silicate and aluminate species in aqueous solutions are condensed to form geopolymeric gels. In this process [SiO<sub>4</sub>] and [AlO<sub>4</sub>] tetrahedral act as 3D network former sites while alkali cations (Na<sup>+</sup> and K<sup>+</sup>) act as charge balancer for the negative charge of anionic tetrahedral Al centre. The 3D network structure is the backbone, contributing to the strength of geopolymer. It is evident that the larger the quantity of dissolved glassy phase, the more sodium (or potassium) aluminosilicate hydrate gel (N-A-S-H) is formed, contributing to higher strength of the

hardened products. Therefore, as mentioned above, fly ash containing a higher quantity of the glassy aluminosilicate phase will generate a geopolymer with higher strength.

Si and Al are the network formers. It is reported that the availability of Al is critical to the properties of geopolymers [30,31]. Fly ash with large amounts of reactive Al usually generates high strength geopolymer [32]. In the 5 fly ashes we studied, fly A, B and C have high Al contents. So in the network formers of Si and Al, apart from their total quantity, the ratio of Si and Al in gel phases may also affect the mechanical properties of geopolymers [33]. The formed gels have varying Si/Al ratios, depending on the composition of the dissolved glassy phase and the alkaline activator. A more recent study [34] found that the strength of metakaolin-based geopolymer increased with the Si/Al ratio increase from 1.80 to 2.33 when  $Na/Al < 1$ . This is also probably due to the decreased porosity by mixing more dissolved silicate. Apparently, it is difficult to define an 'optimal' Si/Al ratio of geopolymeric gels for high strength.

The alkali cations, as the network modifiers, play important roles in affecting the intrinsic properties of geopolymeric gels. Alkali cation  $Na^+$  acts as a charge balancer, located around the negative site of  $[AlO_4]$ . It could present in the pore solution at a molecular level. This role helps the system to achieve stability. Alkali earth cations ( $Ca^{2+}$ ,  $Mg^{2+}$ ) may displace alkali cations through ion exchange and have similar roles as charge balancers. However, when the total charge of alkali and alkali earth cations (M) exceeds the concentration of  $[AlO_4]$ , alkali and alkali earth cations can also work as network modifiers, forming more non-bridge oxygen sites. This role prevents the formation of a polymer structure of a large molecular. From this point of view, alkali and alkali earth cations may have an optimal concentration, which is probably  $M/Al = \sim 1$ , i.e. fully compensating the negative charges of  $[AlO_4]$  in a geopolymer network. Indeed, it was reported that a maximum compressive strength was obtained at around  $Na/Al = 0.965$  in metakaolin-based geopolymers, with lower strengths observed at lower or higher  $Na/Al$  ratio [34]. It is probably reasonable to use the difference between  $(M+Me)/Al$  and 1 to indicate the integrity of the network.

If activator addition is designed to be sufficient, partial dissolution of glassy phases will increase the actual M/Al ratio in the resulting gels. Unfortunately, to date there are no effective methods developed for the prediction of the reaction extent of fly ash. It is therefore difficult to propose an optimal dosage for alkali addition in the design of the geopolymer mix. Again, if glassy phases are assumed to be fully dissolved, the M/Al values range from 0.7 in geopolymer C to 2.0 in geopolymer E. The closest value to 1 is obtained in geopolymer B, at 1.2, which is believed to partially contribute to its high strength. We want to emphasize the importance of this factor in the geopolymer formula, particularly for those systems with predictable dissolution extents of raw aluminosilicate.

#### **2.4 The reactivity index – a tentative format**

In the above results and analysis, we have shown three characteristics of fly ash having significant impacts on its reactivity: (1) physical properties, in particular, SLV affects the dissolution rate and extent of geopolymerisation reaction of fly ash particles, and IPV affects the liquid requirement and consequently the porosity in resulting geopolymer; (2) crystallographic characteristics decide it is only the glassy phase that participates the geopolymer formation; and (3) chemical characteristics of glassy phases determine the concentrations of network formers and network modifiers, which are combined to form the geopolymer 3D network.

We combine the three factors in a comprehensive function provided below:

$$RI = f(SLV, IPV, NF, NM) \quad (1)$$

where SLV and IPV are the effect of the physical characteristics; NF represents the contribution of network formers; NM presents the effects of network modifiers, which can be quantified by the difference between concentrations of M and Al.

At this stage, we have not obtained enough data to complete the format of this function; in particular, the magnitudes of each factor. For each of these identified factors, we have planned special experimental programs. For example, while keep other factors constant, we can study the influence of NF by using synthesized glass to mixing with synthesized crystals, such as mullite and quartz. In this way, we can figure out the basic relationship between NF and compressive strength or other mechanical properties. We can incorporate the relationships for each factor into a comprehensive equation, and finally have the reactivity index.

### 3. Conclusions

In summary, we proposed, for the first time, a reactivity index (RI) for fly ash, which combines the physical, crystallographic and chemical characteristics of fly ashes into one parameter. This comprehensive RI can be an effective tool in evaluating and grading the suitability of fly ash for geopolymer formulation. Then from the extent of the geopolymerization, we can predict the performance of the resulted fly ash-based geopolymer materials. A reliable and predictable geopolymer is a big step to make the new materials acceptable for industry as the green alternative to the current OPC. We acknowledge that in a real situation, a completely full dissolution of glassy phases will never reach, however, our proposed reactivity index provides a reaction potential of a given fly ash.

**Abstract:** Currently, the analysis of the situation and potential future deterioration of concrete in dams affected by expansive reactions is considered a very complex problem. To evaluate and quantify the damage in the affected concretes, can be used complementary analysis such the assessment of macroscopic damage rating index (DRI), using optical stereomicroscopy, or determining the level of damage (DL) using electron microscopy techniques combined with X-ray microanalysis.

To determine the DRI polished concrete surfaces are prepared and evaluated using a stereoscopic microscope. During the observation the presence of microcracks and reaction products are observed and quantified with a relative weight to obtain the DRI. And, the damage of concretes is classified according to a certain ranges.

Also, the use of backscattering electron microscopy (BSE) combined with X-ray microanalysis (EDX) permits to evaluate the presence and degree of damage in concrete, due to internal expansive reactions, like ettringite formation or alkali-silica reaction. Then the deterioration degree of concretes is classified based on specific criteria of classification.

In this paper the results of assessment of concrete from dams are presented to evaluate the deterioration degree using both methodologies. Also, the classification of damage level obtained using macroscopic and microscopic techniques has been evaluated to analyze the relationship between these procedures to known the situation of the dam concretes.

**Keywords:** Damage Rating Index, Damage Level, expansive reactions.

## 1. INTRODUCTION

Throughout the useful life of concrete structures alterations can be produced as a result of environmental factors which could affect the loss of functionality in them, compromising the safety of the structures or the structural elements, according to the degree of deterioration [1], [2]. This deterioration might be associated with different types of factor: chemical, physical, mechanical, biological, etc. In some cases the origin of the damage is directly related to the characteristics of the components of the concrete (aggregates, cement, water, additives, etc.) and the interaction between them or with the environment. In the case of alterations arising from chemical reactions originating internally, in all cases water acts as a vehicle for the reaction and as a basic part of the expansive products formed. Within the expansive processes of an internal origin it is important to highlight, given its impact and the effects produced on the concrete, the alkali-silica reaction and the sulfate attack, although there are other phenomena of a physical origin that have an impact on the freezing and thawing cycles.

The alkali-silica reaction and the sulfate attack are phenomena brought about by the chemical reaction of different components of the concrete which give rise to the neo-formation of products whose main characteristic is that they are expansive.

The formation of these expansive products in the interior of the hardened concrete makes it overcome the resistance to traction of the material and gives rise to the formation of fissures. Another significant characteristic is that its appearance is affected by multiple factors, both proper to the material itself and its components as well as environmental conditions. The coincidence of influential factors and the manifestation of the damage, with similar characteristics, make it essential to carry out a suitable diagnosis in order to program actions on the structure and carry out repair work where deemed necessary. For a correct diagnosis of these phenomena a micro-structural analysis of the affected concrete is essential, specifically using electronic microscopy and microanalysis techniques, together with a correct interpretation [1].

The deterioration caused by the alkali-silica reaction and by sulfate attack can be differentiated using electronic microscopy and microanalysis techniques, considering the representativity of the samples of the structure [3]. On the other hand, could be possible also to observe the damage in concretes at optical microscopy level.

The damages caused by internal expansive reactions in the concrete can be diagnosed unequivocally by using micro-structural analysis techniques based on the study electronic microscopy combined with microanalysis by X-ray [1], by applying the damage level method (DL) [4]. Also, in several papers are described the consequence of ASR at microstructural level [5], [6], [7], [8]. However, it is essential to guarantee the representation of the samples in relation to the structure to be analyzed and the experience of the technicians to have a correct results.

The suitable diagnosis allows it to be established whether the deterioration observed is related with alkali-silica reaction, sulphate attack or the combination of the two processes. Likewise, it is possible to establish the origin of the damage, in spite of the alteration products having the same characteristics [4].

The damages caused by internal expansive reactions in the concrete also it can be diagnosed by using optical microscopy in polished samples, by applying the damage rating index (DRI).

The DRI consists in a semi-quantitative petrographic evaluation of damage in concrete either affected by ASR or other deleterious mechanisms [9]. However, the results can be significantly affected by the experience of the petrographer and since there is currently no standard test procedure available. The method can be fairly subjective and the results quite variable from one petrographer to another. The DRI method can provide very useful relative information when the examination of sets of cores from various parts of a structure (subjected to different exposure conditions or showing various external features of deterioration) is carried out by the same petrographer. The method also allows identifying the progress of ASR or other alterations than formed cracks when cores are extracted regularly from the same structural element and examined once again by the same petrographer. Although, until now the DRI method is currently not a standardized method and there are no accepted ratings for DRI results [10].

## **2. INSTRUMENTAL TECHNIQUES**

### *Backscattering electron microscopy and energy dispersive X-ray (BSE-EDX)*

The concrete samples were prepared and analyzed by BSE-EDX identifying the different structures and the distribution of its analyzing the elemental mapping associated with the images. The samples were imbibed in low viscosity resin, cutted and polished to generate a properly observation surfaces. Microscopic analysis has done with an electron microscopy JEOL JSM-5400 and with X-ray microanalysis OXFORD Link.

### *Optical microscopy*

The concrete samples were first cutted axially and then polished with a portable hand-polishing device. The polished concrete sections were prepared and examined using a strereomicroscope Nikon SMZ-2T.

## **3. CONCRETE SAMPLES**

For this study, concrete samples were extracted from different dams in operation. These dams are located in Spain, two buttress dams in the Northeast and an arch gravity dam in the Midwest. The current use of the dams is hydroelectric.

The concretes were manufactured with a cement type CEM I, without any addition. Aggregates used in the manufacture of the concretes of the two buttress dams, are classified according to standard ASTM C294 [11] as an arenaceous limestones. These limestones are compounds mainly of calcite, also containing quartz, feldspars and mica. Aggregate used in the manufacture of the concrete of arch gravity dam, is classified as a plutonic rock of granite type. This granite are compounds mainly of sodic and potasic feldspars, quartz and mica type biotite and muscovite.

Table 1 gives the location and details of the different concrete cores selected by this research.

## 4. TESTING METHODOLOGY AND RESULTS

### 4.1 Testing methodology

#### Damage level (DL)

The DL is a method which permits to determine the grade of damage and assign a level of damage based on the microstructural studies, by using micro-structural analysis techniques based on the study electronic microscopy combined with microanalysis by X-ray. The gradation of the damage for concretes affected by the alkali-silica reaction and sulfate attack is set out in Table 2, describing the degree of damage for each level, the type of product formed and their location within the material. In both types of expansive reactions five levels of damage are established, which are increased in accordance with the deterioration from 1 to 5, each level corresponding to: low (1), moderate (2), average (3), elevated (4) and extended to the total (5). For its part, the levels of damage associated to an alkali-silica reaction are named DLASR (Level of Damage caused by Alkali-silica Reaction) and DLSA (Degree of Damage by Sulfate Attack) [4].

**Table 2. Definition of damage code as a function of the damage level in concretes affected by alkali-silica reaction and sulfate attack [4].**

Damage by Alkali-Silica Reaction					
Damage Code	DLASR-1	DLASR-2	DLASR-3	DLASR-4	DLASR-5
Damage degree	Low	Moderate	Average	Elevated	Extended to total
Reaction products	Vitreous gels	Vitreous gels and microcrystallines	Vitreous gels, microcrystallines and microcrystalline products	Vitreous gels, microcrystallines and microcrystalline products	Vitreous gels, microcrystallines and microcrystalline products
Location of products	Pores	Pores+aggregates	Pores aggregates+aggregate-paste interfaces	Pores+aggregates+aggregate-paste interfaces+paste	Pores+aggregates+aggregate-paste interfaces+paste (↑fissures)
Damage by Sulfate Attack					
Damage Code	DLSA-1	DLSA-2	DLSA-3	DLSA-4	DLSA-5
Damage degree	Low	Moderate	Average	Elevated	Extended to total

Reaction products	Needle-shaped crystallisations	Needle-shaped crystallisations	Needle-shaped and prismatic crystallisations	Needle-shaped and prismatic crystallisations	Needle-shaped and prismatic crystallisations
Location of products	Small pores	Pores+aggregate-paste interfaces	Pores+aggregate-paste interfaces+paste	Pores+aggregate-paste interfaces+paste+small filled fissures	Pores+aggregate-paste interfaces+paste+filled fissures

### *Damage rating index (DRI)*

The DRI method consists in a count of the number of petrographic features of deterioration commonly associated to ASR on polished concrete sections on which a grid is first drawn (minimum 200 grid squares to be examined, 1 by 1 cm in size). These studies are made using stereomicroscope technique ( $\approx 16\times$  magnification). The DRI thus represents the normalized value (to 100 cm<sup>2</sup>) of the frequency of these features after the count of their abundance, over the surface examined, has been multiplied by weighing factors representing their relative importance in the overall deterioration process [12]. This method is applied in different works for structures affected by expansive reactions [13], [14], [15], [16], [17], [18], [19].

According to Grattan-Bellew, 2012, it is difficult, if not impossible, to determine the minimum DRI that is indicative of significant deterioration of concrete due to ASR. The problem is further complicated frequently by large differences in the DRI's measured by different operators. [20]. From this point of view the DRI factor could be used as a comparison tool between different parts of one structure or the same areas with the time.

Table 3 gives a list of those features and the weighing factors [9], which were used in this research.

**Table 3. Petrographic features and weighing factors for the DRI [9].**

<b>Petrographic features</b>	<b>Factors</b>
Closed/tight cracks in coarse aggregate particle (CrCA)	0,25
Opened cracks or network cracks in coarse aggregate particle (OCrCA)	2
Cracks or network cracks with reaction product in coarse aggregate particle (Cr+RPCA)	2
Coarse aggregate debonded (CAD)	3
Disaggregated/corroded aggregate particle (DAP)	2
Cracks in cement paste (CrCP)	3
Cracks with reaction product in cement paste (Cr+RPCP)	3

## **4.2 Results and discussion**

A calculation of DL, due to alkali-silica reaction and due to sulfate attack, and of DRI has been done to the different cores selected. Also, a comparison between both method of damage assessment is done to evaluate the relationship between them and value the most properly.

The results obtained by the application of DL method can be seen in the table 4. Table 4 shown the damage level of alkali-silica reaction (DL ASR), the damage level of sulfate attack (DL SA) and the combination of both damage (DL ASR-SA).

**Table 4. Results of the DL method for cores extracted from different dams**

UL-PC-14-02(3)	82
UL-PC-14-02(5)	172

The graphic of figure 2 represent the results obtained by the application of DRI method. Cells with different fill patterns give the proportions of each petrographic feature to the DRI value. By this method a single valuation is performed regardless of the damage type.

**Figure 2. Graphic of results of the Damage Rating Index (DRI) (See Table 3 for the acronyms).**

The correlation between the results obtained by the DL and DRI assessment methods is analyzed. It is intended to verify the potential relationship of a general analysis method (DRI) with a specific analysis method for the type of damage (DL).

To compare the results between the method of assessment and taken into account the results obtained, some intervals have been defined. Three groups of damage have been defined, moderate, medium and

high. In table 6 the details of the damage are shown with the classification of DL and DRI damage to the structure analyzed. In the Figure 3 the different quadrants are represented with the limits between them.

**Table 6. Classification intervals**

Damage	DRI	DL ASR	DL AS	DL ASR-AS
Moderate	<160	<1,5	<1,5	<3
Medium	160-220	1,5-3	1,5-3	3-6
High	>220	3-5	3-5	6-10

The evaluation of damage by DL method is considered as reference. Because it is possible to define clearly the origin of damage and qualify it. According with the reference of DL method the classification of intervals has the following characteristics:

- Good correlation with DRI method: Correlation values are localized in the quadrants 3, 5 and 7, according to the Figure 3
- The DRI underestimate the damage: Values sited in the quadrants 1, 2 and 4
- The DRI overestimate the damage: Values sited in quadrants 6, 8 and 9

**Figure 3. Thresholds for DL results ASR, AS and ASR-AS versus DRI.**

Figure 4 represent the correlation obtained by the different evaluation methods of damage, with values DL ASR (Damage Level caused by alkali-silica reaction) and values DL SA (Damage Level caused by sulfate attack) in relation with DRI damage.

**Figure 4. Correlation graphic DL versus DRI with values ASR and SA.**

Figure 5 represents the correlation between the evaluation of damage DRI and the values of the combination of damage by alkali-silica reaction and sulfate attack, DL ASR-AS.

**Figure 5. Correlation between DL and DRI by ASR-SA.**

Analysis of Figures 3 and 5 shown a good fitting for ASR and AS, due to the correlation values are located in the quadrant 3, 5 and 7. Although, the evaluation of AS by DRI method occasionally underestimate the phenomenon (some values are located in the quadrant 4) and eventually overestimate it (values located in quadrant 6). Also when ASR+SA are evaluated jointly there is a good correlation.

The divergence between the mesostructural level of damage (DRI) and the microstructural level of damage (DL) is related with the type of damage caused by each type of deterioration (ASR or SA). In the case of ASR the formation of gels produce a partial densification of the cement paste. And, with the evolution of the reaction the formation of cracks in aggregates, interfaces and cement paste. These types

of cracks are well detected by the DL method. Although, the evolution of SA damage produces the increase of cracks with crystallization of ettringites inside. These cracks are not detected properly by stereomicroscopy. Due to this the SA phenomenon is occasionally underestimate and produces a bad correlation between DRI and DL methods.

### **3. Conclusions**

The use of the DRI and DL evaluation permits define a comparative level of damage between the concrete of different areas of one structure and between different concretes.

The application of these methods of assessment shall be done by well-formed technical, it is necessary to take into account the operator factor.

The DL method of assessment permits to diagnosis the origin of damage (alkali-silica reaction, sulfate attack, frost, etc.), while the method of assessment DRI evaluate the presence of cracks and alterations without the consideration of their origin.

The correlation between the method DL and DRI is good when the alteration is related mainly with ASR. Although, when the main damage phenomenon is SA there is a underestimation of the damage level of the concrete. This is because the cracks are filled by the reaction products and are not clearly detected by stereomicroscopy.

The DRI method is consider more adequate to evaluate the concrete affected by alterations with open cracks, like ASR or frost. While DL method is adequate to evaluate the concrete with cracks opened and filled.

[aandrew.hunting@rmit.edu.au](mailto:aandrew.hunting@rmit.edu.au)

**Abstract.** As the effects of climatic change become more evident and extreme, there is growing pressure on seaport infrastructure stakeholders to ensure that their assets are resilient to the effects of a more aggressive and corrosive climate. In almost all previous literature on condition modeling of concrete structures, a static or at least annually cyclic environment is assumed. However, given the anticipated changing futures in climatic parameters, this research will re-affirm the need for more accurate modeling to ensure that the effects of the changing environment on concrete are quantifiable and suitable for use in industry given today's context of climate change. In response to a gap in understanding of the influences of the environment, first part of this paper describes simulated exposures which were established with variations of salinity, temperature, humidity, and concrete mix design; with the ability of isolating each variable individually. Using these results and a broad review of literature, a more holistic service life modeling approach is presented in the second part which derives quantitative projections of how climate change is already invariably changing the rates of chloride ingress into concrete structures. Preliminary outcomes from the model indicate that the seaport structures will require earlier maintenance intervention compared to the maintenance regimes derived current models.

**Keywords:** Chloride ingress, salinity, climate change, concrete

## 1. Introduction

The ingress of chlorides is the ability for chloride ions to penetrate through the concrete protection cover to the reinforcement bar which initiates the corrosion process within the reinforcing steel.

This process is the principal mechanism responsible for corrosion-related damage to concrete infrastructure and it is directly related to its surrounding environment. This link to the surrounding climate variables implies an added vulnerability of the service life of structures to climate change.

This phenomenon is currently costing western countries around 2.5% of their national annual GDP, or costing the world economy over \$1.8 trillion a year (Schmidt, 2009). This corrosive process occurs more rapidly in structures that are exposed to saline-ridden environments with traces of chloride (i.e. sea water) than what it does in areas without exposure to such chlorides (Emmanuel, Oladipo, & Olabode, 2012). This ingress will often take place through pore spaces in the cement paste matrix and paste-aggregate interfaces or micro cracks (Lindvall, 2007) (Shi, Xie, Fortune, & Gong, 2011).

Work presented here aimed to develop and validate a tool which allows understanding of the effect of changes in climatic conditions on chloride ingress in reinforced concrete, which will lead to initiation of corrosion.

Typically, the time taken for an asset to exhibit structural failure from the corrosion initiation is a shorter than the time taken for corrosion initiation to occur. Therefore, the impacts that vary the time to corrosion initiation (that being the parameters explored in this paper) will heavily impact the service life of the structure.

## 2. Probabilistic Models.

Several studies (Emilio Bastidas-Arteaga, Bressolette, Chateauneuf, & Sánchez-Silva, 2009) (Rajasankar & Iyer, 2006) have attempted to use probabilistic methods to encompass the influence of variables in deteriorating mechanisms of RC structures and understanding the drivers that decrease

the corrosion initiation time. Kong et al. (Kong, Ababneh, Frangopol, & Xi, 2002) presented a concise reliability analysis which illustrated the inconsistencies around concrete mix design, however the research was restrictive as it assumed a static chloride threshold and static environmental salinity.

Further to this research, Trapper (Val & Trapper, 2008) presented a two-dimensional modeling of probabilistic evaluation of corrosion initiation time, however did not manage to encompass the environmental variables such as temperature and humidity. This research utilises this probabilistic evaluation of initiation time and extend this knowledge to encompass environmentally dependent parameters which will feed off the A1B and A2 climatic projections outlined in the Intergovernmental Panel on Climate Change's (IPCC) (IPCC, 2013) 5th assessment report.

### **2.1. Chloride Diffusion.**

The parameters affecting the interactions between moisture, the diffusion of heat, and chlorine concentration was presented by (A.V. Saetta, R.V. Scotta, & Vitaliani, 1993) however the ionic nature of the diffusion of chlorides was neglected. (Johannesson, 1993) examined a numerical model that examined the spatial, time, and interdependent variables influencing the movement of chlorides however excluded the dependency of the surface temperature. Despite the modeling of chloride movement simplistically being considered to occur in a 1-D fashion (i.e. perpendicular to the surface), (J.S. Kong, A. Ababneh, D. Frangopol, & Xi, 2002) developed a model by (Y. Xi & Bazant, 1999) which removed the consideration of convection and formulated the ingress into saturated concrete.

#### **2.1.1. Fick's 2nd Law**

Chloride ingress is typically modeled with the assistance of Fick's 2nd law of diffusion which can be simply described as the random motion of free chlorides from a region of high concentration to a region of low concentration. Fick's second law is used to predict the time variation of the concentration of chlorides for one-dimensional flow in a semi-infinite solid. There have been several models created to expand on Eq1 ((Tang & Nilsson, 1992), (Amey & Miltenberger, 1998; E. Bastidas-Arteaga, Chateauneuf, Sánchez-Silva, Bressolette, & Schoefs, 2010; Frederiksen & Geiker; Saetta, Scotta, & Vitaliani, 1993)), however the law in its most basic form is:

$$\frac{\partial C(x, t)}{\partial t} = \frac{\partial}{\partial x} \cdot \left[ D \frac{\partial C}{\partial x} \right] \quad (1)$$

#### **2.1.2. Crank's Solution**

To transfer this law and solve it with Crank's solution, the assumption can be made that the diffusion coefficient  $D$  and the surface chloride remain constant as boundary conditions. The initial condition as the concentration of chlorides ( $C = 0$ ) for depth from concrete surface  $x > 0$ , at time of exposure  $t = 0$ . Crank's solution of Fick's 2nd law is given below whereby erf is the error function.

$$C(x, t) = C_s \cdot \left[ 1 - \operatorname{erf} \left( \frac{x}{2\sqrt{Dt}} \right) \right] \quad (2)$$

## 2.2. LIFE-365 modeling.

This study and others document the effects of temperature on the results of migration tests, however, there is contention into how this can be accurately mapped and numerically incorporated into modeling. The modeling application known as LIFE-365 (Bentz & Thomas, 2000) uses the absolute temperature in kelvin (K), in which U, is the activation energy of the diffusion process (35000J/mol),  $T_{ref}$  is the reference temperature – typically 293K (20 degrees) and R is the gas constant (8.314J/mol.K) (Ababneh, Benboudjema, & Y. Xi, 2003) which presents the equation to be:

$$D(T) = D_{ref} \cdot \exp \left[ \frac{U}{R} \left( \frac{1}{T_{ref}} - \frac{1}{T} \right) \right] = D_{ref} \cdot f(T). \quad (3)$$

Furthermore, in determining the effective diffusion coefficient, at any time t, for any given temperature, T, Equation 4 may be used:

$$D(t, T) = D_{ref} \cdot f(t) \cdot f(T). \quad (4)$$

Despite the increasingly widespread use of this tool, there is reasonable concern that its inclusion of localised temperature is based upon a seasonal cyclic environment, with no allowance for increases over long periods of time such as those derived from global warming. It is for this reason that further research and definitive solutions on climate change influences are included into the modeling.

## 3. The Surrounding Environment

### 3.1. The Climate.

Following the release of the IPCC's 5th report (IPCC, 2013), there has been firm conclusions drawn that the climate is changing and the degrees of change, notably with respect to temperature; will vary depending on the emissions scenario that will society will follow.

Within this paper, the author will be principally focus on one climate emission scenarios: A1B – a world with very rapid economic growth, for comparison, scenario A2 which illustrates a heterogeneous world with a direction towards a self-reliance and preservation of local resources is also discussed. The specific temperature increases for these emission schemes are shown in table 1.

**Table 1 - Temperature °C increase for A1B and A2 Climate Scenarios**

2030		2055		2090	
A1B	A2	A1B	A2	A1B	A2
0.7 ± 0.5	0.7 ± 0.3	1.4 ± 0.5	1.4 ± 0.3	2.1 ± 0.8	2.6 ± 0.6

These temperatures give an indicative view on what is expected within the above emissions scenarios at three distinct intervals and will later be used in the modeling of probabilistic chloride ingress data.

### 3.2. Effects of the surrounding environment.

Condition modeling of in-situ concrete assets is often a very demanding and laborious task given the extent of variables which can affect any given asset throughout any particular season. One study conducted explored (through both controlled and uncontrolled environments) the effects that ocean salinity and temperature had on the rates of chloride ingress into reinforced concrete. The results illustrated that both salinity and temperature were significant positive influences to rate of chloride ingress (Lindvall, 2007). Despite graphically demonstrating this relationship, there was no numerical relationship drawn between these two events – both within Lindvall's research and more broadly within literature.

With respect to temperature, many studies consider the chloride ingress process to take place under isothermal conditions (Yuan, Shi, Schutter, & Audenaert, 2009), however to negate this cyclic environmental trend; or to a greater extent – climatic change, would inhibit drawing an accurate understanding of the service life implications given the changing climate. Again, there is wide acceptance through both case studies (Durack & Wijffels, 2010; Hussain, 1993) and simulated experiments (Lindvall, 2007) that warmer environments will increase the rate of chloride ingress, however localised temperature influences are often not incorporated into ingress modeling as a parameters, despite it being one of the most influential environmental variables that affect the ion mobility of chlorides (Andrade & Castillo, 2003; Yang, 1999).

Finally, a finite-element framework was created by (Shafei, Alipour, & Shinozuka, 2012) explored the impacts of the physical characteristics of the concrete (mix designs and diffusion characteristics) and the external environmental variables to develop a framework to illustrate that the impacts of these variables have time-dependant and non-linear characteristics. Once again, the ability for this framework to incorporate the effects of a changing climate were negated.

#### 4. Mix designs of concrete.

The typical transport mechanism of the ingress of chlorides is through the process of diffusion through the concrete matrix. The effectiveness of this diffusion is often governed by the contents and proportions of the concrete mix which determines its porosity. Since aggregates can represent up to 75% of the volume of concrete, aggregate will always play a significant influence on the porosity of the concrete.

Basheer et al (L. Basheer, 2005) examined the influences of these proportions, specifically the size distributions of aggregates and found that there was an inverse relationship between the larger aggregates and the increase in concrete strength. Within this aggregate variability, (M.M. Azari, 1995) found that the relationship between chloride diffusion in high w/c ratio concrete mixes is often more prevalent in low micro silica content aggregates which in turn, will significantly affect the diffusion coefficient. A practical investigation into the effects of the w/c ratio is presented in part 1 below.

#### 5. Part 1: Experimental Methodology

As explored above, there is a need to develop a firm link between the effects of a changing environment and future deterioration modeling. The numerical relationship between the environmental influences and the ingress of chlorides will be extrapolated and used within the development of a prediction tool that uses IPCC data to predict long term deterioration.

##### 5.1. Environmental Simulations

There is a increasingly large number of variables that impact the ingress of chlorides into concrete and are usually related to the surrounding environment. In order to segregate the effects of each of these parameters, controlled testing environments were constructed in established humidity/temperature chambers and samples were sprayed intermittantly to simulate different chloride laden environments.

**Table 2 – Proportions of elements within synthetic saline solution**

<b>NaCl</b>	<b>58.490%</b>
<b>MgCL2 – 6H2O</b>	<b>26.460%</b>
<b>Na2S04</b>	<b>9.750%</b>
<b>CaCl2</b>	<b>2.765%</b>
<b>KCL</b>	<b>1.645%</b>
<b>NaHCO3</b>	<b>0.477%</b>
<b>KBr</b>	<b>0.238%</b>

<b>H3BO3</b>	<b>0.071%</b>
<b>SrCL2 - 6H2O</b>	<b>0.095%</b>
<b>NaF</b>	<b>0.007%</b>

The saline concentrations were synthetically produced with a product containing balanced proportions to simulate the concentrations established by the American Standards for Testing Materials (Materials, 2013). Once the concentrate was added, continuous monitoring of the saline levels was recorded to illustrate the effects of the concrete leaching and any evaporation from the tanks with any variances greater than 5% ppt (parts per thousand) duly re-adjusted.

Within the experimental stage of this paper, differing mix designs were selected to illustrate the impacts that mix design will have pore matrix structure and thus chloride ingress. Both a high strength – taken from the specification of a recent port development; and a control mix were used to illustrate the influences of the surrounding environment. Further, it has been widely recognized that a reduction in the water to cement ratio will result in a reduction to the number of voids within the cement pore matrix thus reducing the mobility of chloride ions permeating through the concrete. This investigation will also demonstrate how the vulnerability in concrete to chlorides can be minimized with a change in the mix design of concrete. It is expected that the pozzolanic admixtures in the high strength mix may also provide some resistance to the ingress of chlorides, however this paper will focus primarily on the water/cement ratio being the dominating determinate for the chloride resistance of the concrete.

**Table 3 – Mix designs of concrete samples**

	<b>High Strength (mix 1)</b>	<b>Low Strength (mix 2)</b>
<b>Ingredient</b>	<b>kg/m3</b>	<b>kg/m3</b>
OPC	310	450
Silica Fume	20	-
Fly Ash	100	-
<b>w/b ratio mix</b>	<b>0.37</b>	<b>0.48</b>
20mm Aggregate	790	675
10mm Aggregate	310	675
Fine Sand	451	938
Manufactured Sand	250	-
GLENIUM 107 SURETEC	Slump of 140 +/- 30mm	N/A

Coarse and fine aggregate were tested for moisture content and absorption and the mixing water content was adjusted accordingly. A superplasticiser was added to the high strength mix to ensure workability into the sample moulds given the relatively low water content. 300 X150 \*X150mm samples were half filled, vibrated and finished before being placed into a lime solution curing tank at 20 degrees for 28 days.

**Figure 1 – Setup of testing in simulated environments**

Additional high and low strength cylinders and porosity samples were crushed and tested achieving an average of 37.06 and 59.10MPa respectively. Samples were then inserted into testing environments which included independent pumps and spray systems that showered twice daily to simulate the two high tides and drying time that is experienced within the splash zone. Samples were then exposed for 180 days continuously in climatic controlled conditions.

To facilitate the distinction between the effects of temperature and humidity, the atmospheric variables of the differing areas were as follows:

**Table 4 – Climate and salinity concentrations of chambers**

Chamber	Temperature	Humidity	Solution Concentrations
CH1	15 ° C	50% RH	10ppt, 20ppt, 30ppt, 40ppt
CH2	23 ° C	50% RH	10ppt, 20ppt, 30ppt, 40ppt
CH3	23 ° C	80% RH	10ppt, 20ppt, 30ppt, 40ppt

After 180 days of being exposed to the respective environments 50mm core samples were taken to a depth of 30mm and ground down in 10mm segments with a diamond tipped dry cut as not to wash away any chlorides. Once cut, the samples are ground down with a mortar and pestle and then individually packaged and sent for chloride content testing. Core holes are then filled with an impervious mortar and left to dry before being returned to the saline environments.

The results of the testing at the differing environments were translated into a chloride data analysis where the sum of squares reduction was performed to ascertain the surface chloride and chloride diffusion coefficient. This minimisation of squares was completed using the SOLVER application within Microsoft Excel.

## 5.2. Results

In the experimental planning, there was a variance of concrete mix design to prove the influence that the mix can have on the rate of chloride diffusion. The reduction of water to cement ratio (and thus inclusion of superplasticiser) in the high strength concrete was found to significantly improve the amount of void spaces within the pore matrix. In comparison to a controlled sample, the reduction of w/c ratio was responsible for a 25-30% decrease in the diffusion coefficient which is likely to cause a noticeable difference in the modelling of the chlorides.

The salinity of the solutions within the simulation tanks also acted as an accelerant in the absorption of chlorides through the concrete. Although some literature suggests that the external free chloride content has little influence on the rate of absorption (as there is a fixed diffusion coefficient); this was proved to be inaccurate as the tanks with higher salinity saw more chloride ions permeating through the material at lower depths.

**Figure 2 – Chloride content of concrete in varying environments**

The above illustrates a trend illustrating how an environment with higher saline concentration will inevitably increase the magnitude of free chlorides within the pore matrix. Further to this, the evidence suggests that the increase in both temperature, but more notably humidity – creates a more chloride aggressive environment whereby the chlorides diffuse through the concrete at a faster rate. This phenomenon results from a decrease in the bound chloride content, thus making the active corrosion easier to commence (Hussain, 1993). In addition, this increase in temperature also lowers the activation energy required to catalyse the passive film breakdown (Glass GK, 1997). In modeling the observed behaviour, active corrosion is considered when, in a small exposed area, the corrosion rate of the reinforcing bar is higher than 0.1  $\mu\text{A}/\text{cm}^2$ .

This information further allows the inputs of the model to be tailored to the specific environment and what the intended effects of climate change will be on the localised sea surface salinity.

## 6. Modelling the effects of future climate on concrete deterioration in a seaports context.

The data received from the experimental works outlays the quantifiable relationship between temperature, humidity, salinity, and w/c ratio. This data is then inserted as boundary conditions with a model that uses the most recent climate data for each year into the future and can formulate the change in corrosion initiation given the corrosion activation rate of 0.1  $\mu\text{A}/\text{cm}^2$ .

In bringing together the above temperature and salinity dependent formulae and incorporating them into one holistic equation, this paper is allowing a new version of Fick's 2nd law to be both time and environmentally dependent and responsive to changes in the environment into the future.

$$C(x,t) = C_0 * 1 - \operatorname{erf} \left( \frac{x}{2 * \sqrt{\left( K_t * K_e * K_c * \beta_t * D_c * 10^6 * \left( \frac{1}{t - (t_0 - 1)} \right)^{n * (t - t_0 - 1)} \right)}} \right) \quad (8)$$

Where  $C_0$  is the surface chloride which is extrapolated from the boundary conditions of each test sample in part 1 (dependant on the environment), erf is the error

function,  $x$  is the depth of the test taken,  $K_t$  is the correction factor proposed by (Uji, Matsuoka, & Maruya, 1993),  $K_e$  is the environmental factor (Yoon, 2008),  $\beta_t$  is the temperature factor which has been modified from the works by (Yoon, 2008) to incorporate the results from Part 1,  $D_c$  is the diffusion coefficient which is taken from either of the two sample tests in part 1 (i.e. high or low w/c ratio),  $t$  is the year of observation,  $t_0$  is the time that the specimen was initially exposed to the saline environment, and  $C_{(x,t)}$  is the depth of chloride penetration.

### 6.1. Results of the modeling:

The below results illustrate how a changing climate is impacting on the chloride concentration at the cover depth and the timeframe until the initiation of corrosion. It is evident that the A1B scenario which details sea surface temperatures rising by 2.1 ° C and a slight increase in sea surface salinity brings forward the time for corrosion initiation of reinforcement. Unlike LIFE-365 modeling which assumes a repetitive annual climate, with no provision for long-term localised climatic change, the model proposed within this paper allows for the quantifiable forecasting of asset deterioration incorporating the effects of climate change.

Figure 3a below show the quantitative difference in projected corrosion induced by chloride intrusion for a high strength concrete asset following the IPCC A1B climate future. Figure 3b details a significant difference between the baseline and the climate impacted deterioration curve. Given that asset management remediation works will often commence at a certain corrosion initiation probability trigger, (e.g. 20%) the model indicates a reduction in serviceable lifespan of the asset by over a decade.

It is worthy acknowledging that within the future planning of seaport assets which are classed as long-term critical infrastructure, the accuracy of forecasting productivity downtime and economic spending is paramount.

(a) Change in chloride concentration at cover (50mm)

(b) Probability of corrosion initiation

**Figure 3 – Chloride concentration and corrosion initiation results**

## 7. Conclusion:

The existing numerical relationships between environmental change and concrete deterioration within literature varied significantly and within the context of seaports and high-strength concrete mixes; did not have a finite and quantifiable influencing factor on the ingress of chlorides.

In a changing climate, seaport authorities and governments are becoming increasingly dependent on research which depicts the effects that climate change may have on their structures. As competition on logistics and economic security through sea transport strengthens its hold on future planning, accurate condition deterioration modeling is pivotal for policy makers and seaport stakeholders alike.

Work presented here leads to following conclusions:

- Current climate models indicate a significant change in environmental factors which affect chloride ingress in reinforced concrete structures when exposed to marine environments
- Preliminary results of simulated lab experiments indicate that the temperature rise and increase in humidity as well as increase in salinity of the environment will increase chloride ingress in reinforced concrete structures exposed to marine environments
- Using the A1B climate model from IPCC [9], the results obtained from the experiments, and the approach presented by Trapper [8] a probabilistic model is developed to forecast probability of ingress in chlorides and corrosion initiation time of a selected port structure.

- Outcomes indicate that earlier intervention, as early as 10 years compared to current practice, will be needed to ensure protection of port structures from chloride ingress.

**Abstract:** The Maastunnel in Rotterdam has to be renovated to ensure service life for a few more decades. The concrete of the tunnel is deteriorated. Chloride from deicing salts has penetrated into the concrete and has reached such levels in the material that the reinforcement is heavily corroded. Furthermore the concrete cover has spalled off and disappeared in large sections of the tunnel, especially in the floor of the tunnel. The cross section of the reinforcing bars at those places is also heavily decreased. The intention is now to perform a repair of the cover-zone concrete which will last for the remaining service life of the tunnel without any or limited maintenance.

In the Microlab at Delft University several novel repair materials are developed which are based on fibre reinforced cementitious composites. The new materials enable a good bond with the old concrete and have a crack distributing capability. Furthermore, if the reinforcement bars continue to corrode, the repair material will not fail because it can to a certain extent cope with the imposed strain by the expanding bars. With these materials several patches are repaired inside the tunnel and laboratory specimens for property testing and accelerated corrosion tests are prepared. The paper compares and discusses the performance of the different repair materials in situ and the results of the laboratory testing.

**Keywords:** Immersed tunnel, repair, SHCC, rebar corrosion.

## 1. Introduction

The Maastunnel in Rotterdam is Europe's first immersed tunnel with a rectangular cross section. It is completed in build in 1942 with a length of 1373 meter. Crossing the Maas river that flows through the heart of Rotterdam, the tunnel consists of four tubes combined within a single section: two tubes for cars, one for cyclists and one for pedestrians. It has to be renovated to ensure service life for a few more decades. The concrete of the tunnel is deteriorated. Chloride from deicing salts has penetrated into the concrete and has reached such levels in the material that the reinforcement is heavily corroded. Furthermore the concrete cover has spalled off and disappeared in large sections of the tunnel (Figure 1a), especially in the floor of the tunnel. The cross section of the reinforcing bars at those places is also heavily decreased. Analyses performed, commissioned by municipality of Rotterdam, showed however that the safety of the Tunnel is also guaranteed if the reinforcement at the inner surface of the floor is partly or completely removed from the cross section. Nevertheless, the intention is now to perform a repair of the cover-zone concrete which will last for the remaining service life of the tunnel, with no or limited maintenance.

**Figure 1: a) Inspected floor and ceiling of the ventilation tubes in the tunnel b) damage continuation in the previously repaired patches**

After studying internal reports provided by the municipality of Rotterdam and after having visited the tunnel it was concluded that the most logical and also feasible repair method is the following:

- Remove the concrete in the cover zone that is contaminated to a depth which is two times the original cover depth plus the rebar diameter. By doing so the new repair layer surrounds the rebars at all sides with a layer of uncontaminated material which has the size of the old cover depth.
- Clean the rebars by removing all the rust.
- Add a repair material which does not debond and crack. The risk for failure of the repair material is large because of different moisture conditions and related deformation in the repair material compared to the old concrete. Furthermore the corrosion of the rebars might continue after some time, which will lead to spalling of the repair material.

Even if the repair is performed with good quality materials and all the rust is removed from the rebars there is still a risk that the repair will fail in time (see for example Figure 1b). In the Microlab at Delft University currently several research project are ongoing on the development of new repair materials [1-4] and on the chloride ingress and corrosion of rebars in (cracked) concrete [5-7]. From this research several new repair materials are developed which are based on fibre-reinforcement and show strain hardening capacity (strain-hardening cementitious composites - SHCC [8]). The new materials create on the one side a good bond with the old concrete and have a crack distributing capability and therefore are an excellent candidate as repair material. Furthermore if the reinforcement bars might continue to corrode the repair material will not fail because it can to a certain extent cope with the imposed strain by the expanding bars.

The overall aim of the project is to develop a durable repair system for concrete in the Maastunnel that will prolong the service life of the tunnel for another 50 years without having to perform major maintenance.

This paper discusses part of the project, which is testing the performance of a number of repair mixes in the laboratory and in field tests. In the next section the tests that are performed are described. Subsequently this is followed by a presentation and discussion of the outcome of the tests. Finally some conclusions of the research are given.

## 2. Design of Testing

Two groups of tests have been done for investigating and comparing performance of different types of repair materials which are suitable for repair application in the tunnel. One set of tests has been performed in the laboratory and the second set has been done in the field, inside the tunnel. These tests are discussed in this section.

### 2.1 Laboratory tests

The tests performed on several repair mixtures in the laboratory research are summarized below:

- flexural performance test on the 5 different types of repair materials (Figure 2a). This test is done on 100x100x400mm prisms.
- compression test done on the samples after flexural testing (Figure 2b). 100x100x100mm<sup>3</sup> cubes are cut from the prism specimens and are tested in compression test.

Figure 2: a) Flexural tests on 100x100x400mm<sup>3</sup> samples and b) compression tests on cubes 100x100x100mm<sup>3</sup> cut after flexural tests

Flexural and compression tests are done both on laboratory cured samples (two curing regimes: temperature,  $T=20^{\circ}\text{C} \pm 2^{\circ}\text{C}$  and relative humidity,  $\text{RH}=50\% \pm 2\%$  or  $T=20^{\circ}\text{C} \pm 2^{\circ}\text{C}$  and  $\text{RH}=95\%$ ) and also on the on situ samples. These samples are cast from the same material used in the patches, and were stored in the tunnel until testing (28days). This was done in order to compare laboratory made and cured mixtures with the mixtures that were mixed on-site and cured in the same conditions as patches.

- accelerated corrosion tests done on  $100 \times 100 \times 100 \text{mm}^3$  cubes with a single reinforcing bar of 35mm diameter placed in the middle of the specimen (Figure 3). 2 cubes were tested per each of the applied repair materials.

**Figure 3: Accelerated corrosion tests**

## 2.2 Field tests

The field tests in the tunnel can be described as follows:

- deformation measurements of the applied repair materials. To determine the magnitude of dimensional changes, length change is measured in each patch. This is done by attaching a dial gauge in the middle of the patch, with a measuring length of 10 cm and an accuracy of  $1 \mu\text{m}$  (Figure 4a). For each repair material dial gauge was attached.
- the interface delamination is measured also by dial gauges which were attached in the repair material on one side and in the concrete substrate on the other side (Figure 4b). Measuring length is 5 cm. For each patch, 4 dial gauges were attached around the edges of the repair material.

**Figure 4: a) Dial gauges for deformation measurement inside the material and b) delamination between two materials**

- the surface cracking in the repair materials was investigated with a portable microscope. The number of cracks and the crack width were measured manually.

- pull-off test of the repair material to investigate bond strength between repair material and concrete substrate. These tests are done at the age of 41 days of applied repair materials.

For the field tests patches were prepared using hydro-jetting. Size of the patches were in the range of 500x500x110mm<sup>3</sup> (Figure 5). Patches were water saturated with a dry surface prior to application of the repair material. Patches were covered with a wet geotextile material for the first 7 days.

**Figure 5: Preparation of patch by hydro-jetting (a). Casting of repair patches and corresponding prisms (b)**

Five different mixtures were developed for the application in the tunnel. Overview of all mixture compositions (given without chemical admixtures) is given in Figure 6. In order to make a more clear comparison of the mixtures, also the volume of aggregates, paste and w/b ratio (per weight) is given. Mix 1 has the highest content of aggregates and the lowest content of paste. In order to enable good distribution of fibres and good workability of the mixtures, Mix 2 and mix 3M have the higher content of paste and lower content of aggregates. Mix 3L and Mix 4 are traditional SHCC mixtures without coarse aggregates [3, 4].

**Figure 6: Mixture compositions including amount of water, binder, aggregates and fibres**

### 3. Results

The beam specimens made in the laboratory and also the specimens made in the tunnel were tested at the age of 28 days in 3-point-bending. This is done for comparison with laboratory made and cured specimens, but also to check the properties of the material casted and cured in the same way as patches. First a notch of 25 mm was made in the middle of all of the samples. Then the samples are left to dry for 2 hours before three point bending test. Test was done by controlling the crack opening which enabled that the post-peak behaviour is measured. Samples made from mixtures Mix1, Mix2, Mix3M and Mix4 are labelled with P1, P2, P3 and P4, and correspond to Patch 1, 2, 3 and 4.

**Figure 7: Stress-crack opening diagram of beam specimens casted and cured in the tunnel.**

An example of the 3-point-bending results is given in figure 7, where the tests on the samples made inside the tunnel are shown. It can be seen from the stress-crack opening curves that all mixtures, except Mix 1 in P1 show strain-hardening capacity in bending. This means that after first cracking, stresses that the material can withstand do not reduce (as in Mix 1 where peak strength is equal to first cracking strength) but they increase with further crack opening. Differences are observed between cracking patterns of different samples. In specimen P1 only one crack forms. This specimen exhibits strain-softening behaviour, which is typical of concrete. As a consequence, after the peak load, the load-bearing capacity of the specimen drops. On the other hand, specimens P2, P3 and P4 show strain-hardening behaviour. This means that, after the first cracking, due to fibre activation, they can still withstand increasing stresses, resulting in ductile behaviour. This is important for repair materials, as repair systems are usually not crack free (due to restrained deformations, incompatibility between two materials [9, 10]), and it is important how they behave at higher strain levels. Mix 4 used in P4 shows the highest amount of strain hardening. This mixture has only sand and no larger aggregates. The fibres are more effective in this case. However Mix 2 and Mix 3M with larger aggregates might be more practical. The test results on the specimens made in the laboratory show similar behaviour.

For the accelerated corrosion tests, samples were cast in 100x100x100mm<sup>3</sup> moulds with a plain reinforcing bar with a diameter of 35mm, placed in the middle of the mould. This size and type of the rebar was chosen to be similar to the existing rebars in the tunnel. Note that accelerated corrosion results in uniform expansion around the reinforcement, which is somewhat different from chloride induced corrosion, which results in pitting (i.e. non-uniform expansion). After 1 day, the samples were demoulded and left for 4 days in the fog room ( $T=20^{\circ}\text{C} \pm 2^{\circ}\text{C}$  and  $\text{RH}=95\%$ ) for curing. At the age of 5 days, they were taken out and exposed to accelerated corrosion test. Samples were immersed in water and a titanium mesh was used as a cathode. Applied voltage was 18 V, which should enable that current density is about 200  $\mu\text{A}/\text{cm}^2$  of the steel rebar. The applied voltage was increased in time in order to increase and speed up damage development in the specimens. Images of damaged specimens are made during the exposure period. The results for Mix 1 and 4 are presented in figures 8 and 9. Mix1 exhibited only one crack with a large crack opening, while all fibre-reinforced mixtures had more cracks with by an order of magnitude smaller crack widths.

**Figure 8: Cracking pattern and representative cracks for Mix 1 captured with a) camera and b) microscope**

**Figure 9: Cracking pattern and representative cracks for Mix 4 captured with a) camera and b) microscope**

From the deformation and delamination measurements it is observed that all patches behave according to expectations. Deformation measurement increases only if cracking or delamination occurs. Generally, delamination was not observed in any of the repairs. Mix 1 did not exhibit cracking while the fibre-reinforced mixtures exhibited designed cracking. In pull-off tests, all failures with very low strength happened in the concrete substrate. Therefore, it seems that, in general, concrete substrate is more critical than repair material and bond strength. Still, due to the limited number of pull-off tests, small core diameter and difference in observed failure mode, no statistically reliable data is obtained from these tests.

#### 4. Discussion

High ductility is one of the most important requirements for a good repair material. In the repair system, due to drying and hydration, the repair material tends to shrink. Its deformation is, however, restrained by the concrete substrate, and either cracking or delamination results. However, delamination can only occur at a free end or around existing cracks in the repair material that propagated deep to the substrate. Otherwise, if there is no crack in the repair material or delamination at the free end, delamination beneath repair material, in the middle of the patch can never occur. This is not dependent on the size of the repair and therefore is also valid for bigger repairs. Further on, due to incompatibility in properties between the two materials (thermal properties, permeability properties, conductivity properties), any kind of thermal gradients will induce stresses that might cause cracking. Therefore, repair systems are very susceptible to cracking and are almost never crack free. That is why it is important not only to know how a material behaves under high loads, but it is more important how material behaves under large strain (after some cracking). Furthermore, maximum widths and distribution of these cracks are important for any further deterioration mechanism in the repair system (carbonation, freeze-thaw).

Mixture M1 has the smallest shrinkage. In the fibre-reinforced mixtures, as aggregate amount reduces from Mix1 to Mix4, the amount of material that is shrinking is increasing, meaning that more strain is developing. This strain is sufficient for inducing cracking. Due to the strain-hardening capacity, it might be considered that crack widths will not grow significantly, even in a larger patch, but will distribute at similar distances as already observed in the small patches in the tunnel. The cracks observed in the patches might however only be surface cracks at this stage. Therefore, both fibres and aggregates in repair material mixtures have their own benefits. Fibres are reducing crack widths, which is very important for solving the brittleness issue of a repair material. On the other hand, aggregates are beneficial as they enable reduction of total shrinkage, which is also an important aspect for concrete repair.

Due to big corrosion problems and observed damage in the existing repairs, a series of tests was also performed to assess the resistance of used repair materials to continued corrosion. For this purpose, an accelerated corrosion test was used. As expected, Mix1 exhibited only one crack with a large crack opening, while all fibre-reinforced mixtures had more cracks with much smaller crack widths. Therefore, it is clear that risk of continued corrosion will be less critical for the fibre-reinforced mixtures. In addition, as the material is more resistant to damage due to continued corrosion, it might be possible that less concrete need to be removed prior to repair. From these tests it might be concluded that if corrosion continues and Mix1 is applied, large cracks will develop and patches or repair will most likely spall. If a mix with fibres is applied the risk for large cracks is low and it will not likely result in loose patches.

An important aspect for concrete repair is the bond strength. Due to high restraint level of the repair material (restrained due to dense reinforcement) bond problems and debonding are not expected to be critical for the performance of the repair in these conditions. Furthermore, good bond is an important factor only if the material cracks and debonds. Bond strength will further determine how and where a crack or delamination will propagate. Compared to pull-off test, more influence of the bond can be observed through deformation measurement inside the repair system (delamination and deformation inside the repair material) and visual inspections of the repairs. This is because a pull-off test at certain location will, at best, give the bond strength (only if it breaks exactly at the interface and not in the concrete substrate or repair material), but not the probability of debonding. Due to the making the core, most of the eigenstresses that exist at the interface due to restrained deformations will be released and will not be measured during the pull-off test. Therefore, more crucial tests than pull-off tests for performance of the repair are: visual inspection, quantification of crack widths and crack spacing, and deformation measurements inside the repair system. This type of study will include all the most important parameters (repair material shrinkage, repair material relaxation, repair material E modulus, tensile strength, concrete substrate creep, amount of restraint at the interface, bond strength, environmental conditions, saturation level of the concrete substrate) and their interaction in the specific case study. All these factors are important, but their interaction is complicated and not well known. Therefore, based on a single parameter and test, e.g. bond strength or free shrinkage, performance of repair system cannot be reliably assessed.

## 5. Conclusions

From the laboratory tests and the field tests in the Maastunnel the following conclusions can be drawn:

- With all the proposed mixes a compression strength can be obtained that is in line with the concrete that is present in the tunnel.
- The strength of the concrete made on site in the tunnel is only a few percent lower than the concrete made in the laboratory.
- All mixes containing fibres show a strain hardening behaviour and multiple cracking. The fracture energy of the mixes containing fibres is much higher than the concrete without fibres. Mix 4 shows the highest amount of strain hardening.
- The accelerated corrosion tests performed in the laboratory show that Mix1 (concrete without fibres) results in a single crack with large crack opening (~1.0mm). In the tests with the other mixes the corrosion tests result in multiple cracking and the cracks width stay small (below 0.15mm)
- In the patches made in the tunnel no delamination occurred and only very small shrinkage cracks are observed in the mixes with fibres. Mix 1 (concrete without fibres) no cracks were observed, because of the high volume of aggregates and low amount of paste present, which results in lower shrinkage. In addition, shrinkage reducing admixture was used for this mixture.
- The pull-off tests show that, in general, good bond is achieved between the tested repair materials and the concrete substrate. In most of the tests it was observed that the concrete substrate was the weakest link in the system, probably due to the selected method of surface preparation. Therefore, the pressure that was applied during hydro-jetting in these patches did damage the surface of the concrete. This needs to be kept in mind during the final repair stage of the tunnel. One of the possible ways to reduce the amount of damage is to reduce the pressure that is applied during hydro-jetting. Then, however, it should be checked if the method is fast enough and practically feasible for removing large areas of concrete.

## 6. Acknowledgement

The expert help of the Microlab technicians Ger Nagtegaal and Maiko van Leeuwen in performing the field and lab-tests is highly appreciated.

## **ACID-SOLUBLE AND WATER-SOLUBLE CHLORIDE – TESTING PROFICIENCY AND SPECIFICATION**

(Theme: Concrete Materials & Performance)

Warren South<sup>1</sup>, Tony Thomas<sup>2</sup> and Vute Sirivivatnanon<sup>3</sup>

<sup>1</sup> Cement Concrete & Aggregates Australia.

<sup>2</sup> Boral Limited

<sup>3</sup> University of Technology Sydney, Australia.

### **Abstract**

The importance of limiting the chloride ion content in concrete has always been recognised and specified in structural concrete specifications. The Australian Standard test method for acid-soluble chloride has been revised and published as AS 1012.20.1. At the same time, a newly developed water-soluble chloride test method has been published as a parallel Australian Standard AS 1012.20.2. The paper reviews and report the proficiency of the two test methods and the relationship between acid- and water-soluble chloride based on research and proficiency testing program conducted by Cement Concrete and Aggregates Australia (CCAA). Performance limits specified in international concrete standards are reviewed and recommended to be specified in relevant Australian standards and specifications.

**Keyword:** Acid-soluble, water-soluble, chloride, performance limit

Corresponding author: Dr Warren South [warren.south@cca.com.au](mailto:warren.south@cca.com.au)

## 1. Importance of limiting chloride ion content

Chloride-induced corrosion of steel reinforcement has been found to be one of the most common causes of premature deterioration of reinforced and prestressed concrete structures. The more vulnerable structures are those exposed to external sources of chloride such as from marine environments or from the use of de-icing salts. Chlorides can also come from concreting materials and hence it is important that limits are placed on chlorides from these sources including cement, supplementary cementitious material (SCM), aggregates and chemical admixtures.

Chlorides can exist as surface contaminant as well as chloride-bearing minerals in the aggregates. In hardened concrete, chlorides exist as either '*bound*' or '*free*' chloride in concrete. Chlorides can be bound as reaction products between chlorides and cement hydrates such as calcium chloroaluminate (Friedels salt). It is well recognised (ACI 222R and Byfors *et al.*, 1986) that it is the free chloride that contributes to steel depassivation and subsequent corrosion. In determining the amount of chlorides in concrete, both '*water-soluble*' and '*acid-soluble (total) chloride*' test methods have been used to determine the '*free*' and '*free + bound*' chloride respectively. Bound chloride is therefore the difference between acid-soluble (total) and water-soluble chloride.

Glass and Buenfeld (2000) found that the time to corrosion initiation of embedded steel, due to chloride diffusion from the surface of concrete, is dependent on the corrosion risk presented by bound chloride. Bound chloride may participate in corrosion initiation when the establishment of pH gradients are required to sustain passive film breakdown. This is the result of the effect on the pore solution chemistry of the pH dependent solubilities of solid phases containing bound chloride that are very similar to that of calcium hydroxide. In some circumstances, the time to corrosion initiation may be reduced by an increase in binding because of the possible corrosion risk presented by bound chloride. Hence both free and bound chlorides are equally important and must be controlled.

## 2. Development of water-soluble chloride testing method

In 2007, Cement Concrete & Aggregates Australia (CCAA) began the development of a water-soluble chloride testing method for aggregates. Up to that time, there was very limited work carried out on the difference between water-soluble and acid-soluble chloride in aggregates. Hope *et al.* (1985) focused work on the influence of different testing techniques and sample subdivision on the resultant free water-soluble chloride. They found that subdivision of aggregate samples resulted in extraction of some chloride from the aggregate material that field experience with the aggregate used suggested that this chloride did not materially contribute to corrosion of the embedded steel. They also found that the Soxhlet (high temperature) extraction of ½ inch material was effective in recovering added chloride from the concrete samples and did not extract chloride from chloride-bearing minerals in the aggregate. They suggested that the Soxhlet extraction removed only the chloride which was mobile and able to take part in the corrosion process. In 1996, ACI Committee 222 has adopted a 'Provisional Standard Test Method

for Water-Soluble Chloride Available for Corrosion of Embedded Steel in Mortar and Concrete Using the Soxhlet Extractor’.

There have been reported instances (Gaynor,1985) where quarried stone, gravels and natural sand contained small amounts of chloride that have provided concrete with chloride levels that exceed the permissible levels of 0.2% chloride by mass of cement, the upper limit recommended in ACI 222R. Other reports (Rogers and Woda, 1977) of aggregates with an acid-soluble chloride content of more than 0.1 percent of which less than one-third is water soluble when the aggregate is pulverized for the test. Not all of that chloride will necessarily become available to the paste. Thus ACI 222R indicates that higher levels are tolerable if past performance has shown that the higher chloride content has not caused corrosion.

CCAA investigated the effectiveness of the extraction of water-soluble chloride methods, including the Soxhlet method, in terms of the type of extracting agent and degree of fractured surface of the aggregates. It was found that the use of boiling water on materials passing 850-micron sieve offered a well-balanced measure of the free chloride contents in aggregate. The findings were also confirmed valid in testing hardened concrete (Sirivivatnanon, Thomas & Waye, 2011). The methods and results of the investigation were the basis for the development of an Australian test method for water-soluble chloride.

### **3. Proficiency of Australian Standard testing methods**

Both the accuracy and proficiency of test methods are important to their successful applications. CCAA initiated and conducted proficiency programme for the existing acid-soluble chloride test method AS 1012.20 and the draft water-soluble chloride test method in 2010 and 2011 respectively. Details and findings are described below.

#### **3.1 AS 1012.20 Acid-soluble test method**

A proficiency programme on acid-soluble chloride was conducted based on AS 1012.20 test method. This programme focused exclusively on the analysis of chloride content and did not examine the possible variability due to sampling technique. Samples of three sands C1, C2 and C3, with a range of chloride contents were prepared by Boral Laboratory and sent to seven NATA registered laboratories around Australia.

Six laboratories submitted the results as listed below. One of these six laboratories tested replacement samples after reporting damages to the first samples. The results are summarised in Table 1.

There are inconsistencies in the reporting of test result in both the number of decimal points and significant figures. There appears also to be a limit to the accuracy of the method with some laboratories unable to test sand such as C2 and C3, with chloride content below 0.01%, to an accuracy of 0.001%. This is possibly due to the analytical method used by various laboratories ranging from Mohr’s and Volhard’s titration to potentiometry using various ion-selective electrodes.

Table 1 AS 1012.20 acid-soluble chloride test results (%)

Sand samples Lab	C1		C2		C3	
	No. 1	No. 2	No. 1	No. 2	No. 1	No. 2
1	0.0533	0.0517	0.0016	0.0013	0.0009	0.0008
2	0.044	0.044	<0.001	<0.001	<0.001	<0.001
3	0.038	0.043	0.004	0.009	0.003	<0.002
4	0.05	0.05	<0.01	<0.01	0.01	0.01
5	0.006	0.008	0.001	0.001	0.002	0.001
6	0.0210	0.0230	<0.005	<0.005	<0.005	<0.005
Mean	0.036		(0.0042)*		(0.0035)*	
Repeatability SD	0.0017		-		-	
Reproducibility SD	0.0179		-		-	

SD=standard deviation

( ) \*mean of test results using the upper limits eg. 0.001 as upper limit for <0.001.

For C1 with the mean chloride content is well in excess of 0.01%, the repeatability and reproducibility standard deviations are 0.0017 and 0.0179% respectively. The repeatability standard deviation is within the same range as 0.0015% reported in the ASTM C1152 - Standard Test Method for Acid-Soluble Chloride in Mortar and Concrete. However, the reproducibility standard deviation of 0.0179% is significantly higher than 0.0021% reported in the ASTM C1152. For sand C2 and C3 with lower chloride contents, it is not possible to determine the precision of the method. The cause of such differences in results from various laboratories is unknown, but highlights the need for re-examination of the test procedures.

It should be noted that the AS 1012.20 Acid-soluble chloride test method is re-issued as AS 1012.20.1 in 2014 with no significant changes to the method.

### 3.2 Draft AS 1012.20.2 Water-soluble chloride test method

CCAA sought collaboration from the same seven laboratories to conduct proficiency tests on water-soluble chloride content in accordance with the draft water-soluble chloride determination for aggregates and hardened concrete test method. Three aggregates (CL6, CL7 & CL10) and one chloride solution were prepared by Boral Materials Technical Services and sent to all laboratories. Six laboratories submitted the results as listed in Table 2.

Four out of six laboratories reported the concentration of the standard solution fairly accurately between 33 to 38 mg/L for the solution which was prepared at 35.45 mg/L. Laboratory 1 & 2 reported higher solution concentrations and generally higher results for the three aggregates.

All laboratories are able to report results to 0.001% which is an improvement on the accuracy when conducted to AS 1012.20. The repeatability and reproducibility standard deviations for all three aggregates are similar to those reported in ASTM C1218 – Standard Test Method for Water-Soluble Chloride in Mortar and Concrete.

Table 2 Analysis of all results (%)

Sand samples	CL6		CL7		CL10		Solution* <sup>1</sup>	Notes
Lab/Sample	1	2	1	2	1	2	mg/L	
1	0.010	0.010	0.009	0.009	0.017	0.019	45	or 0.0045% solution
2	0.008	0.008	0.008	0.008	0.025	0.025	43	or 0.0012N solution
3	<0.001	<0.001	0.001	0.001	0.015	0.015	36	Potentiometric titration on - 150µm
4	0.0015	-	0.0014	-	0.0147	-	38	or 0.0038% solution
5	0.0022	0.0012	0.0015	0.0029	0.0127	0.0130	38	
6	0.0085	0.0075	0.0073	0.0068	0.0177	0.0161	33	Dionex IC
Mean	(0.0050)* <sup>2</sup>		0.0048		0.0171			
Repeatability SD	(0.0004)		0.0004		0.0007		0.0013% in ASTM C1218	
Reproducibility SD	(0.0041)		0.0036		0.0043		0.0037% in ASTM C1218	

\*1. Solution was prepared as 35.45 mg/L.

\*2. Use 0.0009 for values reported <0.001 in the analysis.

For CL10 with higher mean chloride content of 0.017%, the coefficient of variation of repeatability and reproducibility are 4.4 and 25% respectively. These are within acceptable range and hence the water-soluble test method gives good precision for aggregates with the AS 2758.1 reportable chloride content.

This draft water-soluble chloride testing method was introduced to Standard Australia CE-012 committee in 2014, in consultation with Standard Australia BD-042 committee for designation as the new Australian Standard AS 1012.20.2. It went to a combined procedures process early in 2015 for possible publication around May 2015.

### 3.3 Conclusion on the proficiency of the two chloride test methods

Both proficiency test programmes focused exclusively on the analysis of chloride content and did not examine the possible variability due to sample preparation technique. The results show that the draft water-soluble test method provides results to 0.001% accuracy demanded by concrete specifications. The water-soluble test method also gives good precision in terms of both repeatability and reproducibility. However, the AS 1012.20.1 acid-soluble chloride test method has failed to provide the same precision except for the repeatability of aggregate with high chloride content well in excess of 0.01%.

## 4. Performance limits for concreting materials and concrete

Australian Standards AS 3972, AS 3582 and AS 2758.1 place limits on acid-soluble chloride in cement, SCM and reportable chloride in aggregates respectively. AS 1379 places a limit on total acid-soluble chlorides in the supplied concrete to ensure durability. There are challenges associated with AS 1012.20.1 acid-soluble chloride determination. The proficiency programme found large variations in the reported results leading to a low precision of the test method. The use of the test method in specifications creates problem in aggregate selection and in determining the risk of steel reinforcement corrosion in hardened concrete. On the other hand, the draft AS 1012.20.2 water-soluble chloride test method has proven to give much improved precision with better repeatability standard deviation than and comparable reproducibility standard deviation to the ASTM C1218 method.

Different international codes and standards have adopted different performance limits for concrete structures. American Concrete Institute (ACI) uses both water-soluble and acid-soluble limits whereas European and Australian Standards adopt acid-soluble chloride limits. These performance limits and corresponding type of chloride are summarised in Table 3.

Table 3 Performance limits and corresponding chloride determination methods

Maximum acid-soluble chloride-ion content, percent by mass of cement		Maximum water soluble chloride-ion (Cl <sup>-</sup> ), percent by mass of cement	
Standard	Reinforced	Standard	Reinforced
AS 1379	0.8 kg/m <sup>3</sup> or 0.20% <sup>a</sup> RC and concrete with tendons, ducts, cast-in inserts, embedded items or other items that require protection.	ACI 318-05 At 28-42 days	0.06, 0.30, [1.00], 0.15 % Prestressed concrete, RC exposed to wet chloride in service, [RC in dry condition in service], Parking structures and those near seawater
ACI 222R-01	0.08, 0.10, [0.20]% Prestressed, RC in wet condition, [RC in dry condition]	ACI 222R-01	0.06, 0.08, [0.15]% Prestressed concrete, RC in wet condition, [RC in dry condition]
European Standard EN 206-1	0.10-0.20 <sup>b</sup> % for prestressed 0.20-0.40 <sup>b</sup> % for RC 1.00% for plain concrete	Canadian CSA A23.1-94	0.06, 0.15, 1.00 % Prestressed concrete, RC in moist or chloride or both, RC exposed to neither moisture nor chloride
British Standard BS 5328-97	0.10 % for prestressed 0.40 % for RC No limit for plain concrete		
Norwegian Code NS 3420-L	0.6% for RC 0.002% for prestressed		

Note: (a). assumed cement content of 400 kg/m<sup>3</sup>.  
(b). the class to be applied depends upon the provision valid in the place of use of concrete.

It may be prudent for Australian standard AS 1379 and other specifications to consider adopting a water-soluble chloride limit for new concrete to alleviate the low proficiency problem in the acid-soluble chloride determination. A water-soluble chloride limit of 0.6 kg/m<sup>3</sup> for new concrete is recommended for AS 1379.

## 5. Discussions

In the Australian Standard for acid-soluble chloride content AS 1012.20, no precision statement is available nor is the stipulation of the accuracy of reporting. The problem affecting the precision of the acid-soluble chloride test (AS 1012.20) has been examined from the viewpoint of the size and sampling method by Forster & Bathgate (2009). The results reported in this paper show that AS 1012.20 test method does not provide a consistently accurate result to 0.001% demanded by concrete specifications. In the case of aggregate with reasonably high chloride content, the test method provides an acceptable repeatability but excessive reproducibility. With the reproducibility standard deviation of 0.0179%, results of two properly conducted tests from two different laboratories on samples of the same material could differ by 0.05% ( $2.83 \times 0.0179\%$ ) by mass. This renders the method and its test result to be unacceptable to all parties.

AS 1379 limits the level of acid-soluble chloride in reinforced concrete to be within  $0.8 \text{ kg/m}^3$ . A typical concrete mix may contain  $700 \text{ kg/m}^3$  of sand from  $1800 \text{ kg/m}^3$  of combined aggregates. The choice of testing laboratory can contribute a difference of  $0.35 \text{ kg/m}^3$  ( $0.05\% \times 700 \text{ kg}$ ) from the sand toward the limit of  $0.8 \text{ kg/m}^3$  for concrete which is clearly an unacceptable uncertainty derived from the testing method. If the method is used to determine acid-soluble chloride in hardened concrete, the results of two properly conducted tests from two different laboratories on the same hardened concrete sample could differ by 0.05% by mass of concrete. This amount is almost the chloride threshold associated with potential corrosion of steel reinforcement. Such discrepancy could easily lead to wrong decision regarding the risk of corrosion of steel reinforcement.

On the other hand, the newly developed water-soluble chloride test method has acceptable repeatability and the highest reproducibility standard deviation of 0.0043%, results of two properly conducted tests from two different laboratories on samples of the same material could differ by 0.01% ( $2.83 \times 0.0043\%$ ). The choice of testing laboratory can contribute a maximum difference of  $0.07 \text{ kg/m}^3$  ( $0.01\% \times 700 \text{ kg}$ ) from the sand toward the recommended water-soluble chloride limit of  $0.6 \text{ kg/m}^3$  for concrete which is a more acceptable level of uncertainty derived from the testing method.

## 6. Conclusions

The lack of precision of the Australian Standard test method for acid-soluble chloride content AS 1012.20.1 has been confirmed and shown to be potentially damaging to decision on the choice of concrete aggregates and the risk of corrosion of steel reinforcement in concrete. The draft AS 1012.20.2 water-soluble chloride test method gives significantly better precision with improved repeatability and reproducibility standard deviation comparable to the ASTM C1218 method. The permissible and reportable water-soluble chloride limits specified for new concrete and aggregate in AS 1379 and AS 2758.1 should also be revised accordingly.

# Integrated fracture-based model for the analysis of cracked reinforced concrete beams

Tahreer M. Fayyad<sup>1</sup> and Janet M. Lees<sup>2</sup>

<sup>1</sup>PhD Candidate, Department of Engineering, Cambridge University

<sup>2</sup>Reader in Civil Engineering, Cambridge University

**Abstract:** Due to the rapid advances in the development of techniques for monitoring and retrofitting concrete, there is a need to revisit and generalize classical theories in order to better assess the strength of existing reinforced concrete structures and to encompass strengthening systems. An improved understanding of concrete cracking taking into consideration local phenomena such as tensile and compressive concrete softening as well as the bond between the reinforcement and the concrete is required. In this paper, a fracture-based model is developed to describe the cracking process in reinforced concrete by integrating different local phenomena to more precisely describe the flexural behaviour of reinforced concrete beams. The model results show a good correlation with experimental data obtained by testing small scale concrete beams subjected to three-point bending. The beams exhibited mode I fracture propagation and during testing crack measurements were undertaken using a non-destructive digital image correlation technique. The stability of the cracking process was found to depend on the concrete strength, reinforcement properties and reinforcement ratio.

**Keywords:** Reinforced concrete, fracture, cracking mechanism, crack propagation.

## 1. Introduction

The traditional analysis of a cracked reinforced concrete section is normally based on the assumption that under flexural loading plane sections remain plane. The effect of concrete in tension is typically ignored after cracking since concrete has a low tensile strength compared with its compressive strength. This approach does not consider the crack propagation process in detail and assumes that once the crack develops the concrete cannot sustain any tensile stresses. However, cracking in reinforced concrete is a sequential process and involves a gradual loss of tensile stresses with crack propagation. Furthermore, many studies have proved the existence of concrete softening in both tension and compression i.e. (1–4). This means that even in a cracked region, parts of the open crack still have some ability to transfer stress. Recognizing that traditional analyses are not sufficient to explain the cracking process in reinforced concrete, different approaches have been used to develop theoretical models for predicting the cracking behaviour of reinforced concrete members e.g. (5–9).

Numerous factors can influence the cracking process and crack bridging in reinforced concrete (RC). These include the concrete properties, the reinforcement properties, the ratio of the longitudinal reinforcement, the bond between the reinforcement and the concrete, and the geometrical properties and the size of the beam. These factors are interrelated and interdependent; for example, the concrete and steel properties can affect the bond which consequently affect the crack bridging and crack opening displacement. This means that developing a full understanding of the cracking mechanisms in reinforced concrete members is difficult and complex. Many variables and different phenomena have to be integrated into the study of fracture to produce more realistic material models that imitate the behaviour of a quasi-brittle material such as concrete.

## 2. Crack modeling using fracture mechanics

Fracture mechanics is a field of solid mechanics that deals with the mechanical behaviour of cracked bodies. It covers rules and principles of crack propagation and remains one of the most frequently used approaches to study and model cracks in concrete structures. Both Linear (LFM) and Non-linear (NLFM) fracture mechanics have been applied to concrete. LFM analysis assumes a singularity of the stress at the crack tip while NLFM approach considers a relaxation of the stresses in the fracture process zone (FPZ) such that there exists a finite value of stress at the crack tip. LFM was applied by Carpinteri (10) when developing a Bridged Crack Model used to study the flexural failure of reinforced concrete beams. It was assumed that when the crack starts to grow, the resultant stress intensity factor  $K_I$  equals the critical stress intensity factor  $K_{IC}$ . More recently, the model has been further extended to

analyze shear cracks where the diagonal tension failure load is determined from an analytical law for the crack trajectory based on experimental observations (11). As LFM is valid when the size of the fracture process zone is negligible, the Cohesive Crack Model (CCM) or Fictitious Crack Model (FCM) was developed as an alternative to model concrete cracks taking into account nonlinear behaviour in the fracture process zone (1). The difficulty of applying the CCM without a Finite Element framework led Gerstle et al (6) to simplify some assumptions related to the FCM to develop an analytical solution for flexural cracks in reinforced concrete beams; however, their model does not consider concrete compression softening or any bond-slip behaviour between concrete and steel. Yet strain softening of concrete in compression can affect the strength and ductility of reinforced concrete members. Fracture mechanics was used by Hillerborg (4) to study compression strain localization in concrete. However, the effect of concrete tensile softening was ignored in his model.

The aim of this paper is to present an analytical solution for the development of flexural cracks in RC beams from the onset of cracking until failure. The local phenomena associated with crack propagation will be considered as well as the interaction between the concrete and the reinforcement where further research is required to quantify appropriate material models.

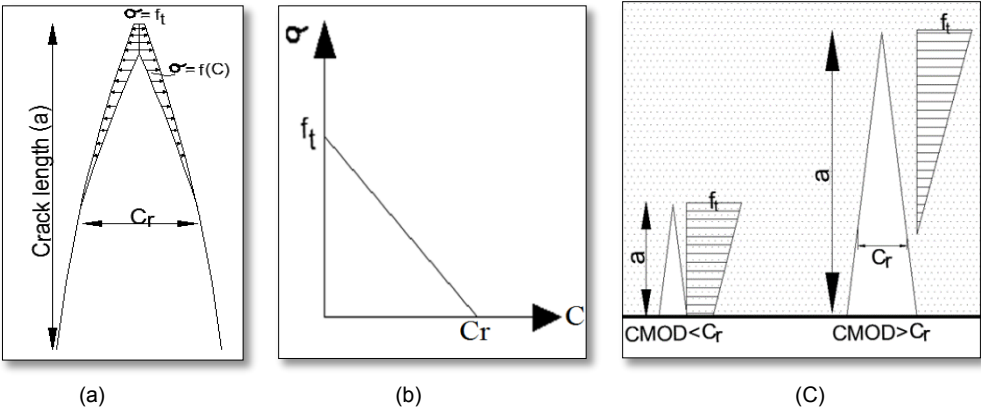

**3. Integrated fracture-based model formulation**

The proposed integrated fracture-based model incorporates post-cracking tensile stresses in the concrete, the bond-slip behaviour between the reinforcement and concrete, and compression softening in the concrete compressive zone. The modeling of each of these aspects is described in the following.

**3.1 Tension behaviour**

The Fictitious Crack Model (FCM) assumes that a crack will propagate when the stress at the visible crack tip reaches the concrete tensile strength ( $f_t$ ). As the crack opens, the stress decreases with increasing crack width ( $C$ ) until it reaches zero stress at a critical width ( $C_r$ ). The residual capacity to transfer stress in this region then needs to be overcome in order for the crack to propagate as shown in Figure (1a). The amount of energy absorbed per unit crack area to open the crack from a width of zero to  $C_r$  is the fracture toughness  $G_{IC}$ . The fracture toughness can be calculated as the area under the stress versus crack width curve ( $\sigma - C$ ) which is called a tension softening curve. For simplicity and suitability for use in a closed form solution, a linear tension softening curve is assumed in the current work (Figure (1b)). With a linear relationship between  $\sigma$  and  $C$ , when the crack mouth opening displacement  $CMOD < C_r$  the stress at the crack mouth opening equals  $(1 - \frac{CMOD}{C_r}) f_t$ . So, the total closing force ( $CF$ ) acting along the crack length ( $a$ ) per unit width is

$$CF = \frac{1}{2} a (f_t + (1 - \frac{CMOD}{C_r}) f_t) = \frac{1}{2} a f_t (2 - \frac{CMOD}{C_r}) \tag{1}$$

**Figure 1: (a) Fictitious Crack Model, (b) linear tension softening curve, (c) cracks with tension softening**

As the applied load increases, the crack opens and propagates but the crack still carries stresses which linearly decrease with the crack mouth opening displacement ( $CMOD$ ). When  $CMOD = C_r$ , the

total closing force =  $\frac{1}{2} a f_t$ . As the crack propagates further and the crack opening exceeds  $C_r$  at the crack mouth ( $CMOD > C_r$ ), the total closing force ( $CF$ ) then becomes

$$CF = \frac{1}{2} a f_t \left( \frac{C_r}{CMOD} \right) \quad (2)$$

### 3.2 Bond between reinforcement and concrete

Bond between reinforcement and concrete is necessary for reinforced concrete to act as a composite material and to transfer load between the two materials. This interaction is represented in the literature as shear stresses ( $\tau$ ) on the interface between the reinforcement and concrete. These stresses are carried by different mechanisms such as mechanical interlock, chemical adhesion, and friction (12). The relative contributions of these mechanisms depend on the concrete and reinforcement properties. The development of bond stresses results in a relative displacement between the reinforcement and the concrete parallel to the reinforcement axis called slip ( $s$ ). The bond-slip behaviour of reinforced concrete affects the crack opening.

Based on test results on the local bond-slip relationship, Eligehausen et al (13) suggested a nonlinear relationship with increasing  $\tau$  and  $s$  when  $0 \leq s \leq s_1$  and until  $\tau = \tau_{max}$ . After the peak, the behaviour can be modeled using a linear relationship between  $\tau$  and  $s$  with a negative slope. Yuan et al (14) used a bi-linear approximation (Figure (2)) to study the performance of the interface between fibre reinforced polymers FRP and concrete. Mohamed Ali et al (15) further idealized a bi-linear relationship as a linear descending relationship and demonstrated its applicability to steel reinforced concrete (Figure (2)). In this case, the function that defines the bond-slip behaviour is

$$\tau(s) = \frac{\tau_{max}}{s_{max}} (s_{max} - s) \quad (3)$$

where  $\tau_{max}$  and  $s_{max}$  are determined experimentally and depend on the concrete and steel properties.

**Figure 2: Bi-linear bond-slip model and idealized linear bond-slip**

The stress-strain behaviour of steel reinforcement is characterized by the elastic modulus  $E_s$  until the steel yields at a stress  $f_y$ . The post-yield behaviour can be approximated as a linear relationship between the strain and stress but with a strain hardening modulus  $E_{sh}$  (Figure (3)).

**Figure 3: Idealized steel stress-strain relationship**

Haskett et al. (16) applied this steel stress-strain relationship and used an idealized linear bond-slip model like that shown in Figure (2) to study reinforced concrete. The stress-slip distribution was defined for two stages of behaviour. In the first stage the steel is elastic. During the second stage, the steel yields and the distribution of the stress-slip changes according to the strain hardening modulus  $E_{sh}$ . Considering the balance of forces and using a partial interaction numerical model, Haskett et al. (16) developed relationships between the applied axial load and the slip at the crack face by treating the elastic and the strain hardening behaviours separately and then summing them together. The elastic steel force  $SF_{el}$  was calculated considering  $E_s$ :

$$SF_{el} = \frac{\tau_{max} \pi d}{\lambda_{el}} \sin \left\{ \arccos \left\{ \frac{s_{max} - s}{s_{max}} \right\} \right\} \quad (4)$$

where  $\lambda_{el} = \sqrt{\frac{\pi d \tau_{max}}{s_{max} E_s A_s}}$ ,  $d$  is the diameter of the bar and  $A_s$  is the area of the bar cross section.

The force after yielding  $SF_{sh}$  takes into account  $E_{sh}$ :

$$SF_{sh} = \frac{\tau_{max} \pi d}{\lambda_{sh}} \sin \left\{ \arccos \left\{ 1 - \frac{s - s_{yield}}{s_{max}} \right\} \right\} + A_s f_y \quad (5)$$

where  $\lambda_{sh} = \sqrt{\frac{\pi d \tau_{max}}{s_{max} E_{sh} A_s}}$  and  $s_{yield}$  is the slip at yielding. For further details, please see (17).

### 3.3 Compression behaviour

Most of the investigations that have been carried out on strain localization in concrete under compression are based on the uniaxial compression behaviour e.g. (18–21). However, the mechanical behaviour of reinforced concrete beams with strain localization in the compression zone has not been studied extensively. Hillerborg (4) developed a fracture mechanics- based model to study compression strain localization. He treated the compression localization in a manner similar to the localization that occurs in tensile fracture. According to his model, the compression behaviour can be described by means of stress-strain diagram until the peak compressive strength is reached and thereafter using a stress-deformation diagram. It was assumed that this localization takes place within a length proportional to the depth of the compression zone which changes with loading. Jansen & Shah (20) showed that the post-peak stress-deformation relationship is a material property and depends on the specimen size. Based on this assumption, Carpinteri et al. (9) developed the overlapping crack model where he refers to the deformation that occurs after the peak load as interpenetration. In this model, instead of identifying a length where strain localization occurs, it was assumed that strain localization develops gradually in the compression zone in a manner similar to cohesive models used to describe the tension zone. The proposed stress-deformation relationship was similar to Hillerborg's. Based on the mathematical aspects of the overlapping model, a numerical algorithm was proposed (22) based on the finite element method to study the behaviour of RC beams. Borges et al. (23) adapted a linear softening curve (stress  $\sigma_c$  – strain  $\varepsilon$  response) (Figure(4)) which requires knowledge of the concrete compressive strength concrete ( $f_c$ ) and the critical damage strain ( $\varepsilon_{cr}$ ) as material properties of concrete. According to this softening curve

$$\varepsilon = \varepsilon_{cr} \left( 1 - \frac{\sigma_c}{f_c} \right) \quad (6)$$

Figure 4: Compression softening in concrete

The assumption of a linear relationship between the concrete compressive stress and strain allows for an analytical solution for flexural cracking at the same time capturing the important features of the behaviour.

### 3.4 Model formulation

In this section, the local phenomena outlined above will be integrated to develop a fracture-based model to describe the cracking process in reinforced concrete and provide an analytical solution for the development of flexural cracks in RC beams from the onset of cracking until failure. To do this, an RC beam with a rectangular cross section and effective depth  $d$  and width  $b$  is subjected to an external bending moment  $M$  will be considered (Figure (5)). From the three cases indicated in the figure it follows that

Figure 5: Crack development stages, (a) when  $CMOD < C_r$ , (b) when  $CMOD \geq C_r$  and (c) with compression softening

#### 3.4.1 Case (a) – $CMOD < C_r$ , Steel elastic

$$d = a + s + t \quad (7)$$

$$t = \frac{\sigma_c}{f_t} s \quad (8)$$

Longitudinal equilibrium gives

$$SF + 0.5 b a f_t \left( 2 - \frac{CMOD}{C_r} \right) + 0.5 b s f_t - 0.5 b \sigma_c t = 0 \quad (9)$$

While the reinforcement remains elastic, the steel force ( $SF$ ) can be determined from Equation (4) so  $SF = SF_{el}$ .

For a similar flexural crack, a relationship between  $CMOD$  and  $\sigma_c$  was developed (6) considering the deformation in concrete and the compatibility of stresses and strain in the top and bottom fibres of the beam section, where:

$$CMOD = \frac{2 \left( \frac{a}{d} \right)^2 \left( \frac{f_t d}{E_c C_r} \right) \left( 1 + \frac{\sigma_c}{f_t} \right)}{\left( 1 - \frac{a}{d} \right) \left( 1 - 2 \left( \frac{a}{d} \right) \left( \frac{f_t d}{E_c C_r} \right) \right)} C_r \quad (10)$$

#### 3.4.2 Case (b) – $CMOD \geq C_r$ , Steel may yield

$$d = a + s + t \quad (11)$$

$$t = \frac{\sigma_c}{f_t} s \quad (12)$$

Longitudinal equilibrium gives

$$SF + 0.5 b a f_t \left( \frac{C_r}{CMOD} \right) + 0.5 b s f_t - 0.5 b \sigma_c t = 0 \quad (13)$$

If the steel remains in the elastic region, the steel force  $SF = SF_{el}$  and can be calculated from Equation (4), and if the steel yields, the force after yielding can be calculated from Equation (5) since  $SF = SF_{sh}$ .

Considering the relationship between  $CMOD$  and  $\sigma_c$  (6)

$$CMOD = \frac{2 \left( \frac{a}{d} \right) \left( \frac{f_t d}{E_c C_r} \right) \left( 1 + \left( \frac{a}{d} \right) \left( \frac{\sigma_c}{f_t} \right) \right)}{\left( 1 - \frac{a}{d} \right)} C_r \quad (14)$$

### 3.4.3 Case (c) – $CMOD > C_r$ , Steel yields, Compression softening

$$d = a + s + t' + x \quad (15)$$

$$t' = \frac{f_c}{f_t} s \quad (16)$$

$$x = t \left( 1 - \frac{\varepsilon_0}{\varepsilon_0 + \varepsilon_{cr} \left( 1 - \frac{\sigma_c}{f_c} \right)} \right) \quad (17)$$

where  $\varepsilon_0$  is the strain corresponding to the compressive strength  $f_c$ .

Longitudinal equilibrium gives

$$SF + 0.5 b a f_t \left( \frac{C_r}{CMOD} \right) + 0.5 b s f_t - 0.5 b f_c t' - 0.5 b x (\sigma_c + f_c) = 0 \quad (18)$$

The steel force ( $SF$ ) can be calculated from Equation (5)

The relationship between  $CMOD$  and  $\sigma_c$  for case (b) can be modified as

$$CMOD = \frac{2 \left( \frac{a}{d-x} \right) \left( \frac{f_t (d-x)}{E_c C_r} \right) \left( 1 + \left( \frac{a}{d-x} \right) \left( \frac{f_c}{f_t} \right) \right)}{\left( 1 - \frac{a}{d-x} \right)} C_r \quad (19)$$

Considering the three cases indicated above, the crack propagation of lightly reinforced concrete beams can then be modelled by solving these equations for given steel and concrete properties.

## 4. Model results

A description of the cracking process is developed using the proposed model for different material properties and beams at different sizes. Figure (6) shows the predicted dimensionless moment  $\left( \frac{M}{f_{cb} d^2} \right)$  versus relative crack length  $\left( \frac{a}{d} \right)$  for an RC beam with the properties shown in the figure and for different reinforcement ratios (0.14% - 2%) where  $\tau_{max}$  and  $C_r$  are material properties to be determined experimentally. There are some kinks in the graphs which indicate a change between different stages of behaviour. With sufficient reinforcement the crack propagates with increasing applied moment. However, with low reinforcement ratios, in some regions, the applied moment shows a decrease in capacity with crack propagation.

The model assumes a gradual loss of tensile strength with crack propagation and that the concrete loses its tensile strength completely when the crack mouth opening equals the critical crack opening

( $C_r$ ). The point at which there is a decrease in the moment capacity is associated with the complete loss of the tensile stresses at the crack mouth as shown in Figure (6). Those stresses are then transferred to the reinforcement. If the reinforcement is not able to compensate for the loss of the concrete tensile stresses, the resistance decreases causing unstable crack propagation as noted for the beams with reinforcement ratios (0.14–0.77)% in Figure (6). Stable behaviour is associated with the development of the crack with increasing load whereas unstable behaviour is associated with the propagation of the crack under decreasing load. With higher reinforcement ratios, the crack propagation stage includes tensile softening until the tensile stresses diminish. If the stresses in the concrete exceed the compressive strength ( $f_c$ ), the concrete in compression exhibits a softening behaviour before failure and this depends on the geometrical and material properties.

Figure 6. Moment-crack length prediction for RC beams with different reinforcement ratios.

## 5. Comparison with test results

To check the theoretical predictions, comparisons with experimental test results were undertaken. In Figure (7) the predictions are compared with experimental data obtained by testing small scale concrete beams subjected to three-point bending. The beams had a width of 100mm, a depth of 120mm and a total length of 840 mm with reinforcement ratios of 0.28% and 0.5% and a concrete compressive strength of 30MPa or 45 MPa. The beams exhibited mode I fracture (crack opening) and during testing crack measurements were taken by means of a non-destructive digital image correlation technique. For further details of the test specimens and analysis techniques, please refer to (24). The beams were tested under displacement control. It is of note that to get a better indication of a decreasing branch of the crack length-moment diagram, the beams should be tested under CMOD controlled tests. This may be a reason why the descending branches in Figure (7) are not always captured; otherwise the model results show a good correlation with the experimental data.

(a) (b) (c)  
**Figure 7. Theoretical predictions versus experimental results.**

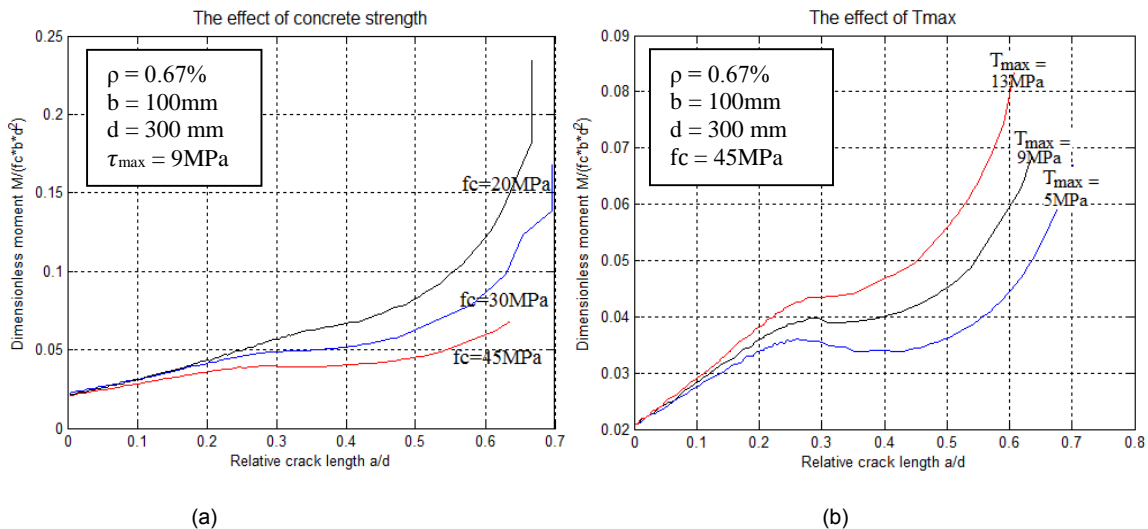

## 6. Ductility in reinforced concrete

Ductility can be defined as the ability of a material to provide sufficient deformation, and hence warning prior to failure. Ductility is very important to ensure adequate warning before collapse. Carpinteri (10) proposed a dimensionless brittleness number based on his developed LEFM Bridged Crack Model to study the stability of the cracking process in lightly reinforced concrete beams and suggested a brittleness number  $N_p$  (subsequently referred to as ductility number (25))

$$N_p = \frac{f_y d^{\frac{1}{2}} A_s}{K_{IC} A} \quad (20)$$

where  $K_{IC}$  is the critical stress intensity factor. Low values of  $N_p$  are a sign of brittle behaviour and high values give an indication of ductile behaviour.

The developed model includes further variables that are assumed to affect the cracking process. These variables include the beam depth  $d$ , beam width  $b$ , concrete compressive strength  $f_c$ , reinforcement ratio  $\rho$ , critical crack mouth opening  $C_r$ , maximum shear stress between the reinforcement and concrete  $\tau_{max}$ , elastic modulus of concrete  $E_c$  and elastic modulus of steel  $E_s$ . Figure (8) shows the effect of  $f_c$  and  $\tau_{max}$  on the behaviour of a reinforced concrete beam. It is noted that for the given parameters decreasing the concrete compressive strength increases the stability of the cracking process; on the other hand, decreasing  $\tau_{max}$  decreases the cracking stability.

(a) (b)  
**Figure 8: The effect of (a) concrete compressive strength (b) shear strength on the cracking process**

According to the developed model, it was found that in general increasing the values of  $d$ ,  $C_r$ ,  $\rho$ ,  $E_s$  and  $\tau_{max}$  increase the stability of the cracking process and helps to avoid a brittle failure due to the fracture of the reinforcement which can lead to a more ductile behaviour. In contrast, increasing the values of  $f_c$ ,  $E_c$  and  $b$  decrease the stability of the cracking process. Therefore, these properties should be reflected in a ductility measure to get a more representative indication of the ductility.

## 7. Conclusions

The proposed integrated fracture mechanics-based model is developed to describe the fracture process in reinforced concrete by integrating different local phenomena such as the tension softening of concrete to more precisely describe the behaviour of reinforced concrete beams. The model is capable of describing the initiation as well as the propagation of flexural cracks. Also, it is able to describe the post yielding behaviour as it considers the softening of concrete in compression and the strain hardening of the reinforcement after yielding. The bond between steel and concrete was modelled using a bond-slip model which gives a more accurate representation of the interaction between the concrete and the steel than the perfect bond assumption and helps to reveal the main parameters affecting the behaviour. Many assumptions related to the material behaviour were used to minimize the variables in the model to get a closed-form solution for the stresses associated with concrete cracking and the minimum reinforcement ratio, however, better accuracy can be achieved by implementing more sophisticated description of the material behaviour into the model i.e a non-linear softening behaviour can be assumed instead of linear behaviour.

**Abstract:** When concrete structures are exposed to fire, they may exhibit fire induced spalling. This spalling severely reduces the ability of concrete to insulate steel reinforcement and may result in premature structural failure. As part of an ongoing research project into the numerical prediction of fire induced spalling, a new coupled hygro-thermo-mechanical model is developed – suitable for modelling the general heat and moisture transfer and mechanical response of concrete wall or slab type elements exposed to fire. This paper presents the developed hybrid fibre-type mechanical model together with mechanical constitutive behaviour, hygro-thermal model and associated coupling. The model is used to simulate an experimental test where spalling was observed and the results are used to propose and discuss a robust theory for the phenomena.

**Keywords:** fire, spalling, pore pressure, hygro-thermo-mechanical, high temperature

## 1. Introduction

Concrete thermal spalling has been defined as “the violent or non-violent breaking off of layers or pieces of concrete from the surface of a structural element when it is exposed to high and rapidly rising temperatures as experienced in fires” (1). It is typically characterised into various types, based on the appearance, sound and violence of the spalling damage. Surface spalling, and in particular explosive spalling (generally characterised by the significant violence of its action), is generally regarded as the most serious form of spalling – posing significant potential risk to structural survival.

**Figure 1. Spalled inner surface of a Great Belt Tunnel element (rebar visible), tested by Hertz (2).**

In traditional concretes (i.e. not densified by SCMs and not having a high strength (2)) spalling upon extensive heating is likely if the moisture content is high. For dense or high strength concretes, spalling is highly likely and may occur multiple times, resulting in a combined section loss of 25 – 100 mm or more from a fire exposed face (3). Any significant amount of spalling will dramatically change the geometry of a member – removing cover and its insulating ability from reinforcement. For these reasons and more, decades of research have been put into trying to understand and mitigate the phenomena behind surface and explosive spalling.

Despite this work, researchers have (as yet) been unable to fully understand the mechanisms behind fire induced spalling. For this reason, its prediction is currently reliant upon empirical data, expert opinion and large scale tests (3) – methods that are generally either inaccurate or expensive (and potentially both).

Since the 1960's, many researchers have speculated on mechanisms responsible for the surface/explosive spalling phenomena in fire exposed concrete. Generally speaking, earlier proposals relied upon quite simplified arguments – consistent with the prevailing basic understanding of the mechanical and hygral processes occurring. A good summary is provided by Connolly (4); the main theories established by the late 90's were:

- *Thermal stress induced spalling* – where sufficiently rapid heating rates lead to a non-linear temperature profile and result in compressive stresses coplanar and near to the exposed surface. When these mechanical stresses exceed the compressive strength of concrete; failure occurs.
- *Pore pressure induced spalling* – with an increasing temperature near a fire exposed face, evaporable moisture within the concrete (and non-evaporable water being liberated) vaporises. The build-up of vapour pressure trying to escape outwards, combining with moisture heading inwards creating an increasingly saturated zone – 'moisture clog' – leads to even greater vapour pressures. When gas pressures exceed the tensile strength of the concrete, spalling occurs.
- *Combined thermal stress and pore pressure induced spalling* – some combination of the previous two effects. For example, Sertmehemetoglu (5) proposed that the compression stresses create internal cracks parallel to the surface and that the internal gas pressures acted upon this weakened zone to cause spalling.

In the last 15 years, a number of sophisticated hygro-thermal and hygro-thermo-mechanical models have been developed by researchers attempting to better understand the phenomena responsible for fire induced spalling – with the eventual ambition of predicting its occurrence. With the development of these models, a number of complementary suggestions as to a 'criterion' for detecting the occurrence of fire induced spalling have been made. These modern criteria have typically taken one of three forms:

- *Simple mechanical model based criteria* – generally based on simplified hypotheses about the stability of a surface concrete laminate. Detailed information about the stresses etc. (from the HTM model) is taken as basic input for the simple model (6).
- *Damage level based criteria* – where spalling is considered to occur at an arbitrary magnitude of mechanical and/or thermo-chemical damage (7).
- *Failure envelope versus pore pressure* – in partly or fully uncoupled models (mechanical and hygro-thermal), spalling is considered to occur when a combination of a gas pressure related tension and mechanical stresses reaches a multi-axial concrete failure envelope (8) (9).

While these spalling criteria have been proposed with some success, none have yet been demonstrated to convincingly and reliably predict spalling within arbitrary concrete sections. Moreover, none adequately explain the mechanics behind the spalling phenomena in a quantitative way and in the context of the established 'ordinary' mechanical behaviour.

In this paper, a new contribution to the research on spalling prediction is presented. A coupled hygro-thermo-mechanical (HTM) model is developed and implemented for studying the detailed mechanisms behind spalling. The model is pseudo-one dimensional, making it appropriate for predicting the behaviour of planar type elements such as floor slabs, walls and tunnel linings. The experimental tests of Ozawa et al. (10) are simulated using the model, as a context for discussing the phenomena of fire induced spalling.

## **2. Coupled hygro-thermo-mechanical model**

### **2.1 Introduction**

With the spalling resistance of concrete floors, walls, road and rail tunnel linings and any other planar type elements being of critical interest, and given that the hygro-thermal processes within these elements is practically one-dimensional, it is logical to develop a pseudo-one dimensional approach to the analysis for spalling prediction.

A comprehensive hygro-thermal model, based largely on the work of Gawin et al. (11), has been described in (12). In this study, the hygro-thermal model is coupled to a suitable mechanical model (for modelling the behaviour of concrete at high temperatures). A partitioned solution approach is taken for the

hygro-thermo-mechanical problem, whereby the HT component is solved individually – followed by the mechanical model – then both are iterated until satisfactory convergence is achieved between exchanged variables. The mechanical model is briefly described below.

## 2.2 Kinematics of hybrid type fibre model

A pseudo-one dimensional mechanical model (referred to as the *fibre model*) is proposed, based on the classical assumption that “plane sections remain plane”. If we consider full 3-dimensional mechanical constitutive behaviour, a suitable infinitesimal (small) strain measure is  $E^T = \{\varepsilon_{xx} \varepsilon_{yy} \varepsilon_{zz} \gamma_{xy} \gamma_{yz} \gamma_{zx}\}$ , noting that shear strain terms are twice the strain terms found in the strain tensor form. The conjugate stress measure according to the usual vector form is  $S^T = \{\sigma_{xx} \sigma_{yy} \sigma_{zz} \tau_{xy} \tau_{yz} \tau_{zx}\}$ . Considering a planar type structural component of thickness  $t$ , a straight line may be defined in the direction of the thickness and the coordinate axis  $z$  defined along this line, with a complementary continuous displacement field being  $w$ . Accordingly, the strain at any location  $z$  along the fibre is described by:

$$\varepsilon_{zz}(z) = \frac{\partial w}{\partial z} \quad (1)$$

The coordinate  $x$  and  $y$  axes are defined perpendicular to the  $z$  axis and to each other. With the condition that plane sections remain plane, the in-plane elongation strains at depth  $z$  are described by:

$$\varepsilon_{xx}(z) = \varepsilon_{xm} + \kappa_x z \quad (2)$$

$$\varepsilon_{yy}(z) = \varepsilon_{ym} + \kappa_y z \quad (3)$$

The terms  $\varepsilon_{xm}$  and  $\varepsilon_{ym}$ , and  $\kappa_x$  and  $\kappa_y$  are the mean elongations and curvatures (respectively) in both  $x$ - and  $y$ -directions. Likewise, the in-plane shear strain at varying depth is described by:

$$\gamma_{xy}(z) = \gamma_{xym} + \kappa_{xy} z \quad (4)$$

Here  $\gamma_{xym}$  and  $\kappa_{xy}$  are the mean in-plane shear strain and twist, respectively. Assuming Mindlin plate theory, the out of plane shear strains  $\gamma_{yz}$  and  $\gamma_{zx}$  are considered constant throughout the thickness. From the described kinematics, the vector of strain parameters applicable to the whole fibre is:

$$\mathbf{p}_m = \{\varepsilon_{xm} \kappa_x \varepsilon_{ym} \kappa_y \gamma_{xym} \kappa_{xy} \gamma_{yz} \gamma_{zx}\} \quad (5)$$

When combined with the elongation strain, these completely define the strain field at any location along the fibre. The vector of net actions on the fibre (per unit width) is:

$$\mathbf{q}_m = \{N_x M_x N_y M_y N_{xy} M_{xy} Q_y Q_x\} \quad (6)$$

The axial forces on the fibre are  $N_x$  and  $N_y$ , for the  $x$  and  $y$  axis orientations respectively. The in-plane shear force acting on the fibre is  $N_{xy}$ , and out of plane shear forces acting on  $y$  and  $x$  oriented faces are  $Q_y$  and  $Q_x$ , respectively. Bending moments acting on the fibre are  $M_x$  and  $M_y$ , causing stress changes on the  $x$  and  $y$  axis faces, respectively, with twisting moment  $M_{xy}$ . These actions on the fibre are chosen (in this order) as they are complementary to the whole fibre strain parameters described in Equation 5.

Following these definitions, it is possible to discretise the fibre and utilise a traditional finite element type formulation along the  $z$ -axis (i.e. with a number of along-fibre displacement degrees of freedom). Combining with suitable numerical integration for the along-fibre stress fields, the equation assembly may be written in the same format as a typical non-linear finite element problem. Solution is achieved using a predictor-corrector type Newton-Raphson method. As the mechanical model makes use of a combination of curvature, strain and displacement degrees of freedom along the fibre, it is a hybrid approach.

Unlike existing approaches to the HTM analysis of wall-like elements, where unrealistic fully fixed boundary conditions and plane-stress assumptions are used (8) (13) (14), the approach described above is able to realistically model the un-constrained (or constrained) curvature and elongation that arises in

concrete walls/slabs. Additionally, it is possible to consider any pre-tension or applied load in the analysis, and the geometric effect of a 'large' element size may be considered by fixing curvature.

### 2.3 Mechanical constitutive model for fire exposed concrete

While the mechanical model (described in the previous section) is pseudo-one dimensional, the high temperature concrete material behaviour must be modelled in a fully three-dimensional sense. For this reason, a suitable comprehensive constitutive model is required. Following the established approach for modelling short term response of concrete in fire, a total strain rate decomposition is considered:

$$\dot{\mathbf{E}} = \dot{\mathbf{E}}_{\sigma} + \dot{\mathbf{E}}_{ft} + \dot{\mathbf{E}}_{tr} \quad (7)$$

The components of the total strain,  $\mathbf{E}$ , are the instantaneous stress-related strain,  $\mathbf{E}_{\sigma}$ , the free thermal strain (FTS),  $\mathbf{E}_{ft}$ , and transient creep strain,  $\mathbf{E}_{tr}$ . Any additional basic creep strain is neglected since for fire spalling analyses, where time duration is short, its contribution is typically minimal (15).

The free thermal strain of concrete heated to high temperatures is typically established by heating an unstressed specimen. It has been established that the expansion strain is dominantly determined by the quantity and type of aggregates in the concrete (3). For siliceous type aggregates the following phenomenological expression (developed from that proposed in (16)) provides a good correlation with experimental data for linear expansion, and is used in the model:

$$\varepsilon_{ft}(T) = \begin{cases} \frac{0.02 V_a}{\ln(5/63)} \ln\left(\frac{650 - \theta}{630}\right) & \text{for } 20^{\circ}\text{C} \leq \theta \leq 600^{\circ}\text{C} \\ 0.02 V_a & \text{for } \theta > 600^{\circ}\text{C} \end{cases} \quad (8)$$

The variable  $V_a$  corresponds to the volumetric ratio of aggregates within the concrete and  $\theta$  is the temperature in Celsius degrees. The three-dimensional strain rate is then given by:

$$\dot{\mathbf{E}}_{ft} = \dot{\varepsilon}_{ft} \mathbf{1} \quad (9)$$

where  $\mathbf{1}$  is the second order identity tensor expressed in matrix form,  $\mathbf{1}^T = \{1 \ 1 \ 1 \ 0 \ 0 \ 0\}$ . Since uncontrolled shrinkage strains occur during any heating process for the measurement of FTS (being almost impossible to separate from pure mechanical strains), they are considered to be implicitly included in this expression.

An approach similar to Nielsen et al. (17) has been taken to modelling the transient creep strains (TCS). Firstly, a dimensionless temperature is defined as  $\bar{T} = (T - 20^{\circ}\text{C})/980^{\circ}\text{C}$ , then a normalised TCS function is defined by:

$$\bar{\varepsilon}_{tr}(T) = \begin{cases} A\bar{T} & \text{for } 0 \leq \bar{T} \leq \bar{T}^* \\ A\bar{T} + B(\bar{T} - \bar{T}^*)^3 & \text{for } \bar{T} > \bar{T}^* \end{cases} \quad (10)$$

where the two constants are  $A = 0.025$  and  $B = 0.7$  and with the dimensionless transition temperature  $\bar{T}^* = 0.3$ . Following the work of de Borst and Peeters (18), the multi-axial transient creep rate is postulated as depending linearly upon the (effective) stress tensor,  $\mathbf{S}$ , according to:

$$\dot{\mathbf{E}}_{tr} = \frac{\beta}{f_c} \mathbf{H} \mathbf{S} \dot{T} \quad (11)$$

where  $\beta$  is the derivative of the normalised TCS function,  $\bar{\varepsilon}_{tr}$ , with respect to temperature  $T$ ,  $f_c$  is the ambient temperature compressive strength and  $\mathbf{H}$  is a compliance matrix (see for example (13)). In this study the Poisson's ratio like parameter used in the compliance matrix is taken as  $\nu_c = 0.35$ . The predictions of this approach have been confirmed to represent well the mechanical behaviour of loaded concrete under elevated temperatures.

Lastly a model for the instantaneous stress-related-strain type mechanical behaviour of the concrete itself is required. Considering that the hygro-thermal component of the overall model requires information on mechanical damage (as it strongly effects permeability), a model with a damage basis is suitable. As a first step, an isotropic damage model has been implemented in this study – while such models cannot

capture anisotropic stiffness effects and do not model unloading well, these limitations are unlikely to have any significant consequences for this analysis. Isotropic damage models have also been used successfully by the dominant HTM models presented in the literature (11) (13).

A modified non-local version (to better represent the multi-axial behaviour of concrete) of the Mazars (19) type isotropic damage model is used to represent mechanical behaviour in the concrete skeleton:

$$\mathbf{S} = (1 - D)\mathbf{C}_e\mathbf{E}_\sigma \quad (12)$$

The undamaged material stiffness matrix is  $\mathbf{C}_e$ , the total scalar damage variable,  $D$ , is determined from a combination of thermo-chemical,  $\chi$ , and mechanical damage,  $\omega$ , as proposed in (20). The damage parameters relate to secant stiffness according to:

$$(1 - D) = (1 - \chi)(1 - \omega) = \frac{E_0(T) E(T)}{E_0(T_a) E_0(T)} \quad (13)$$

where  $E_0(T_a)$  is a representative secant modulus for undamaged concrete at ambient temperature,  $E_0(T)$  is a representative secant modulus for mechanically undamaged concrete at elevated temperature, and  $E(T)$  is the total secant modulus of concrete at an arbitrary strain and at elevated temperature.

The growth of mechanical and thermo-chemical damage variables is controlled by a pair of damage loading functions. The mechanical damage loading function corresponds to  $\bar{\epsilon}$ , the non-local counterpart to the scalar valued function of the strain tensor (the Mazars type strain measure). Appropriate consideration of the effect of temperature on mechanical behaviour is considered through temperature dependence of the chosen damage evolution laws and damage threshold parameter.

Lastly, a total stress tensor is defined based on established poro-mechanics (i.e. akin to an effective stress principle):

$$\mathbf{S}^{tot} = \mathbf{S} - bP^s\mathbf{1} \quad (14)$$

where  $b$  is the Biot coefficient and  $P^s$  is a measure of the internal pressures acting on the solid skeleton (21). The pressure,  $P^s$ , is a combination of that from wetting (liquid water) and non-wetting (gas) phases. In this analysis, the effect of capillary pressure is assumed to be already implicitly considered in the stress-strain behaviour of the material – meaning that  $P^s$  is taken as just the gas pressure. A typical Biot coefficient of  $b = 0.5$  is considered, as suggested by Scherer et al. (22) for cementitious materials.

## 2.4 Effect of moisture on mechanical behaviour

It has long been established that the ambient temperature variation of moisture content (between dry and fully saturated conditions) has a non-negligible effect on the compressive and tensile strength of concrete specimens. While varying magnitudes of this effect have been reported, in general specimens pre-conditioned to a dry state will have a typical UCS increase of 10%, while conversely, samples saturated prior to testing will have a UCS reduction of 10-20% (23). While various hypotheses have been put forward to explain this effect, the most plausible relate to changes in surface energy and disjoining pressure associated with adsorption of water (24) or to a hydrolytic weakening phenomena (25).

Recently, Jansson and Boström suggested that a similar moisture weakening phenomena may also bear some responsibility for the observed spalling phenomena in fire exposed concrete (26). Citing several references, and from experiments of their own, they found that the observed ambient temperature moisture weakening effect only increased with temperature.

In this study, consideration of this moisture weakening effect is made in the HTM model. Based on the available experimental data, a weakening function (of both temperature and humidity) is proposed, whereby the ambient temperature saturated strength is considered 20% less than the dry state strength. At the critical temperature of water ( $T_{cr} = 374.14^\circ\text{C}$ ), the saturated strength is nominally considered to be fully 80% less than the strength when in a dry state. A linear variation of this reduction over varying temperature and humidity is assumed (the reduction is actually transitioned to 0% near the critical temperature, as humidity has no meaning past this point).

### 3. Numerical simulation

To demonstrate the efficacy of the hygro-thermo-mechanical model in simulating the behaviour of planar type concrete elements exposed to elevated temperatures, as well as providing a basis for examining the mechanism responsible for the fire spalling phenomena, a pair of experiments reported by Ozawa et al. (10) are simulated. The experiments were set up to facilitate essentially one-dimensional heat transfer through several unreinforced high strength concrete slabs, each having the plan dimensions of 0.4 m x 0.4 m and an overall thickness of 0.1 m. Each specimen was placed face-down onto an electric furnace that applied a linearly ramped temperature to the bottom face for approximately 50 minutes. At a nominal depth of 8 mm from the heated face each specimen contained 5 embedded steel pipes (filled with hydraulic oil) connected to pressure transducers – allowing internal gas pressures to be measured. A single thermocouple was also present centrally at the same 8 mm depth within each specimen. All samples experienced some spalling prior the termination of testing.

By applying two different curing conditions prior to testing, Ozawa et al. (10) examined the effect of a significant variation in the initial moisture content on the occurrence of spalling. One pair of tests was performed on fully saturated specimens (wet cured for 64 days before testing), and another pair of tests on air dried specimens (also water cured for 64 days, then held in a control room at 20°C and 40% RH for 118 days to partially dry before testing). The reported 28 day wet cured concrete compressive strength was 83.5 MPa and Young's modulus was 41 GPa. The water to cement ratio was 0.3.

Given the specimen geometry and roughly one-dimensional heating exposure, a pseudo-one dimensional HTM model (as proposed) is suitable. In this instance, the results of two of simulations are presented, one for each curing condition. The material properties used in the simulations are given in Table 1.

**Table 1. Material properties and initial conditions used in numerical simulations.**

Parameter	Analysis Value
Porosity (20°C)	10 %
Intrinsic Permeability, $k_{int0}$ (20°C)	$0.5 \times 10^{-19} \text{ m}^2$
Permeability coefficient, $A_{kt}$	0.006 1/°C
Apparent density (dry, 20°C)	2350 kg/m <sup>3</sup>
Dry Compressive Strength (20°C)	83.5 / 0.85 = 98.2 MPa
Dry Tensile Strength (20°C)	4.7 / 0.85 = 5.53 MPa
Initial internal temperature	35°C
Initial internal gas pressure	101325 Pa
Initial water saturation level	0.997 (Saturated) or 0.5 (Air Dried)

For the simulations, 100 quadratic type finite elements were used (refined at both exposed faces) for the hygro-thermal simulation and the discretisation of the mechanical simulation. Zero external loads (i.e. no in-plane moments or out-of-plane moments) are applied to the mechanical fibre model; however, the section is free to experience curvature and mean elongations as the analysis progresses. The analysis time-step is chosen automatically during the numerical simulation to maintain convergence.

In the coupled hygro-thermo-mechanical simulation, it is possible to consider the additional important effect of mechanical damage on intrinsic permeability. For this purpose, a multiplicative factor of the type suggested by Souley et al. (see (27)) is incorporated in the permeability formulation:

$$k_{int}^w = k_{int0} \cdot 10^{A_{kt}(T-T_{k0})} \cdot 10^{A_{\omega}(\omega-\omega_0)} \quad (15)$$

In the presented analysis, the multiplier for mechanical damage of  $A_{\omega} = 5.5$  and threshold for mechanical damage  $\omega_0 = 0.4$  were used, based on published experimental data.

### 4. Numerical simulation results and spalling mechanism

In order to achieve close correspondence of the experimental tests and numerical simulations (giving the greatest chance that other simulation produced data is accurate), researchers will typically attempt to adjust unknown experiment parameters in HTM models so that simulation results match known measurements; e.g. see (8) (13). In the case of the experiments by Ozawa et al. (10), the quoted electric

heater ramp rate was 20°C/min. For the presented simulations, the external thermal boundary conditions were adjusted within reasonable ranges for both air dry and saturated specimens to achieve a good match between simulated temperatures and the measured temperature profile (at 8 mm depth). The simulated temperatures at the surface and at 8 mm depth, compared with measured thermocouple data, are presented in Figures 2a and c. The simulation matches the non-linear development of temperature well.

(a) Temperature vs. time (*Air Dried*)

(b) Gas pressure vs. time (*Air Dried*)

(c) Temperatures vs. time (*Saturated*)

(d) Gas pressure vs. time (*Saturated*)

**Figure 2. Experimental and numerical simulation results vs. time.**

The other main parameter able to significantly affect the results of HTM simulations is intrinsic permeability. No direct permeability measurements were made on the concrete used in the experiments of Ozawa et al., so an estimate must be made by comparison with other simulations. Gawin et al. used an intrinsic permeability of  $2 \times 10^{-19} \text{ m}^2$  for a similar concrete in their work (14). At least an order of magnitude lower permeability than that used for 35 MPa concrete modelled previously (12) is reasonable. In this study the ambient temperature (un-damaged) intrinsic permeability has been taken as  $0.5 \times 10^{-19} \text{ m}^2$ . The resulting simulated gas pressures, along with the measured gas pressures in each test specimen, are presented in Figures 2b and d. Noting that direct gas pressure measurements in heated concrete specimens are notoriously susceptible to leaks and cracking (resulting in low or no measured pressure development), the correspondence between predicted and measured gas pressure development is very good.

Having now fully described the conditions of the analyses, the results may be examined in more detail. Firstly, it is noted that the trend of development of gas pressures predicted in the model and those found experimentally are both very similar. An initial period of approximately 30 minutes having negligible gas

pressure development at approximately 8mm into the slab is followed by a relatively rapid pressure build up before spalling was experimentally observed. Peak gas pressures were measured as 3.5 MPa and 3.2 MPa (with several gauges reading moderately lower) for air dry and saturated specimens, respectively. Marginally lower gas pressures were recorded at the initiation of spalling, particularly for the wet specimen. Corresponding simulated peak gas pressures were 3.1 and 2.6 MPa at spalling – a good match.

In the air dry case, spalling was reported by Ozawa et al. to have occurred at approximately 43 to 44 minutes. In the saturated case, spalling was reported to have occurred between 44 and 49 minutes. In the numerical simulations, spalling is detected (as per the following Section) at approximately 40 minutes for the air dry specimen, and at 41 minutes for the saturated specimen, which is in close agreement. Observed spalling depths were up to 12 mm after testing, with an average depth of around 4-8 mm. The numerical simulations predict that spalling initiates at approximately 6 mm and 3 mm depth for air dry and saturated specimens, respectively.

Ozawa et al. also made some interesting acoustic emission (AE) measurements directly on the slabs during their tests (10). They found that from around 16 to 20 minutes into the tests, AE events gradually started to occur – these picked up from around 25 minutes into the test and continued constantly until spalling. While Ozawa et al. proposed that these events related somehow to water vapour movement, it is proposed here that they relate rather to the internal cracking processes associated with relief of (primarily) thermal expansion strains. Examining Figure 3, which shows the computed mechanical strain related stress along one axis (parallel to exposed surface), we see that from around 23 minutes into the analysis the core zone of concrete is predicted to reach its tensile strength. This matches well with the start of AE event detection. From this point onwards, further thermal expansion is associated with internal rupturing and softening of an expanding internal concrete zone in tension. Clearly fully restrained or plane strain analyses, as employed by many authors using advanced HTM models (i.e. (8) (14) (13)), must be unable to capture internal stress regimes and material behaviour to good accuracy.

**Figure 3. Mechanical strain related stress, parallel to the exposed surface (Air Dried).**

## 5. Mechanics behind explosive spalling phenomena

A new criterion is proposed to explain and detect the occurrence of spalling. As a slab or wall like concrete structure (such as that being modelled) is rapidly heated, the mechanical processes primarily consist of a combination of those shown in Figures 4a and b. The large temperature differential between surface concrete and internal or un-heated concrete, combined with the plane-sections-remain-plane requirement, means that surface concrete fibres experience constrained thermal expansion (see Figure 4a). It is possible that the mechanical stresses, which build up, may exceed the compressive strength of the material – but regardless the displacement type nature of loading strongly encourages failure to be gradual (i.e. assuming no localisation effects).

Further to this, as indicated in Figure 3, it is normal that un-restrained concrete slab sections will experience internal tensile damage/cracking if exposed to rapid surface temperature rise. In this instance,

the imposed 'tension loads' are directly related to the mechanical surface strains and, as such, when the internal core softens, the loads dissipate – making this kind of mechanism also generally stable (see Figure 4b).

**Figure 4. Simplified consideration of imposed strains/actions within concrete near the face.**

Lastly, we consider the internal positive gas pressures, resulting from water vaporisation and dehydration and creating effective tensile stresses in the concrete skeleton (see Equation 14 and Figure 4c). In this case, when the internal gas pressure combined with the prevailing stress regime (which is complex and changes over time) leads to the material reaching the multi-axial strength envelope – the failure cannot be gradual. Once the strength envelope is reached, the mechanical resistance decreases and so the mechanical action must decrease for stability to be ensured. With vapour pressure being basically maintained, instantaneous rupture must eventuate, leaving an unstable cover zone with significant stored strain energy. Here it is proposed that explosive spalling is merely the consequence of pore pressure induced mechanical instability, as a consequence of a softening material. In the HTM simulation, this mechanical instability is generally detected as a negative pivot in the tangent stiffness matrix – where the problem becomes poorly-posed for the imposed gas pressure 'load'.

From the proposed spalling mechanism, it is possible to see why historic attempts at predicting and "simplifying" the spalling phenomena have been largely unsuccessful. The occurrence of spalling at a specific depth within a section appears intricately related to (at that depth) the moisture state, the mechanical stresses parallel to the exposed face (where the stresses at a local depth are strongly related to the rate of temperature increase, the degree of restraint and any external loads applied) and the pore pressures that develop (both in magnitude and the location of pressure peak relative to the current mechanical stress regime). Moreover, the moisture weakening phenomena may also be a significant factor in fire induced spalling – clearly it requires further research.

## 6. Summary and conclusions

Building upon a fully coupled hygro-thermal model for predicting the behaviour of concrete at high temperatures described previously by the authors (12) (28), an additional mechanical model component giving a coupled hygro-thermo-mechanical model has been described. This model has been formulated particularly for the efficient analysis of pseudo-one dimensional conditions, which are commonly encountered in both laboratory fire testing and in practice (e.g. walls, slabs, tunnel linings, etc.).

The instrumented fire spalling experiments of Ozawa et al. (10), on both fully saturated and air dry preconditioned samples, were simulated using the proposed model and a good correlation was observed for the model with the experimental temperature versus pore pressure measurements. The presented numerical model predicts that spalling type failures will occur at approximately 41 minutes from the start of tests, closely matching experimental observations. Additionally, the depths of spalling predicted correspond reasonably with experimental results. A new explanation of the spalling phenomena has been presented.

It is suggested that the described HTM approach shows significant promise for true model-based information on the spalling risk of fire exposed concrete structures. Further work is required to develop confidence in the model for predicting the spalling of arbitrary concrete mixes and fire/loading scenarios.

# In-situ Concrete Strength Assessment based on Ultrasonic (UPV), Rebound, Cores and the SONREB Method

Frank Papworth<sup>1</sup>, David Corbett<sup>2</sup>, Reuben Barnes<sup>3</sup>, Joseph Wyche<sup>4</sup> and Jonathon Dyson<sup>5</sup>

<sup>1</sup> BCRC (WA); <sup>2</sup> Proceq; <sup>3</sup> PCTE; <sup>4</sup> Wyche Consulting; <sup>5</sup> BCRC (NSW).

## Synopsis:

The strength of concrete in a new structure is sometimes called into question. This may be due to cylinders not being taken, poor cylinder production, transport or testing, the actual concrete strength being low or the suspicion that in-situ cylinders are not representative of in-situ concrete. Whatever the reason testing of the in-situ concrete is generally called for. This paper gives a brief outline of the key aspects of strength assessment including a review of concrete supply and testing records, extent of testing required, assessment by cores to AS 1012.14 (1) and AS 3600 (2), ultrasonic (direct and indirect methods) and rebound hammer testing and analysis of in-situ strength using cores and NDT results (including published methods such as EN 12504 (3), EN 13791 (4), BS 6089 (5) and those under consideration by RILEM). If the concrete strength is found to be low, a structural analysis has to be undertaken. The paper includes information of six projects assessed. In two, strengths were low across the whole mine site but in each case only one structure required strengthening. In another, very low strength was identified at an early stage and a risk assessment identified the structure should be replaced. In the others, strengths were found to be adequate.

**Keywords:** Concrete, compressive strength, ultrasonics, UPV, rebound, cores, structural assessment, strengthening.

## 1. Introduction

For many years CSTR 11 (7) was the revered document on assessment of concrete compressive strength from cores. This was updated in 1987 (8). In 2002 CIA Z11 (9) was published and became the Australian reference for assessment of core strengths as a supporting document for AS 1012.14 (1). AS1012.14 provides performance requirements on sampling, conditioning, and reporting on cores and calls on AS 1012.9 (6) as the method of testing concrete samples for compressive strength. However, in 2004 a project report on core strengths by the Concrete Society (10) provided updated information on tests from a range of samples and findings were subsequently incorporated in an updated BS 6089 (5) which is complimentary to BS EN 13791 (4), the European standard on testing concrete strength in structures. Consequently CSTR 11 (7,8), and AS1012.14 (1) and CIA Z11 (9) which are at least partly based on them should be used with caution as some of the analysis methods have been superseded. The Concrete Society issued Advice Note 43 (11) in 2013 which summarises some of the approaches in the new European standards. In this paper some of the differences between European Standards and the methods used in Australia based on CSTR 11 are given.

BS EN 13791 now provides clear guidance on the use of ultrasonic pulse velocity and rebound hammer testing. These methods enable rapid scanning of the concrete to detect variations in strength and BS EN 13791 provides guidance on how their use can be incorporated into reducing the number of cores required. In this paper the methods are outlined with specific reference to direct and indirect UPV measurements and combined use of rebound, UPV and core strengths using the 'SonReb' method.

An outline of the strength assessment on seven projects is given in the paper to show the variety of approaches that may be appropriate. For each project a durability assessment was also undertaken for each structure but this is not included here as the paper's focus is strength and structural assessment. The methods employed for strength assessment range from reliance on 28 day strengths to the use of cores, UPV and rebound testing. The subsequent analysis of the structures included a full structural analysis to determine structural reliability and risk assessment if there is a reduced reliability.

## 2. Methods of Testing

### 2.1 Cores

To maximise the number of cores meeting AS 1012.14 requirements and to minimise damage to the core and structure, the engineer should ensure that the coring contractor has adequate experience in using his equipment to take cores for the specified purpose. On one project in remote Botswana the contractor arrived with a brand new coring machine, no hold down anchors and 5 people. His first core failed the requirements of AS 1012.14 because the machine was not properly secured and because of stop start coring. Being a remote location it took two days to get the team working.

Before coring the reinforcement locations are carefully mapped and marked with due allowance for bar diameter. The upper reinforcement layer can generally be identified using a covermeter but this may miss saddles which may be identified using ground penetrating radar.

Assessment of core strength can be based on BS EN 13791 and BS 6089. A comparison of these with current Australian standards is given in *Table 1*.

**Table 1 : Australian and European Standard Requirements for Assessing In-situ Concrete Strength**

	Not Yet Harmonised with European Practice (based on CSTR 11)		State of the art documents on in-situ strength assessment
	AS 1012.14	CIA Z11	BS EN 13791/BS6089
Core diameter	75mm	75min or 2.5 x agg size	100mm (increase number of cores if using diameters down to 50mm)
Core length:diameter ratio	Close to 2:1	1 to 2 (ideally 1.9 to 2)	1 to 2
<b>Actual Strength Corrections</b>			
Correction l:d	k <sub>1</sub> = 1 for l/d =2 reducing in steps to 0.87 for l/d=1		K <sub>cyl</sub> =2.0/(1.5+1/(l/d))
Correction rebar present	-	k <sub>2</sub> by formula	Avoid rebar
Correction core axis	-	k <sub>3</sub> = 1 perp. to casting direction and 1.08 if parallel	Influence noted but UK Annex NA says no allowance to be made
<b>Core locations limits</b>			
Vertical pours	-	Not from top 20% up to 300mm	Exclude top 300mm. Core top third
Face of concrete	-	Not within 50mm of face	Not within 50mm of face
Number of cores where suspect batch	-	3 from each suspect batch	15 with no NDT, 9 with NDT. Move to reduce the number with NDT
Conditioning	Wet 3d or air 7d	Dry (7d) as AS 3600	Air 3d but allowance can be made for wet cure
End preparation	AS 1012.9	Sulphur cap or ground ends	Ground ends recommended
Provision for outliers	-	No	Yes
NDT assessment	-	-	UPV, pullout and rebound accepted as means of reducing core numbers

### 2.2 Rebound

The original rebound hammer measured the hardness of a material by the degree of rebound. The instrument worked by firing a known mass using a standard spring loading to impact on a rod held in contact with the surface being tested. When the mass hits the rod it rebounds to an extent that depends on the hardness of the surface in contact with the rod. The original rebound hammer measured the rebound value R mechanically as a distance that the mass rebounded from the concrete surface. Extensive testing carried out in the late 1950's gave correlation curves between rebound value and concrete compressive strength.

In 2007 an electronic version of the original rebound hammer was introduced. This instrument measures rebound value (now Q) as the quotient between the velocity of the hammer mass just before and after impacting the rod. The validity of the new measurement principle has been recognized by the major standards bodies.

It should be noted that Q-values and R-values are not interchangeable. Correlation curves developed for the original rebound hammers cannot be used with Q-value and correlation curves developed for the new hammer cannot be used with the classical hammer. The manufacturer provide a strength relationship between Q values and compressive strength based on a lower 10<sup>th</sup> percentile curve. They do not provide direct relationships between Q values and R values, as testing on various types of concrete have shown that the relationship is not constant.

When assessing in-situ compressive strength using cores, EN 13791 requires at least 15 cores to be taken to establish the insitu concrete strength. The number of cores to be taken may be reduced to 9 when used in combination with NDT tests such as rebound hammer or ultrasonic pulse velocity.

In the German national annex to EN 13791 there is also the possibility to assign a compressive strength class based on rebound hammer testing alone, as in many cases, it is not allowed to take cores. EN 13791 is currently under review and there are proposals for reducing the number of cores further when used in combination with NDT testing and also to generally accept the method described in the German national annex.

Testing should be undertaken in accordance with EN 12504-2. A test location should be a minimum 100m thick, 300x300mm test area, minimum of nine readings, impact points >25mm apart, surface clean and smooth. Nine such test locations are required for a test region as described in EN 13791. A core should also be taken at each test location to establish the correlation. The method then uses the core correlation to shift a base correlation curve upwards. The same method may be used with ultrasonic pulse velocity.

### 2.3 Ultrasonic Pulse Velocity

UPV can be determined in number of ways direct, indirect and semi-direct. Only the first two are discussed here. Direct UPV is the most reliable as the velocity is measured across the entire element and gives an average velocity for a large thickness of concrete. Direct UPV can also be measured on cores to give a direct correlation between UPV and core strength.

**Figure 1** : Indirect Pulse Velocity Using Yaman's Five Point Method

However in cases where access to only one face is possible a direct velocity measurement is not possible. Yaman (16) developed a method of measuring the indirect velocity over 4 head spacings (200, 250, 300 and 350mm). This is very similar to the surface velocity method described in Annex A of EN 12504-4. The slope of a straight line plot of time vs head spacing (*Figure 1*) gives an indirect velocity that is very close to the direct velocity for homogeneous specimens. The principle difference between direct and indirect UPV's is that direct measurements are largely through the bulk concrete and indirect measurements are largely through the near surface but Yaman's five point method avoids direct surface effects such as carbonation and finishing. This is particularly useful for assessing slabs. It should be noted however, that typically concrete is an inhomogeneous material and the difference between indirect and direct pulse velocities can vary significantly if surface effects are deep.

In the indirect mode a particular issue is the low signal level compared with direct measurements. The first pulse may not trigger the timer unless the gain is suitably increased. For such measurements, it is advisable to use a waveform display to be certain of correct triggering. This may or may not be apparent from the best fit line through the four data points. Testing should otherwise be undertaken in accordance with EN 12504-4.

## 2.4 SonReb

One issue with combined use of NDT and cores for strength assessment is the number of core correlations required according to EN BS 13791. By reducing uncertainty by combining two NDT measurements the number of correlation points decreases. Breyse (15) describes the SonReb method of combined UPV and Rebound measurement as discussed by RILEM Technical Committee TC 207-INR as follows: *“This combination has received the name of SonReb, for Sonic and Rebound. Rebound and ultrasonic pulse velocity measurements can be carried out quickly and easily. The underlying concept is that if the two methods are influenced in different ways by the same factor, their combined use can cancel the effect of this factor and improve the accuracy of the estimated strength.”* Breyse describes two approaches to the combined assessment based on best fit of data but the multivariate approach A is preferred, i.e.: Approach A :  $f_c = aV^bR^c$  where a,b and c are constants ( $1.15 \times 10^{-10}$ ; 2.6 and 1.3 respectively); V is UPV; R rebound number.

Although standard values for a, b and c are given project specific values are determined.

Generally, the SonReb method provides an increase in correlation accuracy when compared with using either the rebound method or UPV method in isolation.

The data, presented in *Figure 2* was collected by the rebound hammer manufacturer to establish a SonReb curve using the Q-value. It illustrates the benefit of using the combined method. The SonReb method has been established as a national standard in several countries including Italy and China in particular and is currently being considered by the RILEM TC-249-ISC committee dealing with in-situ compressive strength estimation.

a) UPV correlation to compressive strength      b) Q-value correlation to compressive strength      c) SonReb correlation to compressive strength

**Figure 2** : Data from 240 Cubes to Establish SonReb Calibration Curves for Q Value

## 3. Structural Assessment of New Concrete Structures in a Ghana Mine

Shortly after construction deterioration of the primary crusher approach slab led to a preliminary investigation of the strength of concrete. This indicated that there was cause to suspect that the strength of concrete could be lower than design. Subsequently a detailed investigation of the concrete to identify if there are any significant deficiencies in construction was undertaken. For cores testing SANS standards were followed but as there were no SANS standards for non-destructive tests international standards were followed. The specified strengths varied and are shown together with core strength results in *Table 2*.

**Table 2 : Core Test Results From Ghana Mine**

Element Orientation	Vertical		Horizontal	
Specified Strength	40MPa	25MPa	40MPa	25MPa
No of Cores	3	4	-	19
No of Compressive Strength Tests	3	7	-	28
Average Strength (MPa)	34.0	16.1	-	17.8
Standard Deviation (MPa)	-	-	-	6.3
% Failing Individual Result	0%	57%	-	54%
% Failing Average Result	0%	100%	-	71%

The large fraction of cores that failed the individual and average strength requirements, and the margin by which some cores failed, was a serious concern.

Rebound hammer and core testing results from the same location are shown in *Figure 3*. The best fit relationship is achieved at compressive strength =  $2.161e^{0.043x}$  where x is the Q value. The rebound results are from the surface of slabs and the finishing may account for why a high Q value is achieved for a given compressive strength but more likely was that carbonation had occurred hardening the surface strength. This effect means rebound results on the top of the slab are not an effective method of assessing bulk strength. Consequently the assessment was based on core strengths.

**Figure 3 : Core Strength Vs Rebound Hammer**

Based on the core strength tests an equivalent characteristic cylinder strength of 15MPa was determined for the 25MPa concrete and 25MPa for 40MPa concrete. The structural assessment was undertaken in conjunction with the original designers with free and unfettered access to the design calculations. Jointly with the designer critical elements were identified and checked based on the strength of 15MPa and 10 year design life. The structural review identified all structures behaved acceptably at the actual in-situ strengths except for one tall conveyor support. Additional cores from this structure indicated there were still some concerns and hence strengthening was instigated.

#### 4. Structural Assessment of New Concrete Structures in a Botswana Mine Plant

25MPa and 32MPa concrete was specified for footings/slabs and walls/columns respectively but review of the cube test results showed a much lower strength was achieved in practice. Cores were taken from various locations and results were consistent with the cube results. Multiple cube results from the same batch tested at the same age were quite consistent and 7 day results were reasonably consistent at 67% of the 28 day results. This indicates that, failing an unexpected consistent error in testing, the results are a realistic and able to be used as a true indication of the strength of concrete supplied. The results are summarised in *Table 3*.

**Table 3 : Summary of 28day Compressive Strength Test Results**

Period	4 <sup>th</sup> -9 <sup>th</sup> May	Remainder
f <sub>c</sub> cube (MPa)	11	19
f <sub>c</sub> cylinder (MPa)	9	15

Compressive strengths from 2 cores taken from each of three different bases gave a characteristic in-situ cylinder strength of 17.5MPa. This was marginally higher than the 28day cube results and may have an improvement due to the aging.

28 rebound hammer results provided had an average cube strength of 28MPa and a standard deviation of 5.6MPa to give a characteristic cube strength of 18.8MPa.

A review of the mix indicated low coarse aggregate volume and a high proportion of crushed sand. The mix would have had a high water demand and it was concluded that to achieve a workable concrete extra water would have likely been added.

Hence for the project it was determined that:

- a) No further NDT testing was generally required as adequate data was available to give a reasonable estimate of the concrete strength. Originally the client had asked for more detailed NDT testing to show which elements had low strength concrete.
- b) A 28 day characteristic compressive cylinder strength of 15MPa was to be used for structural assessment of all bases except those produced between 4-9<sup>th</sup> May.
- c) For the concrete poured 4-9<sup>th</sup> May the location of the concrete placed was to be identified and design undertaken for strengthening to take the full design loads.

The structural assessment was undertaken of all structures by review of the original designs. This showed that in general the 15MPa cylinder strength was adequate. The exceptions were:

- a) Primary Crusher Base Slab – Development lengths up to 400mm to short due to low strength and low cover. Strengthen to reduce stresses or effectively increase development lengths
- b) Primary Crusher Rear Wall – Will crack as applied moments are 3 times the moment capacity

## **5. Structural Assessment of New Concrete in an Australian Mine Plant**

On this project the concrete strength was called into question when the supervisor recorded that after taking cylinders for strength assessment the concrete water was added to the mix for placement. Cores and NDT were used to establish the actual characteristic strength of 18MPa for most elements, well below the minimum specified strength of 32MPa.

Structural analysis was undertaken to show if these low strengths might be acceptable. A foundation slab was considered as 1m wide strips with actual load points imposed and resisted by soil spring nodes. Although the concrete strength was only 18MPa the authors believe that it is reasonable to extrapolate outside the range of characteristic compressive strengths of 20 MPa to 100 MPa, specified in Clause 1.1.2 of AS3600, provided that a reliable coherent set of core results can be obtained. Of note is the anchorage bond length where requirements will increase beyond those in AS3600 in highly stressed elements. The analysis undertaken indicated that although capacities were significantly reduced most parameters were predicted to be acceptable except for shear and hence a risk assessment was undertaken.

Risk is conventionally assessed by ISO 31000 (12) based on a combination of consequence and likelihood of failure. For some failure modes full probabilistic modelling can be undertaken to assess failure likelihood quite accurately. Where these methods are not possible a qualitative approach can be followed. The consequence of structural failure can vary significantly depending.

Discussions with the owner identified that the increased likelihood of failure was unacceptable because when combined with the consequence of failure the risks during operations became unacceptable. Consequently the concrete was replaced.

## 6. Strength Assessment of an Old Australian Shopping Centre Floor Slab

The strength of a concrete slabs on grade had been called into question. The strength of the surface layer is highly affected by finishing and curing and hence assessment using rebound hammer testing is not recommend as the results are very dependent on near surface properties. It was agreed to undertake widespread testing using indirect ultrasonic pulse velocity to show potential variations in strength. Cores were undertake for calibration of the UPV. Rebound hammer results were also taken over a wide area to determine if it gave any further insight into concrete performance.

UPV results were taken using the five point indirect method. Results were recorded on a spreadsheet which automated a linear regression analysis to check the four results gave adequate correlation (*Table 4*). The velocities, and the rebound results, were plotted in a spreadsheet using conditional formatting to highlight variations (*Table 5*).

**Table 4 :** Indirect UPV Data for Shopping Centre Floor Slab. D is the Transmitter/Receiver Separation and T the Corresponding Wave Transit Time

In the case of the rebound results there appears to be two distinct areas where the 10 percentile strengths are 24.9 and 38.2MPa. These variations are not seen in the UPV results. The Rebound variations may be due to variations in finishing and curing of the two pours and be limited to surface effects.

The UPV results were correlated with strength and gave the following relationship:

$$\text{Strength (MPa)} = 8.5344e^{0.3173v} \text{ where } v \text{ is ultrasonic pulse velocity in m/s.}$$

Converting the UPV to strength results gave a plot of strength as shown in *Table 6*. The colour coding is based on highlighting areas where the strength is less than the required 32 MPa.

## 7. Strength Assessment of New Columns and Walls of an Australian Office Tower

S65 concrete was poured in columns and stair well walls. Cylinder results were marginal and hence strength assessment was requested. An assessment of in-situ strength was undertaken using the SonReb method with UPV and rebound measurements calibrated against core strength tests. The process used for the SonReb method was:

- 1) Mark out reinforcement grid on the concrete surface using GPR so that UPV test results avoided the influence of reinforcement as far as possible.
- 2) Mark out sixteen measurement points for each element. These comprised eight pairs of measurement points precisely on opposite faces of the element. Typically four measurement points were at 0.5m, 1m, 1.5m and 2.0m above base level so that strength with height could be assessed. No significant variation was found (Figure 4)

Figure 4 : Plot of UPV and Rebound With Height for a Shaft Wall

- 3) Assess the path length for the measurement points.
- 4) Take direct UPV measurements using digital UPV equipment with the transmitter on one face and receiver on the other for each of the eight pairs of measurement points. The transmitter and receiver were then swapped at each pair of points to give sixteen direct measurements. The UPV' equipment's built in measuring process takes multiple measurements to give an average of several reading for each result. Results were also verified by the strength of the received signal and only highly reliable results were recorded.
- 5) Prepare the concrete surface using a grinding stone at each of the sixteen points and take rebound measurements using the digital rebound hammer. Ten rebounds were used to give one Q value.
- 6) Enter the data in the results spreadsheet prepared for the project to verify results were sensible and consistent. The formula for strength generally used is  $f_{ck} = a \cdot V^b \cdot Q^c$  where a, b and c are constants V is the ultrasonic pulse velocity in m/s. Q is the rebound value as given in RILEM (14)

## 8. Strength Assessment of 50 Year Old Basement Columns in an Australian Building

On this city centre project the building height was to be increased adding several new floors of office space. This translated to additional load in the basement columns and diaphragm wall. The existing structure had reached its 50 year design life and hence a durability and strength assessment was undertaken to confirm that the load capacity was adequate and that the structure would provide an additional 50 year life commensurate with the requirements for the new structure.

The strength assessment was in two parts. Cores were taken from walls, columns and slabs. For the more critical columns a wider assessment of strength was required. This was achieved by correlating direct UPV results with core strengths and then using UPV results to give an indication of in-situ strengths. The correlation was based on compressive strength  $= 1.0828e^{0.8201v}$  where v is UPV.

**Table 7 : UPV Correlation with Core Strengths**

Col	Pulse Velocity (m/s)			Core Strength (MPa)			UPV Strength (MPa)		
	Bottom	Middle	Top				Bottom	Middle	Top
B10	4.781	4.817	4.849	48.51	63.52	56	43.5	45.1	46.7
G8	4.919	4.953	4.944	58.53	Broke	58.5	50.1	51.9	51.4

Piles were tested using a force vibration test as developed by Davis and Dunn (17). Testing was undertaken by measuring the response from a series of hammer blows on the concrete surface using a geophone held on the concrete surface adjacent to the hammer. Where there was no pile response the test location was moved along until a response was found. Having located the pile the test results were recorded. The received signal was put through a fast Fourier transform to give Mechanical Admittance and Frequency. Mechanical Admittance gives the load deflection curve based on wave theory. Frequency gives parameters of the pile model. Information obtained includes pile length, minimum pile diameter, presence of an end bulb, concrete modulus and safe pile load.

## 9. Strength Assessment of Old Shopping Centre Columns in Australia

Testing was undertaken on ground floor columns of a shopping centre in Queensland testing to assess the capacity for planned extensions. No coring was allowed in the structure and so the completely non-destructive NDT method was proposed. NDT results depend on the materials used and so cylinders made using local materials were used to create a calibration between NDT (UPV and rebound) and cylinder strengths.

Sixteen cylinders were tested. Direct UPV measurements were taken on the cylinders and then once the cylinder has been compressed to 3.5MPa the rebound values were taken using an original rebound hammer. The cylinders were then crushed. The calibration co-efficient were assessed using the equation proposed by Samirin (18), i.e.  $f'_c = aR + bV^4$ . Samin's approach was an early form of combined ultrasonic pulse velocity and rebound for strength assessment and the SonReb equation would be recommended today. Excel's 'Solver' function was used to give the values for a and b of 1.0695 and  $4.96 \times 10^{-15}$  respectively. The correlation achieved was 0.973.

Ten columns were tested. Two rebound hammer tests were carried out in accordance with BS 1881:202 on each face. Two UPV measurements (BS1881:203) were taken between each of the two sets of opposing faces. Care was taken to avoid any reinforcing steel by locating this first using a covermeter.

Column	1	2	3	4	5	6	7	8	9	10
Rebound Number	47.8	54.4	52.1	51.4	53.3	49.8	50	48.5	53.6	54.8
UPV (m/se)	4457.5	4300	4298.3	4173.3	4155	4295	3776.7	4175	4207.5	4100
Calculated Strength (MPa)	53.0	59.8	57.4	56.4	58.5	54.9	54.5	53.3	58.8	60.0

All of the columns were found to have strengths in excess of the 40MPa required for the extension.

## 10. Conclusions & Recommendations

The paper identifies recent changes in the state of the art for assessing the in-situ strength of structures and outlines some of the principles used on various structures. The principles include core testing, rebound hammer and ultrasonic pulse velocity use to support in-situ strength assessment, methods of structural assessment and use of risk assessment to determine acceptability of reduced reliability due to low strength concrete. AS 3600, AS 1012.14 and CIA Z11 represent the current recommendations for structural assessment in Australia. These are now inconsistent with overseas documents on which they were based due to recent developments with the overseas documents. They do not incorporate the use of NDT and do not give structural assessment guidelines. It is recommended that AS 1012.14 and CIA Z11 are updated to reflect the current state of the art and be expanded to give guidance from testing to structural assessment.

# Full Scale Concentric Punching Shear Testing of Two-way Floor with Bonded Post-tensioning and Studrails

Fariborz Moeinaddini<sup>1</sup>, Kamiran Abdouka<sup>2</sup> and Andrew Barraclough<sup>3</sup>

<sup>1</sup>PhD Candidate, Swinburne University of Technology

<sup>2</sup>Senior Lecturer, Swinburne University of Technology

<sup>3</sup>R&D Manager, ITW Construction Systems

**Abstract:** The Use of bonded post-tensioning strands in concrete flooring system is very popular in the Australian construction industry. Two-way post-tensioned floors are susceptible to punching shear failure, and quite often, they are strengthened with shear reinforcement at slab-column connection. Punching shear reinforcement in the form of studrail is favourable type in practice due to its ease of placement and the quick installation procedure compared to other types of shear reinforcement such as shearheads or closed-ties. However, the Australian Standard for Concrete Structures, AS 3600, does not give any guidelines for design and detailing of studrails. In this paper, results from an experiment on a full scale slab-column connection of a bonded post-tensioned flat plate with studrails are presented. In addition, the failure load of the specimen is compared to the failure load of similar post-tensioned and RC specimens with no studrails. The specimen, reinforced with studrails, showed a significant improvement in the punching shear strength and ductility in comparison to the specimens with no shear reinforcement. The significance of using shear reinforcement to avoid the punching shear failure is detailed. Further, different international codes of practice such as ACI 318-11, Model Code 2010 and Eurocode2 are used to calculate the punching shear strength of the experiments to compare the accuracy of prediction of failure load by these codes of practice.

**Keywords:** punching shear, flat plate, bonded post-tensioning, studrails

## 1. Introduction

The use of post-tensioning technique in concrete floors is very common in developed countries due to the better performance of post-tensioned floor in serviceability and ultimate stage as compare to reinforced concrete floors. Two-way flooring systems are susceptible to punching shear failure in the vicinity of slab-column connection. Since punching shear can occur without any warning and can lead to progressive collapse of the building, this phenomenon was researched extensively in the last decades. And as a result, different types of shear reinforcement such as shearheads, bent-bars, double-leg bars, shear bands and studrails were developed for strengthening of floors against punching shear. Studrail is a popular choice for designers nowadays due to its main advantage in placement and ease of use on the building site. As the use of post-tensioning technique in two-way flooring systems have become very common, Carvalho, Melo (1) investigated the performance of unbonded post-tensioning flat plates with studrails. The unbonded post-tensioning technique is the common practice in United States and most of the available literature on punching shear strength of post-tensioned flat plates are from experimental programmes on test specimens with unbonded post-tensioning technique (2). In Australia, however, the industry uses bonded post-tensioning technique predominantly and there is a lack of knowledge on performance of flat plates with bonded strands. In addition, Australian Standard for Concrete Structures, AS 3600-2009 (3), does not provide any guidelines for design of studrails which are the preferred type of shear reinforcement for punching shear in the industry. This has left Australian design engineers without a straightforward guideline on how to design and detail the shear reinforcement to avoid a punching shear failure mode. This paper reports an experimental programme which investigates the performance of bonded post-tensioned flat plates with and without studrails to a punching shear failure mode..

## 2. Background

If a flat plate is loaded by a uniformly distributed load and  $L$  is the spacing between columns, the point of contra-flexure occurs approximately at  $0.2L$  away from the internal columns. To investigate the punching shear strength of flat plates, most of researchers use the point of contra-flexure to test a subsection of the flooring system instead of the whole floor. The floor subsection includes a central column and a flat plate which extends  $0.2L$  from each sides of the column. During the test, the flat plate is supported around its perimeter, representing the point of contra-flexure, and loaded at the centre by an actuator which pushes the column till the failure occurs.

According to Broms (4), if little tensile reinforcement is provided in the flat section, the failure can take place by yielding of tensile bars in the flat plate which would result in a ductile and plastic failure. This type of failure is a flexural failure and the ultimate strength of the floor can be estimated by yield-line theory. The other failure mode can be sudden and without warning failure of the specimen which usually occurs before yielding of some of tensile bars in the flat plate. In this case, punching shear preceded the flexural failure and it can be characterised by the cone type mass of concrete detaching from the flat plate around the column.

## 2.1 Flexural strength of flat plates

Yield-line theory is an upper bound approach to calculate the flexural strength of a flat plate. For example, Guandalini, Burdet (5) carried out a test series with specimens supported on eight points representing the line of contra-flexure. Based on Yield-line theory, Guandalini, Burdet (5) suggested the following equation to calculate the flexural strength of their test specimen:

$$V_{flex} = \frac{m}{r(\cos\frac{\pi}{8} + \sin\frac{\pi}{8})} \frac{B^2 - Bc - (\frac{c}{2})^2}{B - c} \quad (1)$$

In Equation (1),  $V_{flex}$  is the flexural strength of test specimen,  $m$  is the moment strength of specimen per unit length,  $r$  is the radius of the support line,  $B$  is the side dimension of the test specimen and  $c$  is the side dimension of the column. The formula for  $V_{flex}$  can change depending on the position and boundary condition of supports.

## 2.2 Punching shear strength in Australian Standard AS 3600-2009

According to Clause 9.2.3 of AS 3600-2009 (3), the ultimate punching shear strength of concrete slabs  $V_{uo}$  can be calculated using Equation (2).

$$V_{uo} = u d_{om} (f_{cv} + 0.3\sigma_{cp}) \quad (2)$$

Where,  $d_{om}$  is the effective depth of slab,  $u$  is the perimeter around the column at a distance equal to the half of effective depth of slab from the face of column,  $\sigma_{cp}$  is the average effective prestress in the vicinity of column in MPa, and  $f_{cv}$  is calculated by Equation (3).

$$f_{cv} = 0.17(1 + 2/\beta_h) \sqrt{f'_c} \leq 0.34 \sqrt{f'_c} \quad (3)$$

Where  $\beta_h$  is the ratio of larger to shorter column sides, and  $f'_c$  is the compressive strength of concrete in MPa.

When the applied shear force on the critical perimeter is higher than the computed capacity, calculated by Equation (2), AS3600-2009 permits the use of shearheads by which the  $f_{cv}$  can be increased and Equation (4) can be used to calculate the strength of the floor.

$$V_{uo} = u d_{om} (0.5\sqrt{f'_c} + 0.3\sigma_{cp}) \leq 0.2 u d_{om} f'_c \quad (4)$$

Unlike other international standards such as ACI 318-11 (6) and Eurocode 2 (7) (EC2), AS3600-2009 does not provide any guidelines for the design and detailing of shearhead or other types of shear reinforcement.

To ensure adequate shear strength of the slab, Clause 9.1.2 of AS 3600-2009 requires that 25% of the negative bending moment in the column strip and half of the middle strip to be resisted by the reinforcement and prestressing tendons that cross over the column and of a width equal to the twice the thickness of the slab from the faces of the column.

### 3. Experimental programme

#### 3.1 Test setup

Three 3m x 3m concrete plates were built with a thickness of 200mm. Each concrete plate has a 300mm x 300mm x 300mm column cast at the centre of the concrete plate. The specimen was supported on 8 points around its perimeter at the distance of 1440mm from the centre during the test. The dimensions of test specimens and the position of supports are shown in Figure 1.

Figure 1 Dimensions of test specimens and position of supports

A cruciform reaction frame was designed for the purpose of this testing program. The cruciform consists of four 380 PFC beams in each direction. The reaction frame was supported on its four sides by four towers which supported the weight of testing rig and test specimen. The test specimen was suspended from the cruciform by four M36 high tensile bars. The hydraulic jack was placed between the reaction frame and the concrete panel to apply the load to the central column of the specimen. The test setup is shown in Figure 2.

#### 3.2 Detail of reinforcement in specimens

Control specimen C1 was built without any post-tensioning strands and studrails. This specimen had N16 reinforcement bars with average effective depth of 164mm. The reinforcement detail for specimen C1 is shown in Figure 3.

Reinforcement detail of Specimen PE1 was similar to specimen C1, and in addition it had bonded post-tensioning strands in both directions with a draped profile. It is a common practice to place the post-tensioning ducts with a profile to balance the applied bending moment in flat plates. Therefore, the post-tensioning ducts were placed with 100mm effective depth at the sides of the plate and on average 140mm effective depth at the centre of plate. The detail of post-tensioning strands in specimen PE1 is shown in Figure 4.

Specimen PES1 is similar to specimen PE1 except for additional eight studrails. The studrails consist of 10 shear studs that were welded on a rail to be placed around the column area. Figure 5 shows the detail of studrails which were used in specimen PES1. ACI-ASCE Committee 421 (8) recommended placing of the first row of studs at a distance between 0.35d and 0.4d from the face of column and the spacing between studs to be 0.5d. Therefore, the first row of studs was placed at 65mm from the face of column and the spacing between the studs was 82mm. One of the studrails had strain gauges on each of its studs. The strain gauges were installed to monitor the extent that each of the studs contributes in arresting the shear cracks from opening.

**Figure 2 Test setup for experiment on punching shear strength of flat plates**

**Figure 3 Position of tensile reinforcement in specimen C1, PE1 and PES1**

**Figure 4 Position of post-tensioning tendons in specimen PE1 and PES1**

**Figure 5 Position and detail of studrails in specimen PES1**

Specimens PE1 and PES1 were post-tensioned and grouted one week prior to the test at the age of 170 days. Strands were tensioned up to 156kN and anchored. There were immediate losses of post-tensioning strands due to the elastic compression of the concrete and the movement of the grips as the strands are anchored. The force in the strands was calculated with the use of readings from a strain gauge, which was attached to one of the wires of the strand. The forces were varied between 128kN and 131kN after losses. Specimen PE and PES1 had 8 strands in each direction and the average in-plane stress in the concrete was 1.7MPa. Post-tensioning ducts were grouted by a cement and water mix at the same day of stressing of strands.

### 3.3 Material properties

A 32MPa concrete with maximum aggregate size of 20mm was ordered from a local provider in Bayswater, Victoria to cast the specimens on 18<sup>th</sup> December 2013. The mix design was a typical concrete for post-tensioning slabs which would reach 25MPa in four days. The water-cement ratio was 0.57 and the requested slump was 100mm. Specimens were tested six months after they were cast, and within a period of one month. The tests on the properties of the concrete were carried out around the same time as the experiment. Table 1 gives the average properties of material which were determined by testing of samples of materials used in building of specimens. Six standard cylinder samples of 100mm diameter and 200mm height were tested to determine the compressive strength of the concrete ( $f_{cy}$ ). Three cube specimens with side dimension of 150mm were used to determine the cube compressive strength of the concrete ( $f_{cu}$ ). Three cylinder samples were taken from the grout to determine its compressive strength ( $f_{cgr}$ ). The reinforcement bars in the specimens were grade 500, N

type, with a modulus of elasticity of 200GPa. Samples of the rebar were used to determine the average yield strength ( $f_{sy}$ ). Studrails for specimen PES1 were made of normal ductility bars which their yield strength ( $f_{ssy}$ ) was determined by testing of six samples. A tensile test was carried out on a sample of the post-tensioning strands to determine its ultimate tensile strength ( $f_{psu}$ ).

**Table 1 Average value of material properties**

$f_{cy}$ (MPa)	$f_{cu}$ (MPa)	$f_{gr}$ (MPa)	$f_{sy}$ (MPa)	$f_{ssy}$ (MPa)	$f_{psu}$ (MPa)
34.5	44	30	540	510	1770

#### 4. Result and discussion

The first experiment was carried out on the control specimen C1. Specimen PE1 and PES1 were tested in sequence, two weeks after the first experiment. Since the concrete was cast 6 month prior to the testing, it is assumed the concrete properties were constant during the period of the experimental programme, ruling out the effect of varying concrete properties when comparing the test results. Specimen C1 and PE1 failed in a very brittle and sudden manner and a significant drop in the load resisted by the test specimen were observed. The punching action by column was apparent as the column was detached from the slab and the mass of column was held in place by catenary action of reinforcement bars. A different failure mode was observed in the experiment on PES1. The crushing of concrete occurred in the region where studrails were placed. The load resistance of the specimen decreased as the crushing of concrete progressed.

##### 4.1 Load-displacement

The applied load to the column was monitored by a load cell between the reaction frame and the actuator during test. Further, there were eight load cells between the test rig supports and the concrete panel. These load cells were used to have the load applied concentrically and there was no unbalanced moment transferring through slab-column connection during the test. The deformation of the flat plate was monitored by fourteen Linear Variable Differential Transformer (LVDTs) and a photogrammetry technique was used throughout the test load cycle. Specimen C1 resisted 798kN with central displacement of 19.4mm when punching shear occurred and the load dropped to 98kN. Specimen PE1 resisted 1074kN with the central displacement of 21.3mm before the punching of the flat plate. The load dropped to 300kN after the failure. Specimen PES1 resisted 1,264kN with the central deformation of 37.8mm which could attribute to the use of studrails. As the specimen reached the maximum load of 1,264kN, the crushing of concrete was apparent on the compression side of the plate and the load gradually dropped as the displacement increased. Test was stopped when specimen PES1 reached the central displacement of 50mm with corresponding load of 647kN. Figure 6 shows the applied load versus the displacement of the column for specimens C1, PE1 and PES1. It can be seen specimens PE1 and PES1, which have similar tensile reinforcement and post-tensioning strands, plot almost identical load-displacement up to 1,074kN where specimen PE1 fails by punching shear. Specimen PES1, however, could resist further load and displacement with the studrails arresting shear cracks from opening. One observation from Figure 6 is that specimen C1 and PE1, which have no shear reinforcement, fail at a similar displacement 19.4mm and 21.3mm respectively. However, specimen PE1 has a higher stiffness due to bonded post-tensioning strands and could reach a higher load for the same displacement before failure.

##### 4.2 Load-rotation

Rotation of the plate is one of main parameters in Model Code 2010 (9) (MC2010). This code uses Critical Shear Crack Theory (CSCT) (10) to calculate the punching shear strength of flat plates. CSCT suggests the rotation of the plate causes the opening of the critical shear crack, which leads to the punching shear failure. The rotation of the flat plate was monitored with the use of inclinometers on four sides of the square plate as shown in Figure 7 (b). The average rotation of plate is plotted against the applied load for specimen C1, PE1 and PES1 in Figure 8. The maximum observed rotation before failure was 0.0163rad, 0.0178rad and 0.0298rad for specimen C1, PE1 and PES1 respectively. At rotation of 0.001rad, specimen PE1 reached the decompression stage in the plate section at the face of the column. If the decompression rotation of specimen PE1 is deducted from its maximum rotation, the rotation of specimen C1 and PE1 are very similar prior to failure.

Figure 6 Load versus displacement of the column

Figure 7 (a) Rotation of the plate (b) plan view of position of inclinometers

Figure 8 Load versus rotation of the plate in reference to the column

#### 4.3 Strain in studrails

Strain gauges were installed on studs of one studrail in specimen PES1 to monitor the strains during the test. Figure 9 shows the maximum monitored strains in studs during the testing of specimen PES1. Strains in the first six rows of studs are significantly higher than the rest of studs. The most critical studs are the second to fifth row of studs. The failure mode was crushing of concrete in the shear reinforced zone as shown in Figure 10. None of the studs reached the yield strength prior to failure. If it is assumed that strains of studs with strain gauges are similar for other studrails, the estimated load resisted by studrails at failure is 950kN. That means the concrete contribution in load carrying capacity of the plate is 314kN.

Figure 9 Maximum tensile strain in studs during experiment on PES1

Plan view of compression side of specimen PES1

Figure 10 Schematic view of concrete crushing zone in specimen PES1

#### 4.4 Comparison of predicted failure load

The results from the experiment are compared to the predicted punching shear strengths of some of the internationally recognised codes of practice such as AS 3600-2009 (3), Eurocode 2 (7) (EC2), ACI 318-11 (6) and Model Code 2010 (9). Table 2 provides the observed failure load of ( $V_{fail}$ ), the load which flexural capacity of the specimen would reach ( $V_{flex}$ ), the predicted strength by AS 3600-2009 ( $V_{AS3600}$ ), the predicted strength using EC2 ( $V_{EC2}$ ), the predicted strength by MC2010 ( $V_{MC2010}$ ) and the predicted strength by ACI 318-11 ( $V_{ACI318}$ ). The suggested formula for punching shear strength of flat plates with shearheads in AS3600-2009 was used to predict the failure load of PES1. EC2 was not applicable to calculate the punching strength of specimen PES1 since the detailing of placement of studrails did not meet the requirements by EC2. Level of Approximation Three was used to calculate the predicted strength by MC2010.

Table 2 Predicted failure load versus observed failure load

Specimen	$V_{fail}(kN)$	$V_{flex}(kN)$	$V_{AS3600}(kN)$	$V_{EC2}(kN)$	$V_{MC2010}(kN)$	$V_{ACI318}(kN)$
C1	798	1121	608	627	502	590
PE1	1074	1861	793	746	588	775
PES1	1264	1861	1079	Not applicable	1035	1180

All three specimens failed below their flexural capacity. Codes of practice in Table 2 predicted smaller failure loads as compared to the observed failure load. MC2010 has the most conservative prediction compared to the other codes of practice. AS 3600 formula for punching shear strength of flat plates with shearheads, Equation (4), predicts 1,079kN as the failure load of specimen PES1 which had studrails and reached the failure load of 1,264kN. This suggests the current formula of AS 3600, can be used to calculate the concrete crushing strength of flat plates with studrails.

## 5. Conclusion

The results from full scale tests on punching shear strength of three different flat plates presented. The increase in punching shear strength due to addition of bonded post-tensioning strands was apparent. It was observed that the punching shear failure in both specimens, which did not have studrails, occurred around the same central measured displacement. Further, the rotations of plates in the latter specimens were similar prior to failure. The use of studrails in flat plates with bonded post-tensioning improved the ultimate strength and increased the ductility significantly. The maximum strain in different rows of studs was reported and it was observed that the second to the fifth rows of studs underwent higher strains compared to the other rows of studs. Furthermore, studs, which were positioned beyond the sixth row, did not engage by carrying the applied load. The contribution of

studs and concrete in the load resisting capacity is estimated using strains in studrails at the maximum load. The mode of failure for the specimen with shear reinforcement was crushing of concrete in the vicinity of studrails and none of studs reached yield stress before failure. Various codes of practice such as AS 3600, EC2, MC2010 and ACI 318 were used to predict the punching shear strength of specimens. The results showed these codes of practice are predicting a lower failure load as compared to the observed failure load from the experiment.

## 6. Acknowledgment

The authors wish to express their gratitude to ITW Construction Systems Laboratory for providing the fund and space to carry out the testing programme, Smart Structures Laboratory of Swinburne University for providing instrumentation equipment, and Freyssinet for providing the post-tensioning services.

**Abstract:** Structural monitoring systems are important in civil engineering. However, traditional structural monitoring systems have disadvantages such as the shorter life span of sensors relative to that of the structure being monitored. The present study uses carbon fiber reinforced concrete (CFRC) as a structural monitoring sensor to extend the life of a sensor to match that of the structure. There are some known advantages of carbon fiber reinforced concrete, such as high tensile strength and high ductility which increases the seismic capacity and security of structures. However, CFRC has functionality similar to piezoresistive materials which can be used as a self-sensing material for strain measurement and damage detection. This property is based on the reversible effect of the strain on the volume of electrical resistivity and the irreversible effect of material damage on its resistivity. The strain sensing behavior is such that the resistivity decreases reversibly upon compression due to the slight inward push of crack-bridging fibers and the consequent decrease in the contact electrical resistivity of the fiber-cement interface. Similarly, the resistivity increases reversibly upon tension due to the slight outward pull of crack-bridging fibers and the consequent decrease in the contact resistivity. To consider the economic benefits, the fiber content is only 0.2 vol. % which is less than half of the amount used in other references (0.48 vol. %). The experimental results show that the conductivity of current materials is significantly improved by CFRC and that it can be used for strain measurement and damage detection with fiber content of 0.2 vol. %. Moreover, the experimental results of CFRC coated beams and RC portal frame can be kept in a database for applications of structural health monitoring.

## 1. Introduction

This article shows that carbon fiber added into concrete becomes carbon fiber reinforced concrete (CFRC) and with the functionality similar to piezoresistivity material can be used as a self-sensing material for strain measurement and damage detection. It is based on the reversible effect of strain on the volume electrical resistivity and the irreversible effect of damage on the resistivity. The strain sensing behavior is such that the resistivity decreases reversibly upon compression due to the slight push-in of crack-bridging fibers and the consequent decrease of the contact electrical resistivity of the fiber-cement interface. Similarly, the resistivity increases reversibly upon tension due to the slight pull-out of crack-bridging fibers and the consequent decrease of the contact resistivity [1, 2]. The self-sensing ability of CFRC cement-based composite has been well demonstrated under compression and under flexure. With the use of CFRC's electrical resistance change and appearance of structural cracks, we are able to derive an integration of sensors which also possesses material smartness quotient of self-sensing, stability and repetitiveness.

## 2. Basic mechanical test plan

### 2.1 Preparation of materials

The design concrete strength was set at 49.05 MPa. The cement was blended Portland cement. Specimens were prepared from a mix with the following composition: water-to-cement ratio (w/c) = 0.4; sand-to-cement ratio (s/c) = 0.75; silica fume, 15% by weight of cement; methylcellulose, 0.4% by weight of cement; and carbon fiber, 0.2% of total volume. The fiber diameter was 7  $\mu\text{m}$ . The nominal fiber length was 15 mm. A standard mixing procedure was used. A rotary mixer with flat beater was used for mixing. After pouring the mix into oiled molds, an external electric vibrator was used to facilitate compaction and decrease the amount of air bubbles.

### 2.2 Preparation of specimens

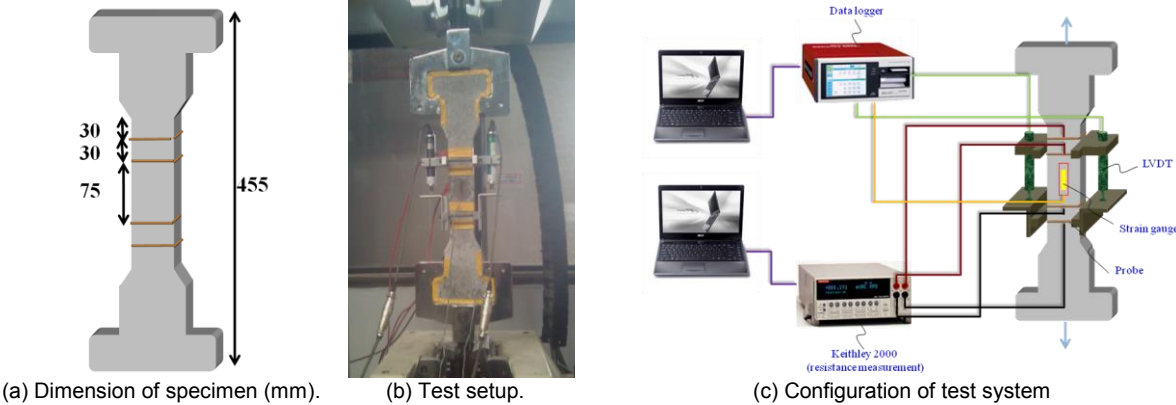

From the aforementioned concrete mixture, 5 CFRC dog-bone-shaped specimens, 4 CFRC cylinders, and 8 different styles of CFRC beams at 28 days age were fabricated for testing. Dog-bone-shaped specimens with dimension of 455  $\times$  50  $\times$  20 mm were prepared for uniaxial tension testing. Cylinders with dimension of  $\phi$ 100  $\times$  200 mm were prepared for uniaxial compression testing. Beam specimens

with dimension of 550 × 150 × 150 mm were prepared for three-point bending testing. The test setup is shown in Figs 1-3.

**2.2.1 Uniaxial tension test**

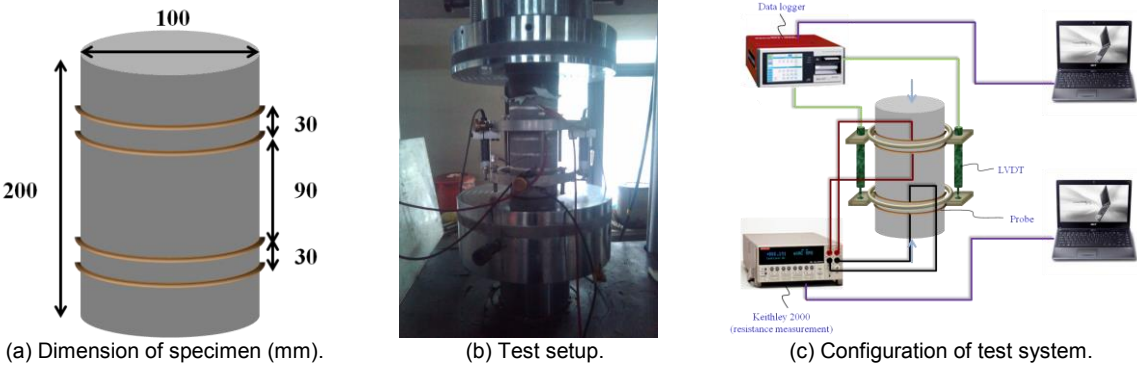

The monotonously tensile loading was applied on the specimen (Fig. 1). Tensile strain of CFRC specimen was measured by LVDT under gauge length equal to 105 mm. The electrical resistance measurements were conducted using the four-probe method, with silver paint in conjunction with copper wires for electrical contacts and the electrode distance was equal to 75 mm (Fig. 1a). The Keithley 2000 digital multimeter was used to measure the electrical resistance of the specimens (Fig. 1c).

**Figure 1. Uniaxial tension test.**

**2.2.2 Uniaxial compression test**

The monotonously compressive loading was applied on the specimen (Fig. 2). Compressive strain of CFRC specimen was measured by LVDT under gauge length equal to 100 mm. The electrical resistance measurements were conducted using the four-probe method, with silver paint in conjunction with copper wires for electrical contacts and the electrode distance was equal to 90 mm (Fig. 2a). The Keithley 2000 digital multimeter was used to measure the electrical resistance of the specimens (Fig. 2c)

**Figure 2. Uniaxial compression test.**

**2.2.3 Three-point bending test**

The cyclical loading was applied on the CFRC beam specimen (Fig. 3). Dynamic strain of CFRC beam was measured by strain gauge, the central deformation was measured by LVDT, and the electrical resistance was measured by Keithley 2000 digital multimeter under gauge length equal to 120 mm (Figs 3a, 3c).

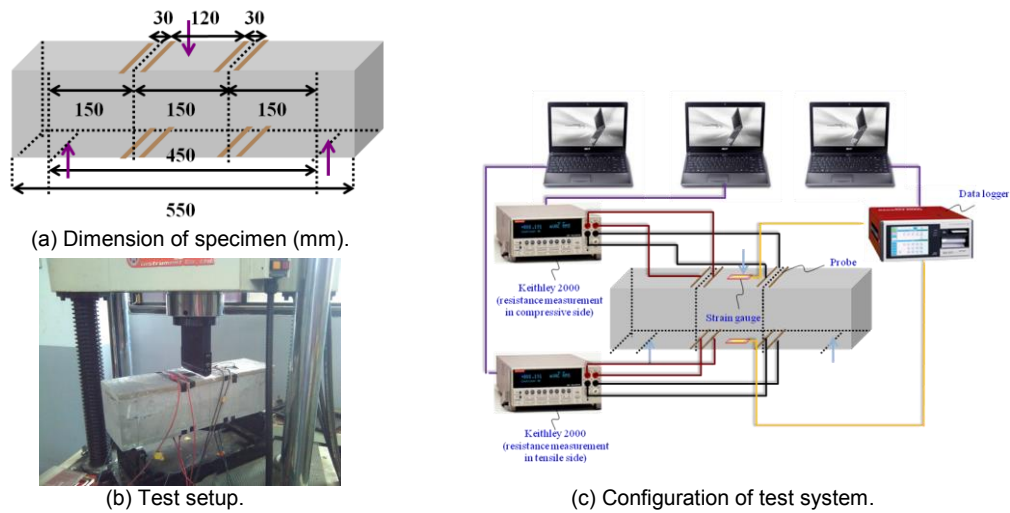

Figure 3. Three-point bending test.

### 3. Results and discussion of basic mechanical test

#### 3.1 Uniaxial tension test

The test results of specimens at 28 days age are shown in Figs 4-6. Fig. 4a shows the relationships between fractional change in electrical resistance (denoted as  $(R-R_0)/R_0$ ) of CFRC and strain measured by LVDT at the middle portion of the specimens. These data existed linear relationship between fractional change in electrical resistance of CFRC and strain measured by LVDT before proportional limit. If it exceeds the proportional limit, the fractional change in electrical resistance increases due to the increase of electrical resistance in CFRC specimen caused by the microstructure changes, micro crack density increases and damage occurrences.

In order to relate the fractional change in electrical resistance to tensile strain, the definition of gauge factor (GF) is fractional change in electrical resistance per unit strain. Before proportional limit, there exist strong linear relationship ( $R^2 \approx 1$ ) between fractional change in electrical resistance and tensile strain of T1 to T5 specimens (Fig. 4b). Similarity of fractional change in electrical resistance and tensile strain under uniaxial tension tests can be used as a self-sensing material for strain measurement within proportional limit.

Fig. 5 shows the stress-strain curves are very similar before proportional limits but have slopes change due to electrical resistances increasing if tensile strains exceed proportional limits. Based on the different phenomena of fractional change of electrical resistance, three regions are considered in this paper, (1) region-I: linear region, the strain sensing via fractional change in electrical resistance with linear relationship and reversibility; (2) region-II: plastic region, the strain sensing via fractional change in electrical resistance still with some proportional relationship and partial reversibility, owing to the crack occurrence and damage accumulation in specimen, but in tensile specimen these are not obvious; (3) region-III: damaged region, the strain sensing via fractional change in electrical resistance is meaningless, owing to the damage occurrence and material failure in specimen. The fractional change in electrical resistance should be changed very rapidly, which can be used for damage detection.

Fig. 6 shows the variation of tensile stress and fractional change in electrical resistance with tensile strain. The fractional change in electrical resistance has a linear relationship with tensile strain in region-I. The fractional change in electrical resistance rapidly decreases in region-III, because of the electrical resistance increase quickly, due to the damage accumulation. The slope of fractional change with tensile strain is a good indicator for damage detection under tensile loading.

The test results are summarized in Table 1. Before proportional limit (tensile strain =  $1 \times 10^{-4}$ ), there exist strong linear relationship between fractional change in electrical resistance and tensile strain, the range of  $R^2$  are 0.93 to 0.97, the similarity of fractional change in electrical resistance and tensile strain under uniaxial tension tests can be used for strain measurement. There gauge factors (GF) are 9.5 to 19.5 and the measurement ranges (MR) are 57.8% to 83.33% of ultimate tensile strain.

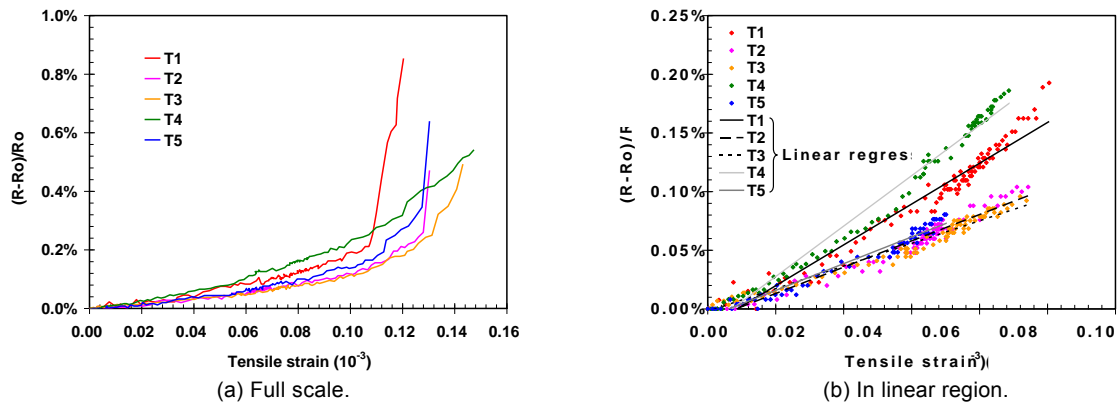

Figure 4. Comparison between fractional change in electrical resistance and strain measured by LVDT.

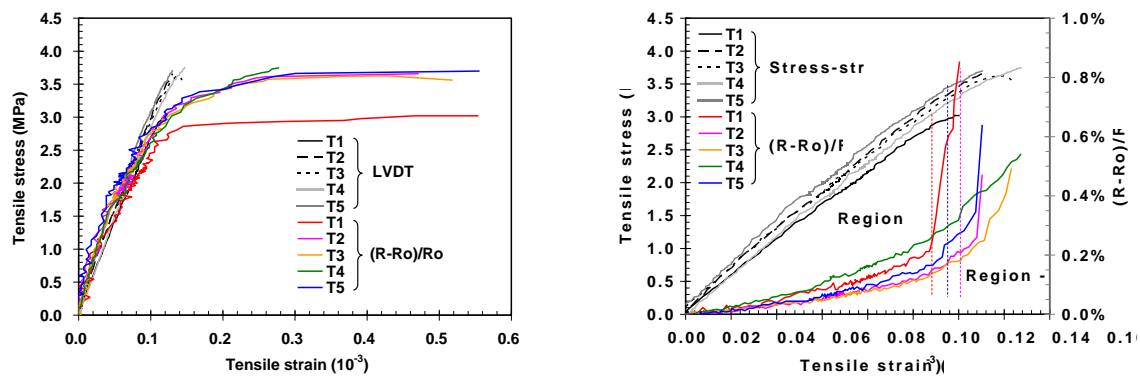

Figure 5. Variation of tensile stress with tensile strain measured by LVDT and CFRC.

Figure 6. Variation of tensile stress and fractional change in electrical resistance with tensile strain.

Table 1. Results of uniaxial tension test.

Specimen	E	$f_t$	$\varepsilon_u$	$R_o$	GF	$R^2$	$(\Delta R/R_o)_L$	MR
	GPa	MPa	$10^{-3}$	$\Omega$			$10^{-3}$	%
T1	25.76	3.02	0.120	26.47	15.4	0.95	0.1	83.33
T2	29.36	3.66	0.173	25.03	10.0	0.94	0.1	57.80
T3	27.48	3.15	0.137	29.23	9.5	0.96	0.1	72.99
T4	27.74	3.75	0.147	36.54	19.5	0.97	0.1	68.03
T5	28.20	3.70	0.130	24.87	11.5	0.93	0.1	76.92

### 3.2 Uniaxial compression test

The test results of specimens at 28 days age are shown in Figs 7-10. Figs 7a, 7b show the relationships between fractional change in electrical resistance of CFRC and strain measured by LVDT at the middle portion of the specimens. These data existed bi-linear relationship between fractional change in electrical resistance of CFRC and strain measured by LVDT before proportional limit. If it exceeds the proportional limit, the fractional change in electrical resistance decreases due to the increase of electrical resistance in CFRC specimen caused by the microstructure changes, micro crack density increases and damage occurrences.

In order to relate the fractional change in electrical resistance to compressive strain, before proportional limit there exist bi-linear relationship between fractional change in electrical resistance and compressive strain. Fig. 8a shows the relation of the fractional change in electrical resistance to compressive strain smaller than  $2 \times 10^{-4}$  and the gauge factor of C1 to C4 specimens are approximately 200 to 250. Fig. 8b shows the relation of the fractional change in electrical resistance to compressive strain be-

tween  $5 \times 10^{-4}$  and proportional limit and the gauge factor of C1 to C4 specimens are approximately 20 to 30. The similarity of fractional change in electrical resistance and compressive strain under uniaxial compression tests can be used as a self-sensing material for strain measurement within proportional limit.

Fig. 9 shows the variation of compressive stress and fractional change in electrical resistance with compressive strain. The fractional change in electrical resistance has a linear relationship with compressive strain in region-I and region-II, the GF1 and GF2 are used for compressive strain measurement. Fig. 10 shows the fractional change in electrical resistance rapidly decreases in region-III, because of the electrical resistance increase quickly, due to the damage accumulation. The slope of fractional change with compressive strain is a good indicator for damage detection under compressive loading.

The test results are summarized in Table 2. Before proportional limit (compressive strain =  $2.57-3.25 \times 10^{-4}$ ), there exist strong bi-linear relationship between fractional change in electrical resistance and compressive strain, the range of  $R^2$  are greater than 0.94, the similarity of fractional change in electrical resistance and compressive strain under uniaxial compressive tests can be used for strain measurement. There gauge factors are 187.1 to 253.0 (for GF1) and 20.9 to 24.9 (for GF2) and the measurement range (MR) are 71.15% to 88.32% of ultimate compressive strain.

### 3.3 Three-point bending test

The test results of three-point bending specimens at 28 days age are shown in Table 3. There are several types of specimens in Table 3, including pure CFRC beam without steel reinforcement (P), pure CFRC beam with steel reinforcement (PS), concrete beam coating CFRC layer without steel reinforcement (Co) and concrete beam coating CFRC layer with steel reinforcement (CoS).

Figs 11a, 11b show the loading protocol, fractional change in electrical resistance, and strain measured by strain gauge at top and bottom of CoS3 specimen. Figs 12a, 12b show the relationships between fractional change in electrical resistance of CFRC and strain measured by strain gauge at top and bottom of CoS3 specimen. These data existed linear relationship between fractional change in electrical resistance of CFRC and strain measured by strain gauge before proportional limit. If it exceeds the proportional limit, the fractional change in electrical resistance increases (tension side) or decreases (compression side) due to the increase of electrical resistance in CFRC specimen caused by the microstructure changes, micro crack density increases and damage occurrences.

In Table 3, (1) comparison of pure CFRC beam, the strain in tension and compression side of P specimens are smaller than PS specimens, but the electrical resistance (Ro) and gauge factor (GF) are greater than PS specimens; (2) comparison of CFRC coating beam, the gauge factor of CoS specimens are greater than Co specimens; (3) comparison between pure CFRC beam and CFRC coating beam, the gauge factor of CFRC coating beam (Co and CoS) are greater than CFRC beam (P and PS). In general, the type of CoS specimen is with the greatest gauge factor.

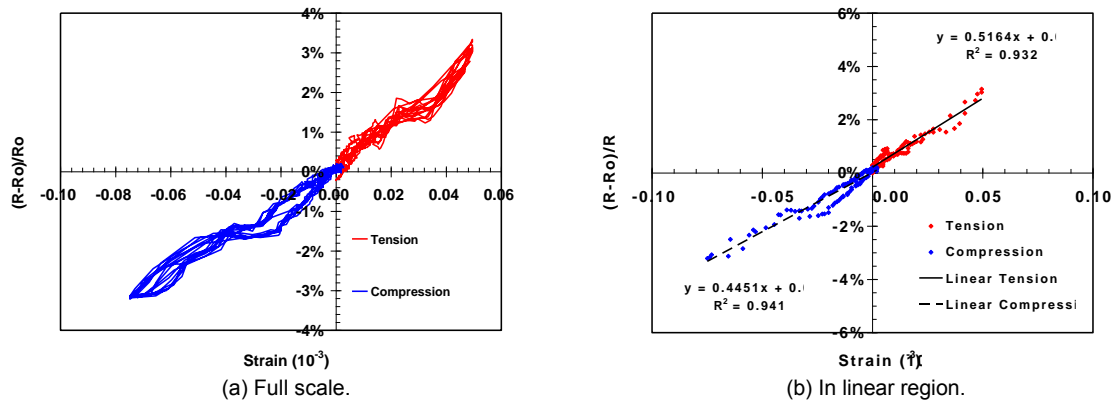

(a) Variation of load with time.

(b) Variation of fractional change in electrical resistance and strain measured by strain gauge with time.

#### 4. RC portal frame push-over experiment

The practical application of pier strain measurement on RC portal frame push-over test is based on the test results of CFRC basic mechanical test. Columns to perform in accordance with the existing highway bridge seismic design specifications design, material strength of the requirements of generally reinforced concrete strength shall not exceed 41.20 MPa, reinforcement strength shall meet the relevant CNS-560 SD280W and SD420W regulations. The results could investigate the feasibility of CFRC for strain measurement of RC portal frame.

##### 4.1 Experiment plan

###### 4.1.1 Specimen design

The experimental plan includes a double-column framed pier, shown in Fig. 13, denoted as RCF (Reinforced Concrete Frame). According to the experimental field position, P1 column for the south side and P2 column for the north side of RCF, respectively. The clear span and clear height of RCF are 400 cm and the columns are using 60 cm square cross-section. Longitudinal reinforcement of RCF configuration are  $16 \times D25$  of steel, reinforcement ratio of about 2.3 %, and in each column, D14 @ 10 cm within the upper and lower plastic hinge zone of the rectangular cross-section of 1.5 times the depth range configuration closed stirrups and tie bars, transverse reinforcement and core concrete volume ratio of about 2.4 %, but non-plastic hinge zone transverse reinforcement spacing relaxed to 14 cm.

###### 4.1.2 Material properties

The material properties of RCF specimen are as follows: the concrete compressive strength = 42.2 MPa, the longitudinal reinforcement yield strength = 521 MPa, the trans-

verse reinforcement yield strength = 335 MPa, concrete compressive strength exceeds 41 MPa, so it is a high-strength concrete.

#### 4.1.3 Specimen configuration and loading protocol

Fig. 14 shows the configuration of the experimental test setup, including steel bracing system, vertical force loading system, lateral force loading system, and test specimen. Vertical force loading system consists of two sets of hydraulic pumps, two axial force beams and four  $\phi 69$  mm of high strength screw combination, which could provide a relatively stable axial force. Displacement control was applied to repeat push-over experiments. Firstly, the vertical load was applied to the top of the column, the design axial force for columns of RCF is  $0.1f'_cA_g$ , namely axial force required for 1500 kN. The first one hydraulic actuator is taken displacement control; but the second one is taken force control. In the course of experiments, the drift ratios (ratio of lateral displacement to column height) are representatives of plus or minus 0.25, 0.5, 0.75, 1.0, 1.5, 2, 3, 4, 5, 6, 7, and 8 %, sequentially. Finally, the fracture of experimental until occurs on longitudinal steel of columns. Each loop has several target displacements, the drift ratio for three laps before the 3 % and from 4 % for two laps until the end of the experiment. The target displacements and force steps are shown in Fig.15.

Figure 13. Design drawing of RCF specimen.

Figure 14. Push-over test setup.

#### 4.1.4 Strain measurement via CFRC

Select the bottom of south side P1 column as a strain measurement region, and CFRC conducted at this region is set to  $600 \times 600$  mm length and width, and thickness of 12 mm for CFRC coating layer. Fig.16 shows the four-wire method is used for electrical resistance measurement, the electrode length is set to 150 mm, and the electrode spacing is 120 mm. The detailed configuration is the same as the three-point bending test for CoS beams in section 2.2.3. Select three positions in which the electrodes are provided, and setting three strain gauges, such as CH-1, CH-2 and CH-3, respectively. After initial electrical resistance measurement of the three regions, select the middle portion for the final experiment. Simultaneous recording force, displacement, strain at three strain gauges, and electrical resistance change of the test, then relate the fractional change of electrical resistance to strain through gauge factor (GF).

Figure 15. The target displacement and force steps.

Figure 16. Test setup of CFRC for strain measurement.

## 4.2 Results and discussion for strain measurement via CFRC

Fig. 17 shows the relationship between the strains measured by strain gauges, and the fractional change in electrical resistance with time. The measurement begin at lateral displacement reach 5 mm ( $t = 0$ ). Both the strain and the fractional change in electrical resistance versus time toward the same variation, and the start point of the electrical resistance change generated earlier than the strain, which displayed the sensitivity and ability of CFRC to predict the deformation of the structure. Referring to Table 3 that containing concrete beam coating CFRC layer with steel reinforcement (CoS) specimen, the mean value of gauge factor (GF) on compression side is 693, and on tension side is 619. Thus by using these two gauge factors, the measured fractional change in electrical resistance could relate to strain, and could be converted to strain. The relationship between strain measured by strain gauge and strain measured by CFRC at bottom of the column versus time are shown in Fig. 18.

Fig. 18 shows the strain measured by strain gauge (CH-3) and strain measured by CFRC versus time toward the same variation, within the lateral displacement of three loops of 20 mm. When the bottom of the column under compression: on the lateral displacement of the loop of 5, 10 and 20 mm, the strain gauges and CFRC could measure the strain on compression side, but the CFRC are more sensitive than strain gauge. The maximum amount of compressive strain is approximately  $5.9 \times 10^{-4}$ , under the lateral displacement of three loops of 20 mm. When the bottom of the column under tension: the strain gauges almost could not measure the strain on tension side, the reason is due to the strain gauge does not locate at the position of the maximum tensile strain occurrence, and therefore loss the sensitivity to measure tensile strain. Nevertheless, the CFRC have a higher sensitivity than strain gauge. The maximum amount of tensile strain is approximately  $1.7 \times 10^{-4}$ , under the lateral displacement of three loops of 20 mm. Obtained from the formula of ACI 318-05 [3] and ACI 363R-92 [4], the concrete at the bottom of the column should be cracking at this moment.

When the lateral displacement of column continues to increase to 30 mm, cracks occur between the CFRC coating layer and the column surface. At this moment, the fractional change of electrical resistance does not change, and the CFRC loss the function of strain measurement. When the lateral displacement of column continues to increase, the situation with the peeling and collapse occurs between the CFRC coating layer and the column surface. A subsequent of study on CFRC for strain measurement, the bond issue between CFRC coating layer and column surface will be the focus of research that must be overcome.

Figure 17. Variation of strain and fractional change in electrical resistance with time.

Figure 18. Comparison of strain measured by strain gauge and strain measured by CFRC.

## 5. Summary and discussion

To consider the economic, the fiber content is only 0.2 vol. % less than half of the amount of 0.48 vol. % used in references. The experimental results of uniaxial tension test, uniaxial compression test and three-point bending test show that the conductivity of materials is significantly improved and CFRC can be used as a strain measurement and damage detection in the fiber content of 0.2 vol. %.

For tension test, the similarity of fractional change in electrical resistance and tensile strain under uniaxial tension tests can be used as a self-sensing material for strain measurement within proportional limit. The slope of fractional change with tensile strain is a good indicator for damage detection under tensile loading.

For compression test, the similarity of fractional change in electrical resistance and compressive strain under uniaxial compression tests can be used as a self-sensing material for strain measurement within proportional limit. The slope of fractional change with compressive strain is a good indicator for damage detection under compressive loading.

For three-point bending test, the gauge factor of concrete beam coating CFRC layer with steel reinforcement is greater than concrete beam coating CFRC layer without steel reinforcement and pure CFRC beam with or without steel reinforcement. Moreover, the experimental results of coating beams can be the database for applications in the future.

For strain measurement of RC portal frame, the strain gauges and CFRC could measure the strain on compression side, but the CFRC are more sensitive than strain gauge. Nevertheless, the strain gauges almost could not measure the strain on tension side, but the CFRC have good accuracy and a higher sensitivity than strain gauge.

Self-sensing of tensile strain, compressive strain and damage detection is effective in CFRC under different loading. The self-sensing ability of CFRC, as shown for the sensing of strain and damage detection, is obviously presented in this paper.

**Abstract:** Cracking, strength loss and long term durability problems can arise if the concrete curing temperature is too high. Conversely high temperature can be beneficial as it gives high early age strengths but lower than expected temperatures can be catastrophic. In this paper the authors discuss various projects they have been involved with where temperature monitoring has been implemented so the project can avoid the problems noted or benefit from the early strengths.

The authors have experience with many methods and techniques for measuring the concrete's heat generating capacity and predicting and monitoring insitu temperature. The paper outlines key aspects of this experience including standardisation of the hot box tests, (CIA Z7/07), use of monitoring and logging devices and standardisation of insitu measurements (CIA Z7/07).

Temperature assessment criteria for prevention of Delayed Ettringite Formation and strength loss are often misunderstood and these are discussed. Thermal cracking criteria is a complex subject and is not included although monitoring temperatures and strain for quality assurance related to crack control is.

Early age strength is important in regards to curing required, time to prestress release, formwork removal and application of loads. Temperature measurement can be used to calculate concrete maturity for the estimation of insitu concrete strength. Examples of maturity implementation for cost and time saving on Australian and overseas projects are provided.

Keywords: Concrete, heat of hydration, maturity, temperature monitoring, insitu strength

## 1. Introduction

The chemical reactions that takes place when cement is mixed with water is exothermic. The heat generated depends on the nature of the cement and mix design but the temperature rise is also determined by how quickly the heat can escape. Controlling and monitoring the early temperature of concrete is extremely important in order that the following do not become problematic:

- a) Cracking due to restrained expansion or contraction as the concrete heats and cools
- b) Strength attained is significantly lower than the strength expected when cured at standard temperatures
- c) Durability is reduced due to the nature of the hydration products being changed by high temperatures. Delayed Ettringite formation is a known manifestation of this.

On the positive side high temperature speeds the cements reactions leading to higher early age strengths and durability. This gives the opportunity for early stripping, loading, stressing and cessation of curing. The insitu temperatures can be monitored to give an estimation of strength with time using a maturity method.

This paper provides information on predicting and monitoring concrete temperature development. A standardised "Hotbox" method for measuring the temperature generated by the cement in a particular mix is outlined and the method of calculating the adiabatic temperature rise of the concrete from this is discussed. Important aspects of modelling the temperature rise in a concrete pour is also provided. Based on the likely insitu temperatures the potential issues outlined above and early age performance can be assessed

## 2. Heat Generation in Concrete

The reaction referred to as "hydration" commences when the cement is mixed with water, but it is not until some hours later that the reactions speed up and heat is released rapidly. This continues for around 15-30hrs after the concrete is placed in the forms. Heat at the centre of the pour can only escape slowly through

the surrounding concrete and hence the temperature at the centre of the pour builds up to a maximum in the first couple of days before heat loss exceeds the heat generated (**Error! Reference source not found.a**).

a) Maximum (slab centre) for different thicknesses

b) Temperature profile across the concrete section

**Figure 1. Temperature rise of concrete during hydration**

The internal temperature of the concrete at a discrete point is a function of how much heat is trapped. For example in a very thick element, a lot of heat will be trapped in the very centre, but closer to the surface there will be less self-insulation by the concrete and the effect of the ambient air temperature from the surrounding environment will become more predominant (**Error! Reference source not found.b**).

Independent of the cement chemistry, mix design and slab thickness there are other factors controlling the maximum concrete temperature and temperature differentials, for example:

- Formwork or insulation will keep the concrete surface warm this:
  - reduces temperature differentials
  - increase centre cool down and hence time to stripping based on allowable differentials
  - reduces the time it takes for concrete at the surface to attain a given strength and durability.
- Removal of formwork or insulation can lead to a dramatic reduction in concrete surface temperature and hence increase in temperature differential and internal restraint cracking risk.
- Use of cooling pipes to keep the centre of the pour cool and keeps temperature differentials low
- Curing by spraying with cold water can act as an extreme thermal shock and hence water should only be applied to the concrete surface immediately after placing and before the temperature rises. This water needs to be trapped in fabric under polythene until differentials have reduced sufficiently to enable stripping of thermal insulation.
- Wind (particularly with evaporative cooling) and rain (that impacts on the concrete surface) causes low surface temperatures and hence high temperature differentials and cracking risk.
- The temperature rise at the centre of the pour is added to the concrete delivered temperature to give the insitu temperature. Keeping the concrete delivered temperature down (by using chilled water, ice or liquid nitrogen in ascending order of cost), particularly combined with low cement contents, may be sufficient to dispense with the need for low heat cements and/or insulation of the concrete.

### 3. Predicting Insitu Concrete Temperatures

Mathematical models are used during design to predict concrete peak temperature, maximum temperature differentials, concrete strain and concrete crack risk.

On one project the concrete supplier's commercial manager undertook to supply the concrete and monitor temperature to ensure compliance with the maximum temperature and temperature differentials specified. It may seem natural for a supplier to take on management for the application of their product and the Contractor to pass the risk to the more knowledgeable supplier. An author was contacted by the supplier with a view to undertake the monitoring. During the phone call the concrete supplier conceded that they had not checked whether the slab would meet specified temperature limits and were simply monitoring to show it had complied. Using Bamforth's curves (Figure 2a) it was established during the call that based on the proposed cement content and type, proposed concrete delivered temperature and pour thickness the maximum allowable temperature and differentials were likely to be exceeded. Ironically if the only action were monitoring then the only result would be proof that the concrete was out of specification and liable for

replacement or significant remedial action. Before monitoring concrete pour temperatures (a relatively simple task indicated in Figure 2b) it is vital the more complex task of a proper thermal analysis is undertaken to ensure the concrete mix and pour are designed to:

- meet specified temperature limits. On one pour in Singapore expensive strengthening was required when maximum temperature limits were exceeded.
- minimise contractors cost. Being overly safe on ensuring compliance can be expensive in time for the contractor but not impact on the concrete supplier.

Specific analysis	
Project	
Element	
Slab thickness	2.2 m
OPC content for strength	525 kg/m <sup>3</sup>
Concrete placing temperature	30 °C

a) Bamforth (8) curves for simple insitu temperature rise assessment

b) Insitu temperature measurement

**Figure 2. Simple Prediction of insitu Temperature Rise and Measurement of it.**

The Bamforth curves only give a first estimate of insitu temperatures but that will enable some refinement of the proposed concrete mix and placing method. Once these estimates show that temperatures may be acceptable, more detailed calculation are required before pouring to verify expected temperatures are safe. Traditionally the adiabatic temperature rise of the concrete was used to precisely predict the heat generating capacity of concrete and from that the insitu temperatures expected in the concrete after placement. However, adiabatic testing is complex, costly and generally laboratory based. More recently, semi-adiabatic testing has become more common because it is simple to undertake on site using concrete from the proposed batch plant as part of a trial mix.

There is no Australian Standard for measuring the semi adiabatic temperature rise but a method has been formalised within CIA Z7-07 (Concrete Institute of Australia “Concrete Durability Series, Performance Tests to Assess Concrete Durability” CIA Recommended Practice Z7/07, CIA 2015, Sydney) called the “Hot Box”. It uses a 1m x 1m x 1m cube of unreinforced concrete. The concrete temperature is measured by temperature sensors. The simplest configuration is to locate one at the centre of the pour and to also measure ambient temperature. An alternative arrangement requires the placement of plastic threaded rods within the box from which multiple temperature sensors are placed at specific points. Traditionally just a temperature sensor was located in the centre of the Hot Box, but a strain gauge can be used to give temperature and strain and this enables the coefficient of thermal expansion of the concrete to be calculated as well. The instrumented Hot Box assembly is held off the ground and sheltered from the elements to reduce external effects on the concrete temperature. It is then filled with concrete and the lid placed on.

From the concrete and ambient temperatures an allowance for heat loss is made to give the adiabatic temperature rise. The calculation assumes a heat loss coefficient which is then adjusted so that the calculated adiabatic temperature stays constant after reaching a maximum. Some contractors have assumed that the Hot Box temperature results are used directly to show whether the concrete meets specified temperature limits but that is not possible. Adiabatic and then insitu calculations have to be undertaken.

Calculating insitu temperatures from the adiabatic temperature rise of the mix, delivered concrete temperature, pour thickness, insulation proposed and ambient conditions is achieved using a spreadsheet

that calculates the temperature at discrete steps across the concrete section as heat is added by the cement hydration, is lost at the boundaries and is transferred from point to point. The effects of pouring in layers and shutter removal can all be built into the calculations.

For the Gorgon MOF wharf, a 0.8m thick slab with 2m edge beams, the construction schedule demanded removal of insulation as quickly as possible. The initial insulation proposed by the contractor was so effective that it would have taken weeks for the slab to cool down sufficiently for stripping to avoid thermal cracks. By minimising the insulation thickness to 10mm, so that allowable differentials were only just met, the stripping time was minimised.

On another project significant wide cracking to insitu decks cast on top of caissons occurred after an analysis to CIRIA C660 (Bamforth P. "Early Age Thermal Crack Control in Concrete": CIRIA Report C660, CIRIA, 2008 London, UK.) indicated crack width would not exceed 0.1mm. Investigation showed:

- a) The caissons were grouted together to form a continuous unit whereas the original analysis treated the caisson as separate units because no information on connection of caissons was provided. This led to very rigid caisson end walls and significant end restraint. A revised C660 analysis indicated the increased restraint increased predicted crack widths to 0.4-0.6mm.
- b) Cover was up to 150mm instead of the design cover of 50mm. The revised C660 analysis indicated the increased cover increased the predicted crack widths from 0.4-0.6mm to 0.8-1.3mm.

The importance of full disclosure and maintenance of maximum cover are apparent

For the Jervoise Wharves temperature predictions for 1.5 and 2 m thick decks showed that the 17mm plywood insulation (Figure 3a) and shutters could be stripped in under 2 weeks. However for the 3m decks the stripping time of the 34mm ply insulations was going to be 3 weeks (Figure 3b). The Contractor was faced with requiring an additional set of shutters to keep up with the construction programme so accepted the use of cooling water pipes. This enabled stripping in 10 days. Water cooling pipes were highly effective (Figure 3c), fast to install and inexpensive in this case where a submersible pump was dropped in the ocean to pump water through the 75mm PVC pipes placed at the centre of the pour.

a) Insulation on a 2m Deep Jervoise Bay Deck

b) Predicted temperature with time for the 2m and 3m Jervoise Bay pour with 34mm of insulation. Note slow cooling of 3m centre.

c) Actual temperature through Jervoise Bay 3m pour using 34mm insulation and cooling water pipes.

**Figure 3. Thermal Analysis at Jervoise Bay**

#### 4. Monitoring Heat of Hydration

Monitoring of heat of hydration in concrete involves the installation of temperature sensors into the concrete before concrete placement. The temperature data is then logged at a certain interval for a specified amount of time. Aspects important for temperature monitoring are equipment choice as well as sensor placement and number. In terms of equipment choice; generally cost, reliability and ease of use are the key factors. Cheaper equipment generally comes with the inherent usability and reliability problems, whilst more expensive systems may alleviate these problems but budgetary concerns may make them prohibitive. The three prime systems used are:

- a) Thermocouple wire and a standard data-logger.
- b) Single channel wired or wireless data-loggers that collect the data for one sensor.
- c) A discrete robust sensor that measures temperature and logs it internally for subsequent download is installed into the concrete.

Potential issues are: Long cable runs and vulnerable on site loggers can make a) and b) expensive, unreliable and difficult to use. Many thousands of the discrete loggers are now used each year in Australia because of their ease of use and reliability.

Liquid nitrogen was used to reduce the concrete delivered temperature and hence insitu temperatures for mass concrete pours for a Dam in Queensland. A fully wired central data logging system was purchased to monitor all pour temperatures but frequent thermocouple failure meant results for many pours were not recorded. A discrete sensor system with internal logging as described in c) was purchased. Site engineers found the system easier to operate and totally reliable.

For temperature monitoring a set of temperature sensors is typically located at each measuring point. The set (Figure 2b) comprises:

- a sensor at the pour centre. This is generally close enough to be deemed the maximum temperature, which is of interest for assessment of DEF and low strength risk
- sensors tied to the reinforcement at each concrete face. This give the temperature differential to the centre and is used to assess internal restraint cracking

Sometimes a set of sensors are also tied to reinforcement at the edge and corner of a pour to enable analysis between the edge temperatures and temperature well away from the edge. Where differential temperatures between new pours and restraining old pours define the stripping time temperature adjacent to the old pour can also be monitored.

## **5. Temperature Induced Defects**

### **5.1 Delayed Ettringite Formation**

Ettringite formation is expansive, and if it occurs after the concrete has become rigid it causes cracking within the concrete. When it occurs after several months or years it is called Delayed Ettringite Formation (DEF). The exact cause of DEF is not entirely known, however it is generally thought to happen where gypsum decomposes during high curing temperatures only to lead to a later reaction causing expansive ettringite when exposed to water. The reaction does not however seem to be such an issue in concrete containing fly ash, slag, silica fume or cement with low alkalis.

The cracking caused by DEF is unsightly, reduces durability and may have structural implications. Micro-cracks allow carbon dioxide and chlorides to penetrate at much higher rates than normal leading to early onset of reinforcement corrosion. To eliminate DEF risk specifications limit maximum concrete temperature during hydration to 70°C for GP cement and 80°C for concrete with fly ash, slag or silica fume (Concrete Institute of Australia “Concrete Durability Series, Good Practice Through Design, Concrete Supply and Construction.” Recommended Practice Z7/04, CIA 2014, Sydney). Higher temperatures can be considered in specific circumstances.

DEF due to high curing temperature was first noted in Australia in steam cured railway sleepers but it can occur in any concrete cured at high temperatures. For example there are concerns that the temperature of diaphragms in steam cured T-Roff beams made from GP cement could exceed 70°C unless steaming is carefully controlled. Hence temperature monitoring of these blocks is often called for. Cases of DEF in mass concrete are uncommon but in the UK. 23 cases of DEF in abutments, wing walls, bridge beams and foundations have been identified by Quillin (Quillin K. “Delayed Ettringite Formation”. BRE Global. Information Paper 11/01, 2001, Watford, UK.).

It is generally practical to ensure critical temperatures for DEF are not exceeded, as it is simpler than detailed studies to enable higher curing temperatures and there is no accepted DEF test to check trial pours (this is the normal approach in specifications).

### **5.2 Damage from Restrained Thermal Cracking**

Where a concrete pour is restrained from contracting after it has reached its maximum temperature and starts to cool it can damage the concrete pour (cracking) or the restraint. The damage can be predicted by considering the restrained strains that occur in accordance with CIRIA C660 (8). Examples of such designs are given below.

Two similar unloaders were constructed at Port Hedland in 2008 and 2011. Both were subject to high ground water levels. It was recognised for the 2008 tunnel that AS 3735 (AS3735 “Concrete structures retaining liquids” Standards Australia, Sydney 2001) steel stress limits would not be an adequate means for

controlling crack widths and hence the crack width design was undertaken to the draft of CIRIA C660 which essentially followed provisions in EN1992-1-1 (9). At this point it had not been realised that the crack width predictions using EN1922-1-1 were significantly smaller than those predicted using the previous and validated UK code BS8007. Reasons for the difference in crack width predictions are given in Papworth (Papworth F. "Cracks in Concrete" Concrete in Australia. Journal of the Concrete Institute of Australia. Sydney, October 2009.). Significant cracking and leakage occurred in the 2008 built unloader walls although the reinforcement ratio was still higher than would have been required using AS 3735 requirements. By the time of the 2011 unloader, modifications had been made to the final version of C660 and a design based on crack widths of 0.15mm at the 95% confidence level and an alternative design of 0.3mm crack widths plus a waterproof membrane. The membrane alternative was pursued but when cost ballooned from an indicative price of \$1m to \$3m tender price the option for no membrane was pursued. Designing to 0.15mm at the 95% confidence level led to very few leaking cracks in the tunnels.

On the same 2011 unloader project the Ingo slab presented some unusual issues. The Ingo slab supports the rail line for the iron ore unloader. The slab incorporates bridge beams supported on pile caps. The interface of the bridge beams and piles was a steel surface to reduce friction and abrasion. The slab and beams would move due to train actions but shear pins at one of the beams were to be grouted after construction to fix it. Pins at the pile caps are intended to limit movement but not rigidly fix the beams. Thermal analysis showed that early thermal movement would exceed significantly the 5 mm tolerance originally allowed for the shear pins if the beams and slab were cast integrally. It was also identified that restraint due to friction with the high potential movement could lead to very high loads in the fixed shear pins. Another concern was for a potentially wide longitudinal crack in the slab due to restraint of the longitudinal beams.

Consequently the design intent was been changed to:

- allow for the high thermal and shrinkage movement in all pins initially (20mm)
- cast each beam in one length and the slab 14 days later in two lengths. The thermal contraction of the beams is then restrained by the slab reducing overall contraction
- delay fixing of shear pins by grouting at 60 days so that thermal contraction and some shrinkage has occurred.
- use a layer of polystyrene to compress and relieve lateral restraint
- cast the beams and slab to minimise frictional restraint.

## **6. Concrete Maturity for Strength Prediction**

### **6.1 Concrete Maturity Method**

Concrete maturity method is a means by which concrete temperature can be used to estimate in-situ strength during the early life. It uses the total exothermic heat produced by the hydration of the cement as a measure of the extent to which the cement has hydrated and as such the amount of strength that the concrete has been gained. In practical terms it makes use of the fact that insitu concrete elements will generally reach higher temperatures than standard cured strength cylinders and hence have hydrated to a larger amount at any given time. This means that concrete insitu will in a lot of cases have reached higher strengths earlier than the strength cylinders. In cold climates lower insitu strengths may results and this is also measurable by the maturity method.

There are two methods by which maturity is calculated. The Nurse-Saul method and the Arrhenius method. The Arrhenius method accounts for nonlinearity in the rate of cement hydration. The Arrhenius method yields a maturity index in terms of an "equivalent age", which represents the equivalent duration of curing at the reference temperature that would result in the same value of maturity as the curing period for the given average temperature. The Nurse-Saul maturity function is the sum of the average temperature for the time interval minus the datum temperature multiplied by the time interval of interest (see figure 4 where the maturity is the sum of the area of the grey columns).

In practice a calibration which relates the maturity and strength for a particular concrete mix must be determined using lab trials. A method for this has been recommended by a manufacturer of temperature monitoring equipment. In the method 17 test cylinders are cast and held in standard curing conditions. Two of the cylinders are monitored purely for temperature and provide the maturity readings at a particular age. After 1 day three cylinders are crushed and the average strength is recorded against the average maturity of the concrete cylinders. This process continues for another 4 sets of strengths data at predetermined times

(e.g. 2, 3, 7, 14, 28 days). Once completed the 5 points on the Strength v Maturity graph are then joined using straight lines to interpolate the points. The use of a straight line between points means the interpolated points are conservative by nature.

In situ the temperature of predetermine points are monitored and the maturity is monitored over time. Using the strength-maturity calibration “goal” maturity levels are determined correlating to required strengths for construction processes such as stripping forms or stressing post tensioning. Once the sensors indicate the goal maturity has been reached then the process begins. Due to the fact that the cylinders for strength determination were kept in generally colder conditions the construction process is sped up as the concrete on site has undergone accelerated hydration at higher temperatures.

**Figure 4. (left) cylinders for a calibration (centre) Schematic of temperature time-factor and temperature history (right) Typical Maturity Curve**

The calibration only relates to the particular concrete mix that has been used in its formulation. Quality Assurance can be performed by which random batches of concrete are tested to see whether the curve is still valid. This entails one temperature monitored cylinder and the crushing of two others.

ASTM C1074-11 (5) details maturity measurement. The major limitations of the maturity method are:

- a) The concrete must be maintained in a condition that permits cement hydration. If the concrete is held in a dormant state at temperatures below a datum it will not increase in strength. The datum temperature is an important factor in the safe use of maturity
- b) The method does not take into account the effects of early-age concrete temperature on the long-term strength.
- c) The method needs to be supplemented by other indications of the potential strength of the concrete mixture.

## 6.2 Port Hedland Unloader Rail Drive Floor

The Unloader TU603 at Port Headland has a rail drive floor. The construction schedule for these pours was tight. The specified minimum stripping time for tunnel roof soffit supports was 9 days for structural reasons. Time based stripping specifications are inherently conservative and the authors were asked to advise on use of maturity measurements for early stripping. The structural engineers indicated that concrete strengths of 20 and 25MPa were required for stripping and loading respectively. Roof slab thicknesses considered were 325mm, 535mm, 915mm and 1230mm.

Twenty cylinders were cast from the mix to be used in the pours. Two had maturity probes inserted and six sets of three cylinders were made for compressive strength tests. One set of cylinders was crushed at 2, 3, 4, 5, 7 and 14 days. The cylinders for strength testing and maturity probe cylinders were kept together at all times with cylinders for strength testing taken out of the curing bath just before testing. From the strength and maturity data of samples cured at identical temperatures (see Section 3) a graph of maturity vs strength was constructed (Figure 5). The maturity probes were set with a base temperature of 5°C.

a) Maturity and Cylinder Temperature

b) Maturity Curve for Project Concrete

**Figure 5. Development of Maturity Curve**

Maturity is calculated for specified strengths by assuming a linear plot between strength data points. From cylinder strength and maturity test results it was found that the strengths of 20 and 25MPa related to maturities of 1844°C.Hrs and 2567°C.Hrs respectively. Further analysis showed that these maturities were likely to be achieved at 2 to 4 days depending on slab thickness. Maturity was measured at the thinnest point of the pour at the level of the top reinforcing mat. Once the maturity criteria were met the formwork could be stripped provided the specified allowable temperature differentials were not exceeded due to thermal shock when the insulating formwork was removed. This was ensured by monitoring temperature differentials and only stripping once the allowable differential minus a thermal shock allowance was achieved.

**Error! Reference source not found.** shows an analysis for temperature with time for the 800mm thick slab cast on plywood but with no top surface insulation. This was calculated for the pour geometry, expected ambient conditions, probable concrete delivered temperatures and placing schedule based on an adiabatic temperature rise assessed from previous hot box test data. With a typical wind and no insulation the top surface is much cooler than the bottom and the top reinforcement is the location where the maturity probes were likely to record the lowest temperature.

**Figure 6. Predicted insitu Temperatures for an 800mm Thick Slab**

Based on the temperature with time profile for the top of the slab the likely time to achieve the required maturities was calculated as 60hours for the 1844°C Hrs (20MPa) and 84 hours for 2567°C Hrs (25MPa). Similar assessments were undertaken for other slab thicknesses.

After the pour was complete the maturity probes that had been installed prior to the pour were turned on and the base temperature set to 5°C. This is a conservative value for maturity assessment but doesn't make a significant difference to stripping times and simplifies the establishment of the system. For the first pour maturity was monitored at three locations on the top reinforcement and one on the bottom reinforcement. Results are shown in **Table 1**. For subsequent pours only the coolest mat (top) was monitored.

**Table 1 Maturity Data for First Tunnel Roof Pour**

Probe Location	Maturity (°C.Hrs)			
	24hr	48hr	72h	96hr
Bottom Rebar	1146	2469	3628	4635
Top Rebar loc. 1	835	1925	2905	3755
Top Rebar loc. 2	898	1992	2965	3820
Top Rebar loc. 3	896	1962	2911	3741

These results, and those on all other slabs, showed stripping at 2 days and loading at 3 days was acceptable subject to achieving other temperature limits related to thermal cracking. Construction of the tunnel roofs was completed in a month. All monitoring was undertaken by the site engineers who commented on the simplicity of managing it using the discrete maturity loggers after the maturity criteria were established.

### 6.3 NSW – Rail Infrastructure

This case study illustrates the use of maturity on precast bridge segments for a raised rail line in a major Australian infrastructure project. Pre-cast facilities producing large structural elements such as bridge segments operate on a tight schedule. They typically cast one segment per mould per day. This schedule is controlled by the strength at which moulds can be opened and segments moved out to cure while the mould is reset. The next hold point was a second strength requirement for segments to be lifted and taken to storage. Maturity was employed as a tool to measure insitu strengths.

A trial mix was tested to determine early age strength of the proposed concrete at critical moments in the casting schedule. 38 cylinders were cast. Two maturity loggers were embedded into two cylinders. Three cylinders were then crushed at 8, 10, 12, 14, 24, 32, 36, 48 hours and 7, 14, 21 and 28 days.

Maturity calibrations usually only entail 5 data points and so the effect of adding additional points to a maturity curve may make the prediction more precise but less conservative depending on the curve section being used. Figure 7 shows two maturity curves for the same concrete. One has five maturity points and one two points. At 280°C-Hours the left hand curve with five points gives a higher strength than the right hand curve with two points while at 560°C-Hours the maturity based strengths are the same.

Additional utility that can be gained from a trial mix with simultaneous maturity calibration includes trouble shooting during the test mix. For example if early strength gain is less than expected temperature graphs can be reviewed to capture heat of hydration information for the samples.

Figure 7. Strength v Maturity Calibrations

Figure 8 CEMEX Headquarters

### 6.4 CEMEX Headquarters, Houston

The 325,000 square foot CEMEX headquarters (Figure 8) is one of the largest green buildings in Houston. A major reason for the eco-rating, was the low amount of fly ash and cement used in the concrete mix. This led to a slow strength development and so maturity was used to maximise the use of early strength that was achieved. The construction company had previously used High Early Strength cement and high cement contents to achieve a 24 hour slab pouring and prestressing cycle based on standard cured cylinders. The use of maturity during Houston's high ambient temperature summer enabled the 24hour cycle to be achieved even with the eco-friendly concrete. Overall these factors also lead to cost saving on the project which was completed ahead of schedule. Switching mix designs was budgeted to save approximately \$130,000 in concrete costs alone for the 14-floor, 325,000 square feet building.

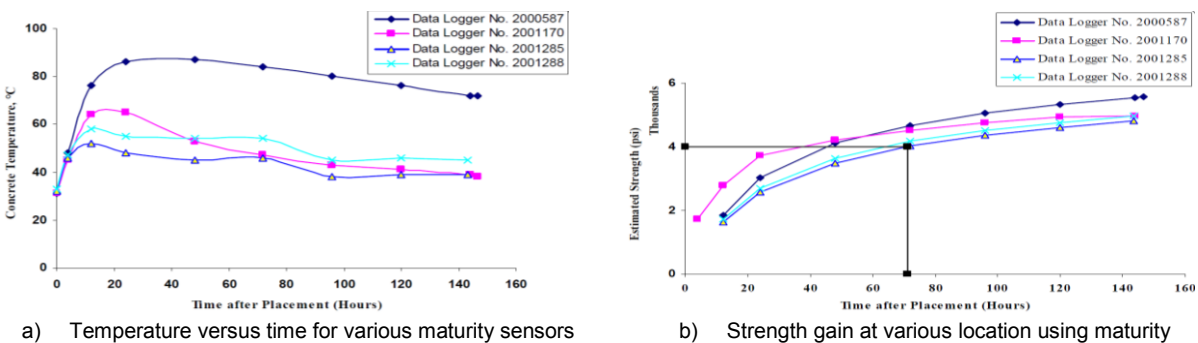

The temperature sensors strategically placed prior to each pour monitor the concrete's temperature and calculate the effects of elevated temperature on strength gain. Tracking the data transmitted by the sensors, the software converted the reported maturity data into actual strength values. Overall the project was finished on time, with the projected savings in time and money as well as the eco-friendly rating.

### 6.5 Amgen OPUS Project - Puerto Rico

This was a pilot project to check the implementation of maturity in Puerto Rico. The project entailed the expansion of a bio-pharmaceutical process facility with over 300,000 square feet to be added during construction. In total 6 placements were monitored for maturity with strength vs maturity calibrations for the design mix also carried out. During calibration 20 cylinders were used. Two for maturity data and eighteen

(i.e. six sets of three) for the strength testing. A line of best fit was used to match the strength-maturity data the equation being  $y=1305.1\ln(x) - 6630.9$ . Data between 800-4900° C.hrs gave an  $r^2$  correlation of 0.9981 (Note that interpolation should be done using straight lines between points, not line of best fit).

For one beam where early strength assessment was critical four locations were monitored for maturity. Loggers 2001170 and 2000587 were placed 1m deep inside a beam with 2001288 and 2001285 placed in the cover region (100mm deep) where the slowest strength gain was predicted. Figure 9a shows the concrete temperatures measured over 160 hours. All of the sensors measured an increase in temperature after placement with 2000587 getting extremely hot due to self-insulation. The two cover sensors do not get as hot. Using best fit equation the strength insitu was calculated from the temperature history. The strength at each sensor location are shown in figure 7b. The goal strength of 4000 PSI was required in the specification for stripping of forms. It was found that this strength was reached last on sensor 2001285 at around 70 hours. Forms were able to be removed 2 days earlier than would have been the case if maturity had not been used and therefore construction was accelerated. Also important to the pilot project were validation checks to make sure there were no significant variations in the concrete mix. None of the 6 validations performed during the project varied by more than 5% from the calibration curves used during the project.

**Figure 9: Maturity Assessment for the Amgen OPUS Project**

## 7. Conclusions

This paper discussed how the heat of hydration of cement leads to a rise in concrete temperatures. It detailed how these temperatures can be predicted and how they should be monitored.

Based on predicted insitu concrete temperatures the risk of damage due to high temperatures and temperature differentials can be assessed. Examples of how this was undertaken on various projects were given. The examples explored:

- Design to maintain crack widths to a level whereby durability is not compromised
- Mix design and placing methods to ensure maximum temperatures do not lead to delayed ettringite formation or low insitu strength
- Design of thermal curing methods to minimize stripping times thereby enhancing the construction program and minimizing construction time

High insitu temperatures can bring advantages. It leads to high early age strengths and this can be measured using maturity methods. Examples are given where maturity measurements were used to enable cost savings, use of eco-friendly concrete, early stripping and accelerated construction.

Temperature prediction and monitoring is an extremely important exercise that should be encouraged by the industry to allow for efficient and durable construction.

# The Role of Dilation in Shrinkage Cracking of Concrete

Suhaila Mattar<sup>1</sup> and R.S. Al-Rawi <sup>2</sup>

<sup>1</sup> Daphne Jackson Fellow, School of Civil Engineering, University of Leeds, UK

<sup>2</sup> Professor of Civil Engineering, College of Engineering, University of Baghdad, Iraq

**Abstract:** The aim of this investigation was to study the role of dilation in delaying shrinkage cracking of concrete and the possibility of producing shrinkage crack-free concrete. The experimental programme consisted of two parts. In the first part, end-restrained concrete beams were water-cured for one and three days before drying under controlled temperature (35 °C) and relative humidity (25%) conditions. In the second part, concrete beams were water-cured for one and three days before drying in outdoor summer conditions in Baghdad, Iraq. For all specimens, various parameters were measured, including free-shrinkage strain, tensile strain capacity, elastic tensile strain capacity, creep in tension and cracking time.

The experimental results show that none of the concrete specimens dried under natural outdoor conditions cracked in spite of high temperatures (up to 60 °C) and low relative humidity (less than 15%). This is due to dilation in the form of increased creep in tension with variations in temperature and relative humidity. Increasing water-curing duration usually delays shrinkage and always delays or prevents cracking; it increases tensile strain capacity, which reduces the probability of cracking for all specimens dried in natural or controlled conditions.

**Keywords:** concrete, shrinkage, creep in tension, tensile strain capacity, dilation, end restrained shrinkage.

## Introduction

Dilation can be defined as a strain opposite to shrinkage and thermal contraction. It can be expected to prevent or delay cracking and to reduce crack widths. In 1986, Al-Rawi and Al-Qassab (1) found that the observed crack width is less than the calculated maximum crack width for reinforced concrete beams cast in I-shaped moulds and subjected to drying shrinkage conditions. Many other researchers (2,3,4) and practical cases (2) have shown that crack widths observed by microscope are less than those measured by demec points and calculated by equations. Salman (5) reported that concrete beams treated with gypsum and cured for 3 days did not exhibit any cracking under outdoor exposure conditions. He attributed this to the addition of gypsum, which led to expansion and development of compressive stress along the concrete beam due to restraint at the end of the beam supported by the flanges. As a result, lower tensile stress will develop in the concrete beam which is less than the tensile strength of concrete. Another reason is that water-curing results in an increase in the tensile strain capacity of the concrete. These two effects combine to minimize restrained shrinkage stress within the concrete beam, thus delaying or preventing cracking.

Adday (2) found the same results. He indicated that covering concrete with polyethylene sheets for one day after casting, then water-curing for one week in the laboratory prevented cracking, even though the concrete beam was highly restrained and subjected to high temperature and low relative humidity for long periods. This showed that under outdoor exposure conditions, the cracking tendency of large beams seemed to be very low and the probability of cracking much less than under laboratory conditions.

Al-Rawi and Salih (6) showed that in a study of a concrete mass (850 m<sup>3</sup>), no shrinkage and thermal cracking takes place despite the fact that the temperature difference between the core and the surface of the concrete mass reached 41 °C and temperature cycles (daily rise and fall) on the surface of the concrete mass cause expansion at the surface due to repeated creep cycles (dilation), which reduces the possibility of cracking.

The above-cited studies (2,5,6) conflict with the prevailing conclusion in the literature, which is that subjecting concrete to high temperatures and low relative humidity increases the probability of cracking due to increased drying shrinkage, as the beams subjected to drying in outdoor exposure

conditions in the summer in Iraq did not show any cracking. This may be because the large variation in temperature and relative humidity between day and night increased creep in tension, which could be more than the increase in shrinkage. Therefore, the probability of shrinkage or thermal cracking decreases. The fact that creep increases with fluctuations in temperature and relative humidity has been studied by Al-Rawi and Kammouna (7).

Given the findings in the studies cited above (1,2,3,4,5,6,7), the term "dilation" of concrete is defined in this project to include factors that delay or prevent shrinkage or thermal cracking of concrete. These factors are:

- i. Water (moisture) movement caused by water-curing concrete before drying.
- ii. Increased creep of concrete in tension due to temperature fluctuations.

## Experimental Work

### Concrete Mixes

Four concrete mixes were designed according to ACI 211.1–91. The slump was chosen to be 100 mm for all mixes. Trial mixes were made, and slump testing was carried out according to ASTM.C143/C143M-05a to ensure the desired workability. Adjustments then were made to the calculated properties. Table 1 shows details of concrete mixes employed in this study. Mixes then were cast in special moulds and vibrated and trowelled to obtain an even surface.

**Table 1. Details of concrete mixes.**

Mix	Mix proportion (by wt.)	Water/cement (by wt.)	Cement (kg/m <sup>3</sup> )	Sand (kg/m <sup>3</sup> )	Coarse aggregate (kg/m <sup>3</sup> )	Water content (kg/m <sup>3</sup> )
A	1:2.8:3.64	0.75	288	791	1020	216
B	1:2.06:2.93	0.62	350	720	1020	216
C	1:1.74:2.66	0.55	400	667	1020	216
D	1:1.32:2.18	0.48	520	637	1020	216

### Moulds

Moulds used were made of a steel channel section fabricated into I-shapes, as shown in Figure 1. Concrete was cast into them and subjected to drying shrinkage restrained by the flanges (8). Naturally, the restraint is not complete, and some contraction of concrete will take place. The mould is designed such that this contraction is relatively small, and the restrained shrinkage induces cracking across the web of the beam. Shallow mould depth enables fast drying, without significant differential shrinkage. To minimize friction between the steel mould and the concrete, the web part of the mould is greased and lined with a sheet of polyethylene.

For each mix, three moulds were cast and then dried, either in a room with controlled temperature and relative humidity, or exposed to the weather outdoors. For each mix, one of the three moulds was cast with an artificial opening in the middle of the web to allow determination of free shrinkage, and the two others were used for the restrained shrinkage test.

**Note:** Each specimen was given a set of letters and numbers to describe it.

A, B, C, D: Concrete mixes shown in Table 1; i: indoor exposure conditions; o: outdoor exposure conditions; 1 and 3: water-curing durations.

**Figure 1. I-Shaped mould (not to scale).**

### ***Curing and Exposure***

Generally, the surface was covered with polyethylene sheets for 24 hours to prevent plastic shrinkage cracking. Curing was effected by covering the concrete beam with canvas sheets wetted with water for the specified curing period. After curing, the concrete beams are left in the moulds to achieve restraint and dried either in a room with controlled temperature and relative humidity or outdoors, subjected to natural drying conditions. For those beams dried indoors, the temperature was constant at  $35\text{ }^{\circ}\text{C} \pm 5\text{ }^{\circ}\text{C}$ , and the relative humidity was  $25\% \pm 2\%$ .

### ***Free Shrinkage Strain Measurement***

Free shrinkage was defined as the average strain over the length of the web of concrete beams. A diaphragm was introduced in the middle of the web prior to casting, dividing the beam into two halves. The diaphragm was removed the next day, leaving an artificial opening. This arrangement allowed free shrinkage to take place, as there was no restraint. Demec points were fixed on either side of the artificial opening, 100 mm apart. The increase in gauge-length between these points was measured by demec extensometer when the beams were exposed to shrinkage conditions, with 100 mm in length in an accuracy of 0.002 mm/division, and it was taken as free shrinkage along the whole web length less the 100 mm distance between the demec points. This was based on the assumption that the coefficient of the thermal expansion of steel is approximately equal to that of concrete. The difference, if any, is usually not great, and in any case, it also exists in restrained shrinkage. The fact that free shrinkage strain was averaged over a fairly long length (1700 mm) minimized experimental errors.

### ***Restrained Shrinkage Strain Measurement***

The restrained concrete beams were water-cured in the laboratory for the specified curing periods. During that period, demec points were fixed at 100 mm intervals on the surface along the centre of the web and on the steel moulds. Then the beams, still in their moulds, were transferred either to a room with controlled temperature and relative humidity or outdoors to dry. The concrete was allowed to shrink until either cracking occurred or until it reached a fairly stable state, and demec readings were taken continuously by a demec extensometer until the end of the test. Then, parameters were calculated, as described below.

#### ***Loss of Restraint (LOR)***

In most practical cases, full restraint does not exist, i.e., not all the shrinkage of concrete is restrained. This means that some movement of moulds takes place and leads to some loss of restraint. In the moulds used in the present study, loss of restraint was measured as the mean contraction of the steel mould or, alternatively, contraction in the web length of the beams at the time of cracking.

#### ***Tensile Strain Capacity (TSC)***

Tensile strain capacity was defined as the difference between the free shrinkage strain during cracking time and the strain due to loss of restraint.

$$\text{TSC} = \text{Fsh} - \text{LOR} \quad (1)$$

where:

TSC = Tensile strain capacity (mlths).

Fsh = Free shrinkage strain (mlths).

LOR = Loss of restraint (mlths).

### ***Elastic Tensile Strain Capacity (ETSC)***

This was defined as the observed free contraction of concrete at the onset of cracking. In the present study, this was found by measuring the change in the strain at either side of the crack at the onset of cracking. This means that the elastic tensile strain capacity is equal to the difference between the strain just before cracking and the strain just after cracking.

$$\text{ETSC} = \text{Strain just before cracking} - \text{strain just after cracking} \quad (2)$$

### ***Creep in Tension (Creep Prior to Cracking)***

Concrete was subjected to very high tensile stress prior to shrinkage cracking, and the stress/strength ratio might have been close to unity for a considerable period of time. Under these conditions, significant creep can take place. This is because creep is time-dependent and it increases sharply with the increase in stress/strength ratios. It also increases under the environmental conditions that promote drying. This phenomenon can be termed relaxation, because it takes place at a practically constant length and is effective in reducing tensile stress in the concrete. Relaxation can be viewed as increasing the tensile strain capacity of concrete and consequently reducing the possibility of cracking. In addition, it can decrease crack width. Creep in tension is defined as tensile strain capacity less elastic tensile strain capacity.

$$\text{Creep in tension} = \text{TSC} - \text{ETSC} \quad (3)$$

### ***Cracking Time***

Cracking time is defined as the number of days required for cracking to occur. Cracking time has received little attention in other research. It seems, however, that cracking time can be used as an index to compare the possibility of cracking of various mixes exposed to differing conditions.

## **Results and Discussion**

### ***Free Shrinkage Results***

Figures 2–5 illustrate the effects of prolonged water-curing on free shrinkage of concrete specimens. In general, long-term shrinkage of concrete specimens that have been water-cured for three days and then subjected to drying is higher than shrinkage of those water-cured for one day. However, in the first few days, the shrinkage of specimens cured for one day is higher than those cured for three days. The reason for this is that specimens cured for three days absorb more water than those cured for one day. During the three days, there is expansion of specimens rather than shrinkage. After water-curing, when the concrete begins shrinking, it reaches its original length (zero expansion) within three to six days. After a few more days, the shrinkage of specimens cured for three days usually exceeds that of those cured for one day.

Figures 2–5 also show that drying conditions affect shrinkage. All specimens subjected to natural outdoor conditions have higher shrinkage than specimens dried in controlled temperatures and relative humidity indoors. The final (one-month) shrinkage values show the same trend, because the specimens subjected to natural outdoor conditions were exposed to maximum temperatures exceeding 60 °C and relative humidity of less than 15%, in contrast to the moderate conditions of 35 °C temperature and 25% relative humidity for specimens dried indoors.

**Figure 2. Effect of water-curing duration and exposure conditions on free shrinkage development with age for concrete beams (mix A).**

**Figure 3. Effect of water-curing duration and exposure conditions on free shrinkage development with age for concrete beams (mix B).**

**Figure 4. Effect of water-curing duration and exposure conditions on free shrinkage development with age for concrete beams (mix C).**

**Figure 5. Effect of water-curing duration and exposure conditions on free shrinkage development with age for concrete beams (mix D).**

## **Restrained Shrinkage Results**

### **Indoor Concrete Specimen Results**

Table 2 shows the restrained shrinkage results of indoor concrete specimens. Results show that prolonged water-curing increases the tensile strain capacity of the various mixes of concrete up to 47%. This is because the necessity for curing arises from the fact that the hydration of cement is greatly reduced when the relative humidity within the capillary pores drops below 80% (9). Furthermore, water lost internally by self-desiccation must be replaced by water from outside. Therefore, the quality of the concrete depends on the gel/space ratio of the paste. Greater hydration will lead to a higher-strength concrete. In addition, prolonged water-curing delays the advent of shrinkage and produce stronger concrete that is able to withstand a larger shrinkage without cracking.

Table 2 shows that the trend of elastic tensile strain capacity is similar to that of tensile strain capacity, because the same factors affect them both. The elastic tensile strain capacity of concrete specimens cured for three days was not measured, because no cracks occurred in these specimens. Creep strain of concrete subjected to restrained shrinkage is the difference between tensile strain capacity and elastic tensile strain capacity. This has been ignored by some researchers, while others have attributed to it as much as 75% of free shrinkage. The results of Al-Rawi (8) show that the creep strain is quite significant and therefore must not be ignored.

Table 2 shows the creep values of concrete specimens water-cured for one day before drying. In general, creep increases with increased cracking time, and factors that increase cracking time also increase creep strain. Its value, however, depends to a large extent on test conditions. The creep of specimens water-cured for three days was not measured because the increase in curing time delays shrinkage and prevents cracking. This gives enough time to develop creep, which means higher creep than the specimens water-cured for one day.

Cracking time is defined as the number of days required for cracking to occur; it can be used as an index to compare the possibility of cracking of various mixes. Table 6 shows the cracking time of concrete exposed to indoor drying conditions after being water-cured for one day.

The reduction in water/cement ratio results in earlier shrinkage cracking, in spite of increased tensile strain capacity. This is consistent with increased drying shrinkage (rapid drying shrinkage does not allow relief of stress by creep and leads to cracking). This trend confirmed results reported by Al-Ali (4), who showed that the cracking tendency of concrete (cracking age) was affected by the mix richness; concrete with a higher cement content suffered a higher cracking tendency (earlier cracking age). Shah and Weiss (10) found that the reduction in water/cement ratio decreased cracking time. They explained this as a result of increased total shrinkage, decreased stress relaxation and increased brittleness and stiffness.

Table 2 shows that prolonged water-curing prevents cracking of concrete. Drying the specimens for 30 days resulted in no cracks in specimens water-cured for three days. Figures 2–5 show that shrinkage in specimens water-cured for three days exceeds that of those cured for one day. At the same time, water-curing increases concrete strength and tensile strain capacity.

This shows as incorrect the supposition that the higher the shrinkage of concrete, the higher the probability of cracking, because it ignores the possible increase in tensile strain capacity, as in the present case. In addition, the literature calls for low shrinkage of concrete to avoid shrinkage cracking, but this is not always correct, as the present results show that higher shrinkage leads to less probability of cracking.

**Table 2. Results of indoor concrete specimens.**

Specimen notation	Cracking time (day)	Free shrinkage (mlths)	Loss of restraint (mlths)	Tensile strain capacity (mlths)	Elastic tensile strain capacity (mlths)	Creep (mlths)

### **Outdoor Concrete Specimen Results**

Restrained shrinkage movements were measured for outdoor specimens cast for one month in the summer (July and August) in Iraq without any cracking. After 30 days, the specimens (water-cured for one day) were artificially cracked to measure the properties, as shown in Table 3.

Table 3 show the tensile strain capacity of outdoor specimens, which exhibit the same trends as indoor specimens. The tensile strain capacity of concrete increases with increased cement content. Longer water curing increases the tensile strain capacity of concrete specimens more than 6.0%, as illustrated in Table 3. This, as discussed previously, is because prolonged curing delays the advent of shrinkage and produces stronger concrete, which is able to withstand greater shrinkage without cracking.

The tensile strain capacity measured in outdoor specimens was greater than that of indoor specimens, and the increase in tensile strain capacity reached more than 75%. This is expected, because outdoor temperatures reached more than 60 °C, which means faster development of strength (accelerated curing), which means faster development of tensile strain capacity.

Generally, the tensile strength capacity of concrete achieved much higher values than those reported in the literatures, which generally are 100–200 mlths. Tensile strength capacity values found in the present work were more than 597 mlths. None of the specimens exposed to outdoor conditions cracked. The researcher cracked those specimens water-cured for one day at 30 days of age and then measured the elastic tensile strain at the time of cracking. Table 3 shows the elastic tensile strain capacity for cracked mortar and for the uncracked specimens that were cracked by the researcher. This means that the values obtained for elastic tensile strength capacity are greater than the values reported here. The creep of outdoor specimens was measured as the difference between tensile strain capacity and elastic tensile strain. Creep was measured when the specimens were artificially cracked at 30 days of age. Table 3 shows that creep values are relatively high. They also are greater than the creep values of indoor specimens because of the longer cracking time (30 days). The creep developed during the 30 days period is higher than the creep of indoor specimens.

**Table 3. Results of outdoor concrete specimens**

Specimen notation	Cracking time (day)	Free shrinkage (mlths)	Loss of restraint (mlths)	Tensile strain capacity (mlths)	Elastic tensile strain capacity (mlths)	Creep (mlths)	Average Temperature and R.H**
Ao1*	No cracking	503	26	477	221	256	Temp=65 °C R.H=12%

\* The specimens were artificially cracked at 30 days of age.

\*\* These data were recorded by the researcher.

### **Results of Dilation**

The previous results show that dilation is associated with restrained drying shrinkage and is found in many forms. The effects of various factors on dilation are described below.

#### **Effect of Water Curing**

It can be seen from the results of both indoor and outdoor specimens that prolonging water-curing to three days prevents cracking. This is because increased water-curing duration causes expansion, which also can be called dilation. Dilation due to water-curing reduces the probability of cracking. It can prevent cracking or at least decrease crack width. In this case, dilation delayed early shrinkage of specimens, and consequently, the cracking resistance of the concrete was increased because water-curing increases the strength of concrete. The tensile strain capacity increased so that shrinkage strains remained less than the tensile strain

capacity, as shown in Figure 6. No crack occurred in any concrete specimen water-cured for three days.

**Figure 6. A sketch of tensile strain capacity and related concrete parameters for various water-curing periods under outdoor exposure conditions.**

TSC<sub>1</sub>: Tensile strain capacity for specimens water-cured one day.

F<sub>sh1</sub>: Free shrinkage for specimens water-cured one day.

LOR<sub>1</sub>: Loss of restraint for specimens water-cured one day.

ETSC<sub>1</sub>: Elastic tensile strain capacity for specimens water-cured one day.

C<sub>1</sub>: Creep for specimens water-cured one day.

TS<sub>2</sub>: Tensile strain for specimens water-cured three days.

F<sub>sh2</sub>: Free shrinkage for specimens water-cured three days.

Note: In outdoor exposure conditions, no cracking took place whether water-curing was for one day or three, i.e., in both cases curves (2) are applicable.

### ***Effects of Fluctuations in Temperature and Relative Humidity***

Specimens subjected to outdoor exposure did not crack whether cured for one day or three. This means that other factors affect the cracking tendency of outdoor specimens. Results reported in Table 3 show the maximum and minimum temperature, average relative humidity and wind speed of exposure durations in summer in Baghdad. It can be seen that the change in temperature between day and night is more than 40 °C. The relative humidity ranged from 12% during the day to 23% at night in July and from 17% during the day to 28% at night in August. These fluctuations in temperature and relative humidity led to higher rates and magnitude of creep, as shown in Figure 5, partially relieving the restrained shrinkage stress.

In this case, dilation occurs because of increased creep due to relatively large fluctuations in temperature and relative humidity. This agrees with the argument proposed by Al-Rawi and

Kammouna (7), who claimed that the temperature rise increases the rate of creep, resulting in higher creep values. They found that changes in temperature and relative humidity from 21 °C and 50% to 42 °C and 23% caused a sudden increase in creep of approximately 280 mlths. The increased creep of concrete in tension with increased variation in temperature is attributed to the fact that the coefficient of thermal expansion of water is much higher than the coefficient of thermal expansion of concrete. Therefore, with increases in temperature, the water in concrete pores expands much more than the concrete. This causes pressure, leading to expansion of the concrete. With decreases in temperature, the water in concrete pores contracts but obviously does not lead to contraction of the concrete. Repeated heating and cooling of the concrete means repeated expansion, but no contraction, which means higher creep (transitional thermal creep) of the concrete in tension.

## Conclusions

The following conclusions can be drawn.

- 1- Concrete water-cured for three days after casting shows significant expansion. When such concrete is dried indoors for one month, it shows shrinkage higher than concrete water-cured for one day followed by one month of drying indoors. Concrete dried outdoors shows similar trends as concrete dried indoors, but it shows higher shrinkage due to higher temperatures (more than 60 °C) and lower relative humidity (less than 15%).
- 2- All specimens subjected to natural drying conditions outdoors have tensile strain capacity higher than the specimens dried in rooms with controlled temperature and relative humidity. This is because outdoor temperatures reached more than 60 °C, which causes faster development of strength (9), resulting in increased tensile strain capacity.
- 3- Prolonged water-curing increases the tensile strain capacity of various mixes of concrete, whether they are exposed to indoor or outdoor drying conditions. Specimens water-cured for three days gain greater strength during these three days, and higher tensile strain capacity is gained compared with specimens water-cured one day.
- 4- Prolonging water-curing to three days prevents cracking of concrete. Concrete specimens subjected to outdoor conditions did not crack whether water-cured for one day or three. This is due to the higher rate and magnitude of creep (dilation) and to partial relief of restrained shrinkage stress. This dilation occurs due to relatively large fluctuations in temperature, which cause higher creep, resulting in relief of tensile stress on the concrete and prevention of cracking.
- 5- Fluctuations in weather conditions between day and night in the summer in Iraq could be an advantage regarding shrinkage and thermal cracking of concrete. This is because such weather increases tensile creep significantly (up to more than four times the tensile creep achieved in steady moderate weather), thus increasing tensile strain capacity of the concrete by more than 46% and reducing the possibility of cracking.
- 6- Considerable savings in steel reinforcement of concrete can be made in fluctuating, hot, dry weather.
- 7- Magnitude of shrinkage is not the only factor affecting cracking of concrete. Tensile strain capacity, including dilation, is another factor.

# High-Absorptive Normal-Weight Aggregates used as Internal Curing Agent

Pericles A. Savva<sup>1</sup> and Michael F. Petrou<sup>2</sup>

<sup>1</sup>Phd candidate in Civil and Environmental Engineering, University of Cyprus

<sup>2</sup>Professor of Civil and Environmental Engineering, University of Cyprus

**Abstract:** High performance concrete (HPC) in the early age suffers high shrinkage. Two well established methods for compensating early-age shrinkage have been the incorporation of pre-saturated lightweight aggregates (LWA) and the addition of dry super absorbent polymers (SAP). LWAs and SAPs are purely water reservoirs which have little or no contribution to concrete final performance. Consequently, the space occupied by these reservoirs yield to additional porosity which is known to deteriorate concrete mechanical properties. An effort to reduce early-age shrinkage using high-absorptive normal-weight aggregates (HANWA) has been conducted on concrete mixtures with water to binder ratio of 0.25. The HANWA concrete mixtures were compared with a mixture including low-absorptive normal-weight aggregates (NWA) and two different mixtures including low-absorptive aggregates and two different types of SAP. Tests on resistance to chloride penetration, vacuum porosity, and compressive strength have been conducted, in order to assess the mechanical and durability properties. Furthermore, autogenous shrinkage and maturing temperature of these mixtures have been monitored during the first week of hardening. The results show that autogenous shrinkage can be reduced using HANWA for internal curing (IC) maintaining mechanical and durability properties intact.

## 1. Introduction

Concrete has a relatively low tensile strength compared to its compressive strength. The first week of the material's life-cycle is very crucial and along with the constituent material's it defines its final performance. Fresh concrete maturing is strongly depended on environmental conditions since the water evaporation and the cement hydration rates are greatly affected by temperature, humidity and wind speed. Consequently, drying rate and hydration products dispersion are two dominating parameters that define the material's quality. However, the volume variations that occur in early-age concrete are not exclusively attributed to the evaporation rate. It has been reported that shrinkage will occur due to chemical and physical intrinsic properties of cement even in a completely isolated environment (1). Swelling will occur during the initial maturing period due to the formation of ettringite and osmotic pressure (2). Neville (1) has clarified that in most cases shrinkage will overcome swelling. The mechanisms that cause shrinkage have been studied thoroughly and there are evidence that along with drying shrinkage, concrete contracts due to autogenous and chemical shrinkage.

Autogenous shrinkage was first recognized and introduced in concrete technology by Lynam in 1934 (3). It is a general term that describes the material's bulk volume variation. Autogenous shrinkage is the sum of chemical shrinkage and self-desiccation. Chemical shrinkage occurs because the reactants occupy 8-10 ml for every 100 g cement reacted less volume than the initial products (2), whereas in the case of supplementary material's such as silica fume, the reduction in volume may occur up to 20 ml for every 100 g silica fume reacted (4). Chemical and autogenous shrinkage begin to diverge when concrete develops adequate strength to support the formation of voids within its structure (2,5). Self-desiccation is the result of two governing physical processes that appear due to insufficient water. Specifically, disjoining pressure between the material's particles occurs where high RH levels exist and the water adsorption is obstructed due to insufficient space. Reduction in RH levels will result in disjoining pressure decrease causing the material contraction (4). Furthermore, a partially fluid filled pore will result in fluid-air menisci formation that exhibits tensile stress (4). The pore surrounding walls will develop compressive stresses in order to restore equilibrium resulting in further contraction (6).

It is therefore understandable that the practice of increasing cement quantity and decreasing water quantity has a severe influence on the material's shrinkage (7). During the last two decades, high performance concrete (HPC) has been introduced and increasingly used in the construction sector due to

its high strength and high durability properties. In order to achieve such properties, among other modifications in the mixtures constituent materials, cement quantity is increased whereas water quantity is decreased.

An effort to reduce HPC shrinkage has been focused on utilizing water from the inner structure of the material, by dispersing micro-reservoirs of water, providing IC. IC have attracted great attention after Ole Jensen's comprehensive work (8,9) at the early 2000s. Two well established methods of IC are the use of SAPs and LWAs. Both methods, however, evidently cause deteriorating side effects on the material's performance. The effort of this research was to provide IC to concrete and maintain its properties intact.

## **2. Research significance**

The main objective of IC is to provide additional water in dense concrete to reduce the early-age shrinkage. The quantity of IC water required to compensate autogenous shrinkage can be calculated based on Benz equation (10). The difficulty in IC is to provide the full quantity of IC water without compromising the material's performance. For example, increasing LWA in order to satisfy the IC requirements may endanger the mechanical properties of the mixture. Employing SAPs to compensate autogenous shrinkage has proven to be a very effective method but the material's mechanical properties are evidently deteriorated (11). Furthermore, using shrinkage reducing agents (SRA) in the mixture, although durability indicators may remain unaffected, the compressive strength is reduced (12). In this research, the water reservoirs employed were part of an existing constituent of the mixture (aggregates) and consequently the material's properties were expected to be improved.

## **3. Experimental methods**

### **3.1. Mixtures**

Five mixtures have been prepared in order to evaluate the IC effectiveness. Two mixtures included HANWA which are designated as HANWA-SSD and HANWA-DRY and their difference lies on the state of the aggregates prior entering the mixture. In the first case the aggregates were saturated surface dry (SSD) and in the second case the aggregates were dry and the appropriate amount of water needed to reach SSD was added to the mixing water. This practice lies on the assumption that the aggregates will absorb the additional water and therefore the w/b ratio would not be increased. If his assumption is true, then the mixtures' properties should remain the same. Furthermore, three mixtures with NWA have been also prepared. The two mixtures included two different types of SAP (T1, T2) and the third mixture was the control (CTRL) mixture with no IC agent.

The mixtures have been made in a horizontal rotary mixing machine. The slump of each fresh concrete mixture was measured in order to maintain consistent workability. Furthermore, the mixtures' temperature prior to cast was recorded as well as the ambient humidity and temperature. Finally, the mixing water was kept in a chamber for 24 hours before mixing to ensure constant temperature. After the specimens were cast, the molds were covered with wet burlaps in order to prevent moisture loss to the environment. 24 hours after casting the specimens were demolded and wrapped with polyvinyl chloride membrane in order to provide sealed conditions for curing. The efficiency of the membrane was verified with consecutively mass measurements. The specimens were kept in a room with controlled temperature and humidity. The concrete temperature evolution and autogenous shrinkage were monitored. Also, the compressive strength and vacuum porosity were measured at 3, 7, 28 and 90 days and rapid chloride permeability (RCP) at 7, 28 and 90 days.

### **3.2. Materials**

The cement utilized for this research was CEM I 52.5N. The fraction of the aggregates utilized as IC agents was 4-10mm since their  $WA_{24}$  was 5.2% (Table 1), which is considered adequate. A similar fraction (4-8mm LWA) has been also used by Weber who established their effectiveness (13). The aggregates water absorption ( $WA_{24}$ ) was calculated based on EN-1097-6 (14) (Table 1). The sand has a fraction of 0-4mm and its  $WA_{24}$  and fineness modules are presented on Table 2. Polycarboxylate polymer superplasticizer (SP) was used in order to maintain the mixtures workability within a slump range of 70-100mm (within a range of  $\pm 15$ mm). The utilized SAPs were Poly (acrylic acid) partial sodium salt for T1 and Poly (acrylic acid), partial potassium salt, slightly cross-linked for T2. The SAPs were prepared with bulk polymerization technique. It has to be mentioned that concrete using SAPs yielded from bulk polymerization technique demonstrate a superior performance as opposed to suspension technique in terms of strength evolution (15). The conclusions of a round-robin test (RRT) (11) support that small and

spherical SAP particles are more effective in terms of (11) compressive strength than irregular larger particles. The polymers were tested in suspended pore solution using the teabag method and it was concluded that their absorbing capacity was 29g/g for SAP-T1 and 26g/g for SAP-T2. Therefore, the amount of SAP required to carry the necessary quantity of IC water was 0.18% and 0.2% with respect to cement mass for T1 and T2 respectively.

The aggregates used as IC medium in this study (HANWA) are crushed limestone quarried in Cyprus. It has been shown that the specific aggregates contain mainly micritic calcite which in restricted areas yields to microspar. More specifically fossils, whose composition is mainly recrystallized sparry calcite, were observed, whereas micritic endoclasts and non-carbonate grains such as quartz, chert and spinel were sparsely observed. Traces of anhydrite were also observed. The HANWA high absorptivity is attributed to the significant intraparticle porosity obtained within fossils, whereas elongated pores have been formed due to recrystallization of spar crystals. More mineralogical information about the aggregates can be found in reference (16).

### 3.3. Mix proportions

The predominant reason for implementing IC in concrete is to reduce autogenous shrinkage which is more intense at low water to binder ratio (w/b) and increased cement content. The mixture was intentionally designed with low w/b ratio and high cement content (Table 2), in order to evaluate the effectiveness of the IC method. The amount of coarse aggregates was calculated based on IC water requirements (Bentz equation (10)) and the aggregates desorption properties (Figure 2). It has to be mentioned that the mixtures SAP-T1, T2 have a reduced amount of fine aggregates since the IC water occupies a specific volume.

Table 1: Aggregate properties EN 1097-6(14) (g/cm<sup>3</sup>)

	$\rho_b$	WA <sub>24</sub>	FM	Fraction
NWA	2,74	1,1%	-	4/10
HANWA	2,30	5,2%	-	4/10

Slump	70	100	85	85	80

## 4. Results and Discussion

### 4.1. Aggregates desorption

In order to ensure that HANWA would be able to function as IC medium, the aggregates should be able to release the majority of the IC water at high RH levels. Javier Castro (18) suggested that an efficient aggregate would release its majority of moisture at high RH and more specifically at 93%. The HANWA used in this research were washed in a 63 $\mu$ m sieve and then oven dried until constant mass was reached. Afterwards the aggregates were placed in a wire basket and immersed in 20°C water for 24h. Then they were placed in an environmental chamber where the temperature was maintained at 23 $\pm$ 1°C and the RH was decreased gradually from 95% to 80% with 1% interval. The RH was decreased each time when the aggregates reached a constant mass. It has to be mentioned that based on Bentz equation the required amount of IC water was 0.51kg per kg of cement. Based on Figure 2, the HANWA aggregates release 65% of their moisture at 93% RH, whereas another 15% of their moisture is released to a RH level of

85%. It is expected therefore that HANWA will be able to provide the majority of IC water at early-ages. It was expected that due to their smaller pores as opposed to LWAs which is reflected on desorption curve, HANWA beneficial effect would occur more gradually and last for a longer period of time.

Figure 1: HANWA desorption properties

#### 4.2. Autogenous shrinkage

The effectiveness of an IC medium is also reflected on the mixtures shrinkage since the reason for implementing IC is to reduce the early-age volume variations that cause excessive internal stress and lead the material to cracking. Therefore autogenous shrinkage experiments have been conducted in order to evaluate the effectiveness of the selected IC medium. Sealed concrete prisms with strain gauges attached on their longitudinal opposite faces have been tested for 7 days after final setting. The mixtures have been cured for 7 hours after casting and directly sealed after demolded with polyvinyl chloride membrane. The membrane at the strain gauges location was removed using surgical blade and epoxy resin covered the surface. After the resin was solidified the strain gauges were attached and the specimen was wrapped again with membrane to ensure no moisture exchange with the environment. The experiments were conducted in an environmental chamber with constant temperature ( $25\pm 1^\circ\text{C}$ ) and RH ( $60\pm 1\%$ ). Each strain gauge was connected to a strain indicator and the results were logged using a pc unit with a time interval of 15 minutes.

Figure 2: Autogenous shrinkage

The IC mixtures observe a clear reduction in autogenous shrinkage (Figure 3). The reference mixture as expected exhibited the higher shrinkage whereas SAP-T1 the lowest. SAP-T1 observes no volumetric variations in contradiction to others reports that have employed up to 0.6% SAP (with respect to cement mass) in order to fully diminish autogenous shrinkage (8). It has to be mentioned that concrete

performance is deteriorating when SAP quantity is increased. HANWA-SSD, HANWA-DRY and SAP-T2 exhibit similar behavior. HANWA mixtures appear to be effective in internal curing, since the lower of autogenous shrinkage can be attributed to water replenishment or increased w/b ratio. SAP-T2 seems to perform differently than SAP-T1. The performance of a mixture containing SAP in terms of autogenous shrinkage is not depended on the absorbing capacity of the polymer but it depends on their absorption and desorption rate. The fact that SAP-T1 and T2 have similar pore fluid absorption capacity does not imply that the absorption and desorption rate will be similar. Reinhardt (19) has concluded that the desorption or drying rate of SAPs would vary from the outer surface to the core of the polymer due to the large surface area and weak bond between the polymer particle and water molecule. It can be concluded that the surface area of the SAPs would significantly influence the desorption properties of each polymer. Furthermore, the absorption rate and carrying capacity of each polymer varies with its degree of anionicity whereas and cross-linking density. Based on Figure 3, SAP-T1 appears to be the most effective IC medium used in this research regarding autogenous shrinkage, whereas the rest of the IC agents. The rest of the IC agents reduce also significantly the autogenous shrinkage as opposed to the CTRL mixture.

### 4.3. Maturing temperature

Three thermocouples were embedded in a concrete prism at three mid-height points along the specimen right after the mixtures were cast. The specimen was sealed to ensure no moisture exchange and the temperature was kept constant ( $23\pm 1^\circ\text{C}$ ). The mixture's maturing temperature has been monitored until constant temperature has been reached.

Figure 3: Maturing temperature

Based on Neville (1), the rate of heat evolution is comprised of three temperature peaks. The first which is the higher occurs at the point the cement comes in contact with water; its duration is very short and corresponds to the surface hydration of the cement particles and especially  $\text{C}_3\text{A}$ . The second peak happens at approximately 10 hours after the initial contact but occasionally can be observed as early as 4 hours. The third stage is observed in most types of cement and happens due to an extended hydration of  $\text{C}_3\text{A}$  because of gypsum exhaustion. It is widely known that gypsum is added in cement production in order to restrict the violent hydration that occurs after  $\text{C}_3\text{A}$  comes in contact with water. On Figure 4, the second stage of heat evolution is clearly observed as well as a very smooth increase at late hours which is likely to correspond to gypsum depletion. Furthermore, it has to be mentioned that the HANWA-IC mixtures exhibit a higher temperature at the second stage and this is attributed to the availability of IC water which is supplied to the mixture from the aggregates walls. It can be observed though that the slope of HANWA-SSD is steeper. It has to be mentioned that water is withdrawn from HANWA when the RH drops and negative pressure is developed within the material's pores. It is therefore concluded that the HANWA-DRY aggregates do not absorb the whole additional quantity of water which finally participates in the w/b ratio delaying the RH drop. The increased temperature peak is attributed to higher w/b ratio. Furthermore, SAP-T1 and CTRL mixtures have observed similar heat evolution; however the SAPs peak value is slightly shifted. The results of a RILEMs RRT (11) have shown that mixtures including IC water would observe an increased setting time. SAP-T2 exhibits a very different maturing behavior from the

other mixtures. In order to assess the behavior of the specific mixture the material's microstructure have to be examined. It has to be mentioned though that the specific type of polymers observed a high reduction in mass at the first hours during the tea-bag test.

#### 4.4. Compressive strength

The results of compressive strength as well as the standard deviation are presented on Table 3. The specimens have been cured in sealed conditions at temperature  $23\pm 1^\circ\text{C}$ . Each value represents the average of minimum three cubic specimens (100x100x100mm). It is concluded that the compressive strength of IC mixtures was reduced compared to the CTRL mixture. This was expected at early-ages since the IC mediums are not directly contributing to the material's mechanical performance. Their contribution though is reflected on the evolution of their mechanical properties and durability indicators (Table 2-4). Especially in the case of HANWA-SSD the material demonstrates a constant increase in its compressive strength and at the age of 90 days its compressive strength is equal to the CTRL mixture. Additionally, the water adjustment in HANWA-DRY mixture is not justified. The compressive strength of the specific mixture is consistently lower than HANWA-SSD and this is attributed to the additional water which participates to the w/b ratio and leads to additional porosity (Table 4) and reduced compressive strength (Table 3).

Based on the results (Table 3) it seems that unlike the rest of the mixtures, HANWA-SSD is the only mixture that is continuously gaining strength. The reduction in compressive strength for concrete including SAP is observed in both SAP-T1 and T2 mixtures. It seems, however, that both mixtures partially recover the initial loss at 28 days, due to extended hydration. It seems though that between 28 and 90 days, no significant gain in compressive strength has occurred in the specific mixtures and this is attributed to the SAPs water exhaustion. It can be concluded that despite the beneficial effect on durability indicators, a permanent reduction in compressive strength was observed when SAPs were included.

Table 3: Compressive strength

	3DAYS		7DAYS		28DAYS		90DAYS	
	$f_{cm}$ (MPa)	SD (MPa)	$f_{cm}$ (MPa)	SD (MPa)	$f_{cm}$ (MPa)	SD (MPa)	$f_{cm}$ (MPa)	SD (MPa)

SAP-T1	62,58	4,07	72,92	2,25	80,43	5,14	81,66	1,55
SAP-T2	66,03	4,69	67,34	5,41	81,63	8,14	78,81	7,44

#### 4.5. Vacuum porosity

The specimens have been kept in a sealed chamber where the pressure was removed. The specimens were subjected to vacuum for 24 hours before being immersed in water. The specimens were then stored for another 24 hours immersed in water. Immersed and saturated mass was then recorded and after the specimens were placed in an oven with constant temperature of  $105^\circ\text{C}$  until constant mass was reached. The dry mass of the specimens was recorded and the porosity of each specimen was extracted. It has to be noted that the results correspond to a single test conducted on a different specimen at each time interval.

Table 4: Vacuum porosity

	3 DAYS	7 DAYS	28 DAYS	90 DAYS
CTRL	12,48%	11,42%	9,40%	8,22%
HANWA-SSD	14,81%	14,02%	13,69%	12,66%
HANWA-DRY	15,49%	14,70%	16,58%	17,10%
SAP-T1	17,49%	15,24%	15,27%	14,53%
SAP-T2	17,35%	16,32%	13,69%	17,77%

The difference of HANWA-SSD and HANWA-DRY mixture is also reflected on the results of their porosity (Table 4). The HANWA-DRY mixture exhibits higher porosity than the HANWA-SSD mixture. The results

support the argument that the water calculated for the aggregates to reach SSD state was partially participated to the w/b ratio increase. Furthermore, the HANWA-SSD mixture exhibits the lowest porosity after the CTRL mixture verifying its IC effectiveness. SAP-T2 porosity was unexpectedly high at the age of 90 days. SAP mixtures observe a high reduction in porosity at early-ages. It is believed that the majority of SAP water was exhausted and therefore a further reduction at late ages was not possible. The CTRL mixture is consistently improving. The continuous reduction in porosity is an indicator of pores sealing due to hydration products. The same observation was not possible in the case of SAP mixtures due to additional pores introduced by SAP particles.

#### 4.6. Rapid chloride permeability

The rapid chloride permeability (RCP) test was conducted based on ASTM C1202 (20). The experiment assesses the concrete's ability to resist chloride intrusion. The specific test is widely used because it is fast and needs about 24 hours to prepare the sample and 6 hours to complete an experiment (21). The experiment measures the electrical conductivity or resistance of a 50 mm thick disk concrete specimen for a period of 6 hours. It is assumed that the resistivity is directly related to the pore network or concrete permeability, although some claim that the relation is not strictly correct (22). The samples cannot be reused because of concerns over leaching in a moist environment and the exposure to chlorides during the test, which may change the pore solution conductivity. Rapid chloride permeability test can be used for quality control and concrete durability research (23). The specimens are positioned in a measuring cell which contains a fluid reservoir at each face. One reservoir is filled with sodium chloride solution and the other with a sodium hydroxide solution. The reservoir containing NaCl is connected to the negative terminal and the NaOH reservoir to the positive terminal of the microprocessor power supply unit.

The high charge indicates a highly permeable mixture. It can be observed that the lowest permeability at early ages was exhibited by the CTRL sample and its behavior is consistent with the previous measurements. Additional porosity in IC mixtures seems to enhance the pore network and increase the permeability. In the case of SAPs additionally voids interconnect the material's pore network whereas in the case of HANWA extended pore network occur due to the interconnection provided by the aggregates body. However, refinement of the pore network regarding the IC mixtures was expected at later ages due to solidification of the products extracted from the extended hydration.

Although porosity reduction is more effective in the case of HANWA-SSD, it seems that SAP-T1 mixture is more effective in terms of permeability reduction. Since permeability is highly depended on the pores interconnection and not the porosity, the small size of the SAP particles benefits the pore network sealing. Considering the smaller size of SAP particles which yields to better dispersion, the pore network is more likely to be sealed. After the SAP water exhaustion, however, the space occupied by the polymers remains empty, increasing porosity, without necessarily affecting permeability. The larger particles of HANWA are able to reduce the porosity since no additional porosity is introduced to the mixture. Regarding the pore network, however, their efficiency is limited.

Table 5: RCP results (Coulombs)

	7 DAYS	28 DAYS	90 DAYS
CTRL	3695	2352	1378
HANWA-SSD	5850	3022	2137
HANWA-DRY	5433	4410	2202
SAP-T1	6554	3831	2198
SAP-T2	4972	4258	2333

## 5. Conclusions

In this research, the effectiveness of using HANWA as IC agents without compromising any other properties of the mixture has been evaluated. The specific IC medium has been compared with well established IC mediums and the results indicate that it can perform very well. HANWA has been investigated in order to evaluate whether a reduction in autogenous shrinkage could be achieved, without compromising any other properties. Based on the results, the specific IC medium in SSD state reduces the autogenous shrinkage effectively. The specific mixture seems to recover the loss in compressive strength and continuously gain strength due to the presence of water from the inner core that benefits the degree of hydration. Additionally, in comparison with the rest IC mixtures, HANWA-SSD is the only mixture that consistently exhibits a reduction in porosity with time. It is believed that the specific IC

medium is able to utilize IC water even at later ages. This is attributed to the fact that the HANWA do not release their total moisture content at high RH which means that the aggregates' hold moisture in their small pores. The pressure required to extract water from smaller pores is higher, thus the water will be extracted when the RH drops at lower levels. Finally, the specific mixture along with SAP-T1 mixture has observed the greater reduction in RCP values. Even though the size of the IC particles utilized in the case of HANWA-SSD does not contribute to the pore network sealing as explained above, the specific mixture has exhibited a superior performance improving its durability properties. An extended investigation regarding the in depth material's performance is in progress.

# Tensile Properties of Early-Age Concrete

Duy NGUYEN<sup>1</sup>, Vinh T.N. DAO<sup>2</sup>

<sup>1</sup>Ph.D Student, School of Civil Engineering, The University of Queensland

<sup>2</sup>Lecturer, School of Civil Engineering, The University of Queensland

**Abstract:** Despite significant research, early-age cracking remains an ongoing major concern to the concrete construction industry, seriously compromising the performance and aesthetics of concrete structures. More effective crack control requires an improved knowledge of tensile properties of early-age concrete.

In this paper, the tensile properties of concrete at very early ages and their measurement are first reviewed, and the need for further study is clearly highlighted. On that basis, key features of an improved testing system that effectively addresses major drawbacks in current test setups are outlined. Notable features of this system include (i) an air-bearing box to float test specimen, thus effectively eliminating friction and (ii) the novel use of Digital Image Correlation (DIC) for reliable, non-contact capturing of the required displacement fields. The displacements as directly measured by DIC in this study appear much smaller than those estimated from LVDTs readings in previous research, leading to significantly smaller Young's modulus and fracture energy. The substantial variation highlights the need for an accurate and reliable displacement measuring system. Further improvement is being underway at The University of Queensland to develop such system.

**Keywords:** Early-age Cracking, Tensile Properties, Fracture Properties, Direct Tensile Test, Digital Image Correlation (DIC).

## 1. Introduction

Early-age cracking may occur in concrete structures from as early as several hours after casting. These cracks and their further development at later ages can seriously compromise the integrity, durability, aesthetics, and long-term service life of wide-ranging types of concrete structures. Despite significant research over the past decades (1-4), cracking in early-age concrete remains widespread, making it among the most common causes of structures' deterioration and litigation in the construction industry (5, 6).

In principle, cracking occurs when the tensile stresses arising in the concrete reach their tensile strength or, equivalently, when the restrained shrinkage strain reaches tensile strain capacity of concrete at that age. Once occurred, existing cracks would develop further if sufficient energy is provided. Indeed, very often, cracks developed at early-ages would propagate and become unserviceable at later stages due to subsequent shrinkage/loading.

Proper assessment of early-age cracking risk in concrete therefore requires an adequate knowledge of tensile and fracture properties of the materials being considered. Such knowledge can generally be derived from reliable data on complete tensile stress-strain curves of concrete at relevant ages. Unfortunately, such useful data are currently very limited, especially for concrete during the first hours after casting. (In subsequent discussion, the term "very early-age concrete" refers to concrete with ages of less than 12 hours after casting.)

As a corollary, there is a lack of appropriate technical guidelines for prediction of these properties in current codes of practice. Eurocode 2 BS EN1992-1-1:2004 (7) and Japanese standard JSCE-SSCS – 2007 (8) appear the only two available standards providing formulae for the estimation of concrete properties from an age of several days following casting, though their predictions differ greatly from each other – No formulae for concrete during the first day is available yet.

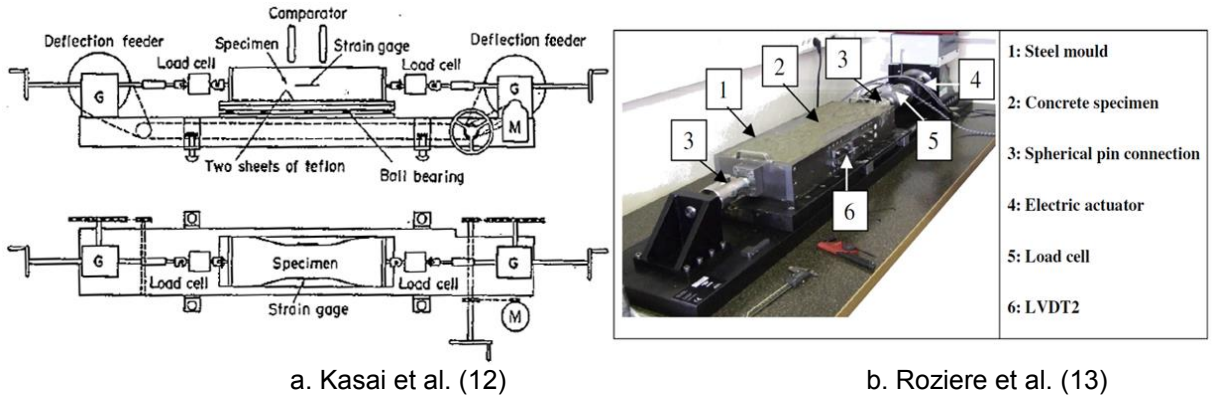

In this paper, current knowledge of tensile properties of concrete during the first several hours after casting, together with techniques for their measurement, are first reviewed. On that basis, an improved testing system that effectively overcomes major drawbacks in current test setups is described. Finally,

initial test results derived from the obtained full stress-strain curves of very young concrete are presented. These include tensile strength, Young’s modulus, tensile strain capacity, and fracture mechanics parameters.

**2. Review of Tensile Properties of Early-age Concrete and Tests for their Measurement**

Despite their significance in assessing associated early-age cracking risk in concrete structures, tensile properties of concrete during the first several hours after casting have been investigated by *only few* researchers (9-11) – due mainly to the considerable practical problems to be overcome when testing early-age concrete. Specifically:

- Due to its low tensile strength, minimisation of friction between test specimens and supporting surface during testing becomes highly critical. Various measures have been attempted (9, 10), including several layers of special materials such as Teflon (12) or PTFE (13). The best available measure is possibly the air-bearing box which “floats” the test specimen on a thin layer of air, thus effectively eliminating all friction – The system was initially proposed by Hannant’s group (10) and subsequently further improved by Dao et al. (11).
- Due to its fragility, disturbance to test specimens must be minimised throughout the moulding, handling and testing processes.
- The fragility of concrete has important implications on reliable deformation measurement – Methods for deformation measurement in previous research can be categorised into three groups:
  - i. Strain gauges are attached to the mould (14, 15), giving total deformation of the whole specimen – Deformation over the region of interest has to be estimated from the measured total deformation, typically by finite element modelling. This “estimation” procedure inevitably has introduced additional uncertainties that has not been appropriately taken into account, raising doubts over the reliability of obtained results.
  - ii. Strain gauges are attached to the posts cast into concrete (16, 17) – The likely movement of the posts in young concrete and the resulting disturbance may have significantly compromised the measurement accuracy; but again, the effect of this disturbance could not be quantified.
  - iii. Digital image correlation (13, 18): DIC is a form of data extraction through image analysis, and has been one of the most effective ways for macroscopic displacement tracking, mechanical and structural testing both in 2D and 3D areas. Although DIC has been widely employed in testing of mature-age concrete (19-22), its application to concrete during its first day is very limited. In order to apply DIC, concrete surfaces need to be treated with appropriate materials to create a sufficiently contrast pattern for the cameras to recognize, while respecting its continuity and strength. Wet-, soft- and dark coloured surfaces of the specimen at early age make the pattern application a real challenge. Nguyen and Dao (18) appeared to be the first to report the successful use of DIC for tensile testing of very early-age concrete. Another such DIC application was recently published by Roziere et al. (13).

**Figure 1. Typical direct tensile testing systems.**

Also, due to the weak nature of very early-age concrete, vertical test specimens as in (23, 24) cannot be used - Specimens have to be tested in horizontal position (12, 13, 15, 16) (Figure 1). Test specimens typically have a dog-bone shape with two enlarged end regions, a reduced middle region to

promote failure therein, and curved transition zones to minimise stress concentrations that could initiate undesirable cracking outside the middle region (Figures 1 and 4). Prismatic specimens have also been used (23-26) but generally for concrete of more than 12 hours only when sufficient strength has developed enabling adequate gripping of specimen ends. Furthermore, prismatic specimens applied in those systems with glued grips at two ends (24) or a centrally embedded bar (23, 25, 26) might raise questions on the effectiveness of the glue on young concrete, as well as on stress concentration at the embedded bar.

During testing, specimens are subject to either load-controlled or displacement-controlled loading. To capture complete stress-strain behaviour, displacement-controlled loading has to be applied. The chosen displacement rate should be slow enough but not too slow to enable full stress-strain curves to be captured while minimising the test time for each specimen. Displacement rate representative of actual early cracking conditions has also been used (13), although it seems too high to produce a full stress-strain curve.

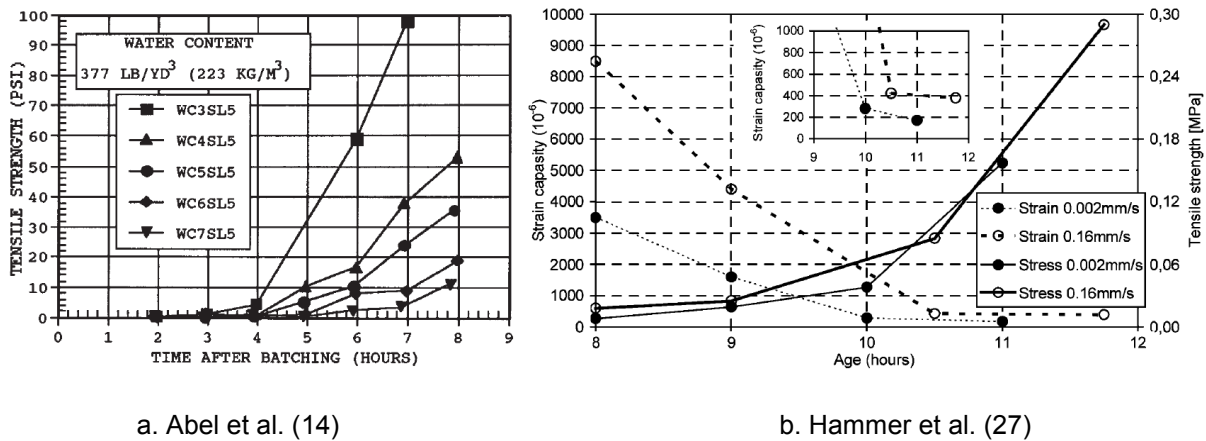

Figure 2. Typical development of early-age tensile strength.

Figure 3. Typical stress-displacement curve (11).

Using the above-mentioned test systems, initial relevant data have been collected – However, useful data are still very limited, with full stress-strain curves reported by only few groups (10, 11), enabling somewhat improved knowledge of tensile properties of very early-age concrete:

- The stress-displacement relationship for early-age concrete generally follows the typical response of a quasi-brittle material in tension (10, 11) (**Figure 3**). However, as highlighted earlier, the accuracy and reliability of measured displacements in previous studies may have been compromised due to limitations inherent in their test setups.
- There was a dormant period during the first several hours after casting in which the tensile strength and Young's modulus of concrete increase very slowly, followed by a period of significantly more rapid development (11, 14, 27) (**Figure 2**).
- Tensile strain capacity tends to decrease rapidly at first, then slightly increases to a stable level after several days of age (12-15, 27).

- However, reported development rates are different between studies due to variations in testing (and associated reliability) as well as types of concrete tested.
- Fracture characteristics are also reported by Dao et al. (11) based on very limited test results.

An ongoing research program at The University of Queensland aims at providing a more comprehensive reliable knowledge of very early-age concrete through addressing the above-mentioned limitations of current test systems. Key details of that research are presented in subsequent sections.

### 3. Experimental Program with Improved Testing System

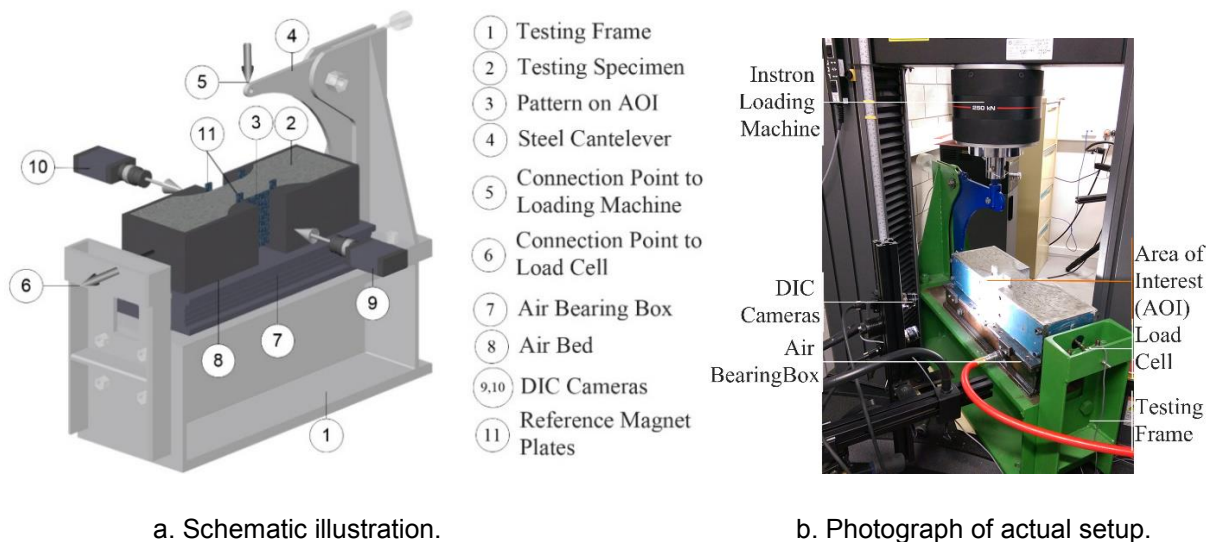

#### 3.1. Direct Tensile Testing System

The improved direct tensile testing system used in this study is shown in **Figure 4**. The test apparatus comprises an air-bearing box ③ and a lever arm ④ attached to a small steel frame①. The lever arm was pin-connected to the frame and was self-balanced in the test position, enabling the direction but not the magnitude of the force applied through the Instron load cell ⑤ to be altered. The specimen ② is placed on top of the air-bearing box ③ with one end pin-connected to the test load cell ⑥ and the other to the lever arm④.

During test, the test apparatus is placed on the horizontal platform of a displacement-controlled Instron testing frame (**Figure 4**). Notable features of this unique test apparatus include:

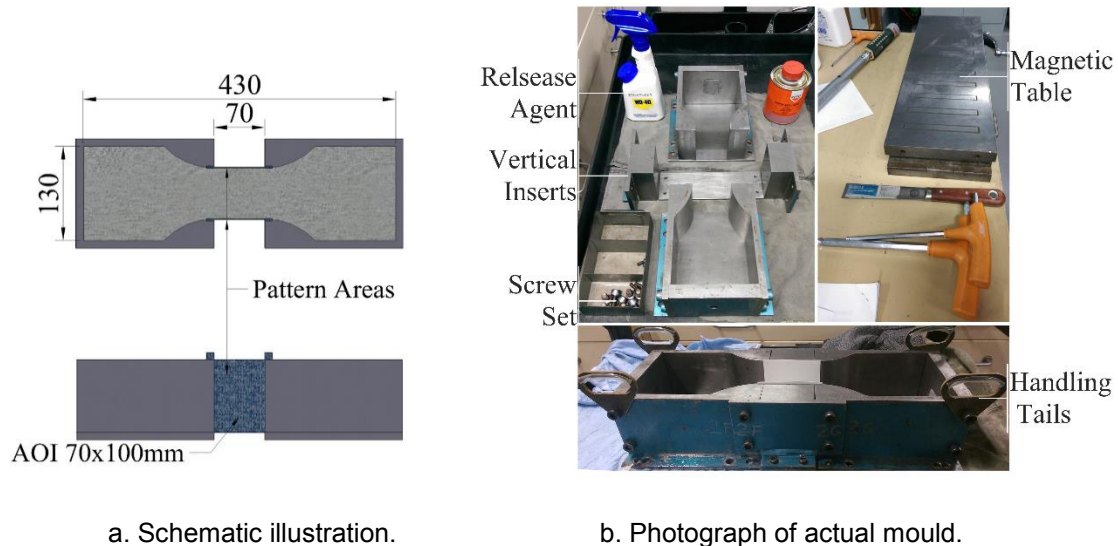

- Air-bearing box: The upper plate of the air-bearing box has 32 holes, 1 mm diameter each symmetrically distributed under the two halves of the mould. The levelness of the upper surface of the air-bearing box after placement in the test position is ensured by using an electronic leveller with an accuracy of 0.1 degrees. During testing, the air bearing box provides a uniform air cushion to float the test specimen that effectively eliminates friction between the specimen and the supporting base
- Digital Image Correlation (DIC): The novel application of DIC enables the desired deformation over the whole areas of interest (AOIs) to be reliably captured in a non-contact way. The successful use of DIC in testing of concrete several hours after casting has thus effectively addressed major shortcomings of previous set-ups.

High resolution professional cameras (⑨,⑩ in **Figure 4**) are employed at both sides of the exposed neck (i.e. AOIs) to capture required displacement fields. All cameras are synchronized to work together with the loading process by a “sync” software developed at UQ Structures Laboratory. Four reference magnet plates [11] attached to the steel mould at the upper corners of AOIs provide a direct mean to verify displacement analysis from DIC system. More details about the verification will be provided in the subsequent section.

**Figure 4. Direct tensile test setup.**

The steel mould is made of 11 different parts connected to each other by a set of screws. Two mould sides are firmly connected by two vertical inserts (Figure 5b), forming a rigid formwork and nurturing the specimen inside. A magnetic table is employed to assist the mould assembling, ensuring a planar bottom surface. The reduced middle region of test specimen (i.e. AOI or Area of Interest) has 100x70mm<sup>2</sup> in cross-section and 70mm in length.

**Figure 5. Testing mould.**

### 3.2. Testing Procedure

Mixing is carried out in the laboratory using a 0.07 m<sup>3</sup> rotary drum mixer. Concrete placing temperature is assumed equal to laboratory temperature (20°C), provided that all the mix ingredients are stored in the laboratory conditions for at least 7 days before being collected. Age zero is determined at the time water is added.

Upon preparation, test specimens are immediately covered by damp clothes to minimise any moisture loss until actual testing in an air-conditioned room with negligible wind, stable temperature (18-20°C) and humidity (60%).

Typical test procedures are as outlined below:

- When ready, test specimen is carefully placed on the air-bearing box and connected to the testing frame. An air pressure of 140kPa is supplied to facilitate the process and float the specimen on a thin layer of air to eliminate friction between test specimen and supporting surface.
- The air is then turned off for further manipulation. Two centre vertical inserts are unscrewed and removed, exposing the concrete neck for pattern application.
- In order to create surface pattern with appropriate contrast, white paint is first applied, followed by a reasonable waiting time for the paint to dry out *before* the application of black paint. Provided that both white and black paint do not form a continuous layer on AOIs, the paint does not affect recorded tensile properties of concrete.
- Two camera systems are then installed with the camera axes perpendicular to concrete captured surfaces (AOIs). Distance from the camera lens to concrete surface is 20-25 cm. Pixel resolution of the cameras is 2448x2048, and intensity resolution is 8 bit.
- The loading process starts with camera capturing. Displacement rate chosen is 0.03-0.05mm/min (compared to a constant rate of 0.05mm/min in (15), 0.3-1.2mm/min in (12) and 0.75mm/min in (16)). Readings from the load cell and Instron machine are recorded along with image capturing until cracking. Post calibration of DIC cameras is to be conducted after removing the specimen, using calibration boards with appropriate size and shape. After the calibration is successfully finished, captured images can be imported and analysis starts.

The reliability of the improved test setup and procedures has been verified using several methods. One such verification is the displacement rate as measured by DIC compared with the applied

displacement rate: The four reference magnet plates with surface patterns similar to concrete AOIs are attached onto the two steel mould halves, two on each half (**Figure 4**). It is evident from **Figure 6** that the reference plates move relative to each other at a rate identical to the applied displacement rate, giving confidence on the reliability of DIC readings.

**Figure 6. Reference plates moving at applied displacement rate, giving credibility to DIC reliability.**

**4. Initial Results**

One test series has been conducted using the improved test system detailed above. Mix design used is as shown in Table 1.

**Table 1 – Concrete Mix Design**

Ingredients	GP Cement (kg)	10mm Aggregate (kg)	5mm Aggregate (kg)	Coarse Sand (kg)	Fine Sand (kg)	Water (L)	Slump (mm)
Quantity/m <sup>3</sup>	380	520	435	490	295	240	80

In this study, besides a test series in which displacement-controlled loading is increased continuously until failure (**Figure 7a**), another series in which *cyclic loading* is applied to investigate tensile properties during unloading (**Figure 7b**) – This tensile behaviour during unloading has not been studied in previous research.

**Figure 7. Typical stress-strain curves.**

As illustrated in **Figure 7**, in both cases of loading a complete tensile stress-strain relationship is successfully established. Stress values are obtained from load cell's data file, assuming uniform stress distribution across the section. Strain values are averaged from both DIC systems. From each side, a full field of displacement/strain also allows further comparison/judgement at different positions. In cyclic loading, the first cycle starts at the beginning to approximately 30-40% of the estimated tensile strength, then comes the unloading process. When tensile stress reduces to zero, the second cycle initiates and continuously increase to failure.

#### **4.1. Tensile strength $f_t$**

As illustrated in **Figure 8a**, concrete tensile strength is very low during the first 3 hours but accelerates quickly to several times larger in the next few hours. An obvious development trend is also observed, although slightly deviating from previous study for the same mix design (15) – This deviation is possibly due mainly to the different curing applied: While moisture loss from test specimens are minimized by effective covering in this study, such covering of specimens was not provided in (15).

Tensile strength and its development described are consistent with the hydration process: The dormant period with minimal hydration lasts for approximately 2-4 hours for normal concrete as used in this study. Following this dormant period, initial set commences (28, 29) and significant ongoing hydration results in rapid increase in tensile strength.

#### **4.2. Tensile strain capacity $\epsilon_{max}$**

Tensile strain capacity in early age concrete were reported to firstly decrease sharply over time, from thousands of micro-strain to possibly as low as tens of micro-strain (12, 30, 31), then gradually increases to a relatively stable value.

The tensile strain capacity derived from data obtained in this study, as in **Figure 8b**, appears to agree well with that from previous study for similar mix design (15).

#### **4.3. Young's modulus $E$**

In this study, due to the nature of early-age concrete, the range of stress in the ascending curve for linear fitting proposed is between 5%-20% of the ultimate stress instead of the widely instructed range 5%-40% in current standards (32). A narrower stress range ensures the linear elastic characteristics of concrete to be illustrated more effectively and reduces scattering in calculated results. Young's modulus increases quickly over time, from only about  $10^4$  kPa at 3hr age to  $(2.5-3.0) \times 10^4$  kPa at 8hr age (**Figure 8c**). The developing rate is much lower compared to that in (15) (**Figure 8d**), possibly due to (i) the lower tensile strength and (ii) more importantly, the more reliable measured strains in this study. Detailed analysis of displacement field recorded by DIC in this study indicates that the

correlation assumed in (15) between deformation over the region of interest and measured total deformation of the whole specimen may be inaccurate in many cases.

In **Figure 8h**, Young's moduli obtained from different loading stages in a cyclic series show some characteristics, including: (i) fast growing of modulus from (3-4) hour to 7 hour age and (ii) significant variation between the first and the second loading stages. For specimen at 3h15m age, Young's modulus in the second loading is approximately 30% higher, illustrating the sensitivity of very young concrete to early loading due to its visco-elastic nature.

#### **4.4. Fracture properties**

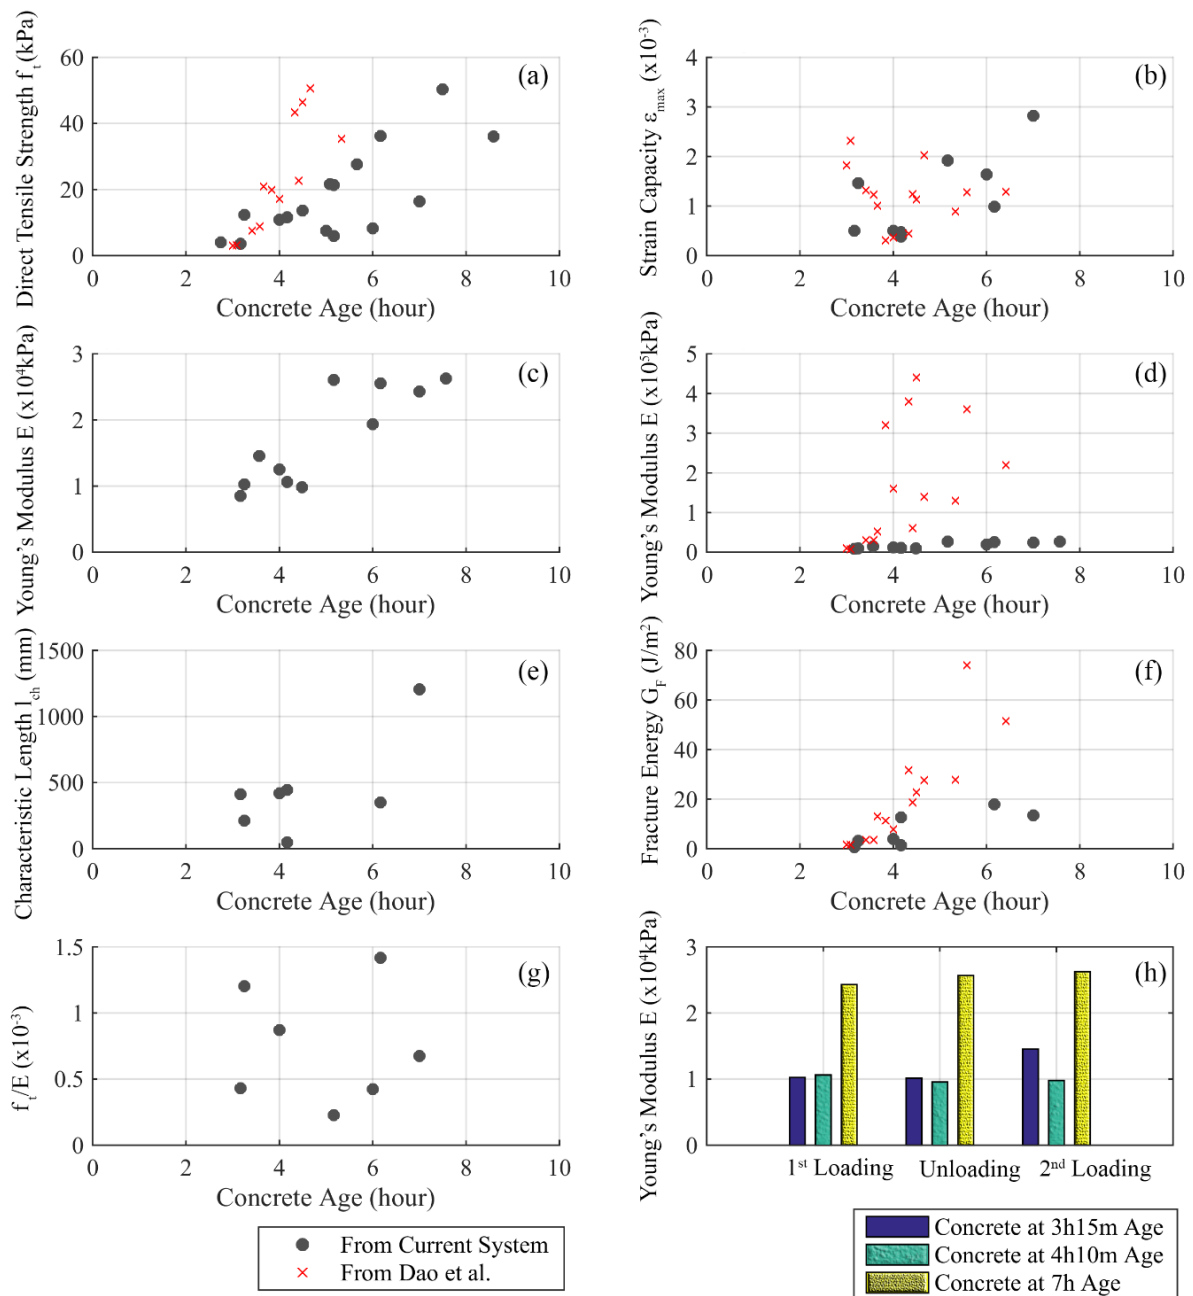

From obtained test data, stress-crack opening relationship can be extracted, from which fracture properties can be derived. Important fracture properties include  $G_F$  (**Figure 3**) and  $l_{ch}$ , which is given as:

$$l_{ch} = \frac{G_F E}{f_t^2} \quad (1)$$

**Figure 8f** provides fracture energy development over time. The increasing trend is generally observed, however the developing rate of fracture mechanics in this study is significantly lower compared to that in (15), similar to the case of Young's modulus. Again, this difference is possibly due mainly to the use of DIC for displacement measurement in this study: The displacement recorded by DIC is much smaller than that estimated in (15) from displacement measured by LVDTs attached on the steel mould. This clearly highlights the need to have an accurate and reliable system for displacement measurement – Further improvement is being underway at The University of Queensland to develop such system.

In **Figure 8e**, there seems to be an increasing trend of characteristic length  $l_{ch}$  over the first several hours. However further data are needed before development trends can be identified with confidence.

**Figure 8. Initial test results: (a) Tensile strength, (b) Tensile strain capacity, (c) to (d) Young's modulus from this study and from (15), (e) Characteristic length, (f) Fracture energy, (g) Tensile strength to Young's modulus ratio and (h) Young's modulus in cyclic loading series.**

## 5. Summary and Conclusions

This paper first provides a critical review of current knowledge of tensile properties of concrete during the first several hours after casting and of techniques for their measurement. The current dearth of useful data on tensile properties of very early-age concrete, despite their significance in assessing associated cracking risk, has been highlighted. This is argued as a result of the considerable practical problems to be overcome when testing very early-age concrete due to its weak nature.

On that basis, the paper outlines key features of an improved testing system that effectively addresses major drawbacks in current test setups. Notable features of this system include (i) an air-bearing box to float test specimen, thus effectively eliminating friction and (ii) the novel use of DIC for reliable, non-contact capturing of the required displacement fields. Finally, initial test results derived from the obtained full stress-strain curves of very young concrete are presented:

- The obtained stress-displacement/strain curves and development trend for different tensile properties are similar to those in previous research.
- However, displacements as directly measured by DIC in this study appear much smaller than those estimated from LVDTs readings in previous research. This has resulted in significantly smaller Young's modulus and fracture energy. The substantial variation also highlights the need for an accurate and reliable displacement measuring system. Further improvement is being underway at The University of Queensland to develop such system.

Importantly, the above-described improved system for direct tensile testing of very early-age concrete can now be used to obtain full stress-strain curves for various concrete mixtures typically used in practice. This will form a solid basis for more reliable assessment of cracking risk in concrete structures at early age, and thus more effective control of such cracking risk.

**Abstract:** Early-age contraction of concrete may cause excessive cracking in restrained concrete structures within the first few days after casting. The magnitude and rate of development of early-age deformation of Australian concrete is often not known reliably and restraint to shrinkage is often poorly modelled in structural design. In order to accurately quantify the early-age deformational characteristics of concrete, including shrinkage and tensile creep, a comprehensive experimental program is being conducted at the Centre for Infrastructure Engineering and Safety at UNSW. Dog bone-shaped specimens were tested in portable creep rigs specially designed to test the specimens in direct tension. The specimens were loaded at the ages of 1, 2, 3, 5 and 7 days in order to measure the tensile creep coefficients at different loading ages. Shrinkage was also measured on accompanying specimens. The tests were performed under constant sustained tension. Autogenous shrinkage was measured on dog bone specimens. Compressive creep was also investigated for the same concrete mix. Comparisons of the creep coefficient versus time curves for tensile and compressive creep at different loading ages are presented in this paper. Tensile creep was found to be significantly larger than compressive creep for the same loading level.

**Keywords:** Compressive creep, cracking, early-age concrete, laboratory tests, shrinkage, tensile creep.

## 1. Introduction

Early age concrete is a continuously changing material due to the fact that it undergoes chemical and physical changes as soon as it interacts with the environment. It is also a highly variable material, with early-age deformational characteristics varying significantly from specimen to specimen. At early ages, concrete is prone to volumetric changes due to thermal and moisture related shrinkage. When there is restraint and concrete is prevented from shrinking freely, tensile stresses develop in the restrained concrete and, because of its low tensile strength, particularly at early ages, these stresses often exceed the tensile strength of concrete and cause cracking in the young concrete. Early age cracking of concrete is, and has always been, a concern for engineers.

All concrete structures are restrained to some extent, whether externally by the supports or by adjacent parts of the structure or internally by the embedded reinforcement. In a restrained concrete member, as the concrete shrinks, the tensile stress that develops in the concrete is relaxed by tensile creep. Early-age cracking in restrained concrete is therefore dependent on the tensile creep of concrete at early ages, as well as the magnitude of shrinkage, the development of the tensile strength of concrete with time and the degree of restraint. To predict early-age cracking, it is important to accurately quantify the early-age tensile creep and shrinkage of concrete.

Despite its importance for the assessment of cracking, the tensile creep characteristics of concrete are rarely measured and even more rarely considered in structural design. Traditional focus has been on measuring and predicting the creep of concrete in compression and assuming that the creep behaviour in tension is similar to that in compression. In the literature, there is limited information on the tensile creep of concrete loaded in direct tension at early ages. Accurate measurements of tensile creep are difficult to obtain. Because of the necessarily low stress levels, the tensile strains to be measured in a tensile creep test are small. When the concrete is also shrinking, the specimen in direct tension may actually be shortening and the measured strains will be compressive. Even in specimens where drying is prevented, autogenous shrinkage will be taking place in the first few days and weeks after casting rendering the measurement of tensile creep problematic. The large variability of shrinkage and creep from specimen to specimen in concrete at early ages further complicates the issue. Because of these difficulties, some researchers (1-4) have used uniaxially restrained shrinkage test to indirectly measure the tensile creep characteristics of concrete. Relatively few experimental programs (5-7) have been conducted where tensile creep was measured in direct tension tests. In this paper, an experimental program to measure early-age tensile creep using uniaxial direct tensile loading tests is described. In order to examine the effect of the age at loading on tensile creep, tests are conducted on specimens loaded at different ages under similar environmental conditions and with the same stress-strength level. Early-age compressive creep on specimens loaded at the same ages

as the tensile specimens has also been measured and the results are compared with early age tensile creep measurements.

## 2. Experimental program

A series of tensile creep tests has been undertaken as part of a more comprehensive experimental program carried out at the Centre for Infrastructure Engineering and Safety (CIES) at UNSW Australia. The aim is to calibrate and quantify the early age deformational characteristics of Australian concrete. In this paper, the effect of loading age on early age tensile creep is investigated and comparisons are made between tensile creep and compressive creep. All tests are to be performed on one type concrete – a 32 MPa normal class concrete (GP cement and w/c = 0.55). Further testing is currently underway to determine the effects of varying the type of cement, the type and grade of aggregate and the water cement ratio. As the main objective of the research program is to better characterise and evaluate the potential cracking of on-site concrete at early-ages in restrained shrinkage conditions, creep and shrinkage tests were conducted under ambient conditions. The relative humidity varied between 55-70% and the temperature varied from 15°C to 22°C (day and night temperature). Comparisons are made between results for tests performed simultaneously.

### 2.1 Concrete mix

In the first stage, a normal concrete mix was selected and a sufficient number of cylinders and prisms were cast and tested to determine evolution of compressive strength, tensile strength and elastic modulus at the age of 0.75, 1, 2, 3, 7 and 28 days. For each material test, three specimens were tested in order to assess the statistical variation and this practice was repeated for each batch. Table 1 shows the mix design selected for this experimental program.

**Table 1. Mixture proportions of concrete (kg/m<sup>3</sup>)**

Components	GP Cement	Sand	Gravel (10mm Basalt)	Water
Mass	380	545	1265	210

After selecting the desired concrete mix, cylinders and prisms were subjected to compressive, indirect tensile or Brazilian and flexure tests according to Australian Standards to study the strength evolution in concrete. The evolution of concrete mechanical properties is presented in Table 2. Specimens were cured in laboratory ambient conditions after demoulding because all the creep tests were also performed inside the laboratory under similar environmental conditions. For each concrete batch, compressive strength, elastic modulus, indirect tensile strength and modulus of rupture were measured. The statistical variation of mechanical characteristics of concrete for all the batches was less than 10%.

**Table 2. Mechanical characteristics of concrete**

Age (days)	Compressive strength (MPa)	Modulus of rupture (MPa)	Indirect tensile strength (MPa)	Elastic modulus (GPa)
0.75	13.18	2.57	1.20	18.35
1	15.28	3.11	1.40	20.35
2	21.55	3.785	2.10	22.05
3	24.64	4.03	2.54	22.7
7	32	4.56	2.94	27.78
28	37	4.84	3.47	28.58

## 2.2 Creep tests

### 2.2.1 Tensile creep

In order to measure tensile creep, a creep rig specifically designed for this project was used to test dog bone specimens loaded in direct tension. The sustained stress is applied to each creep specimen by a simple lever arm arrangement using dead weights. The dimensions of the dog bone specimens were 200 x 300 x 35 mm and are shown in Figure 1.

Figure 1. Dog bone specimen

The dog bone specimens are fixed into the creep rig by means of two steel plates glued to each end of the specimen with high strength epoxy. Two threaded bolts are also cast in the specimen and are further connected to the steel plates at each end as shown. The purpose of gluing steel plate to the specimen is to ensure an even stress distribution from the applied tensile load. Strains are measured using strain gauges attached to each 35 mm thick face of the dog bone specimen at the centre position at mid-height where the width of the specimen is 70 mm. The strains are recorded at regular intervals with a data acquisition system.

Creep rigs were installed in the laboratory and tests were performed under ambient conditions. A total of 12 creep rigs were constructed on two platforms with each platform able to test six specimens simultaneously, as shown in the Figure 2. As early-age creep was of interest, the tensile creep tests were performed over a two to three week period. All specimens were loaded to the same stress level, namely 50% of the tensile strength of the concrete measured at an age of 2 days. To examine the effect of age at first loading, specimens were loaded at an age of either 1, 2, 3, 5 or 7 days.

The load was transferred to the specimens by lever arms with the help of high strength steel chains in order to induce a purely uniaxial force and to avoid any bending of the specimen. With the lever arm ratio of 5 to 1, a steel block of 50 kg mass imparted a maximum uniform stress of 1 MPa across the 70 mm by 35 mm section at the mid-height of the specimen, representing 50% of the tensile strength of concrete at the age of 2 days. S-type load cells were used to check the applied load in each individual test rig.

### 2.2.2 Compressive creep

Compressive creep was measured in standard creep rigs in accordance with Australian Standard AS 1012.16 AS 1012.16-1996 (R2014) : "Methods of testing concrete - Determination of creep of concrete cylinders in compression. Concrete cylinders of 100 mm diameter and 200 mm height were loaded in the creep rig. A total of three specimens were stacked in the creep rig for simultaneous loading. Longitudinal strains were measured using a 100 mm Demec gauge. On each specimen, a total of three Demec targets were attached at the mid-height of each cylinder and evenly spaced around the circumference at 120 degrees. Two cylinders were kept in the same environmental conditions to serve as companion specimens to measure the free shrinkage strain.

**Figure 2. Tensile creep rigs**

All specimens were covered with wet burlap and polyethylene during a 24-hour period after casting. They were then removed from their moulds and left in laboratory ambient conditions. The compressive creep tests were run over a period of 18 to 20 days.

Compressive creep was also measured on unsealed cylindrical specimens loaded at either 1, 2, 3, 5 or 7 days and a comparison was made between tensile creep and compressive creep for the same concrete mix, loaded at similar stress level and at the same age.

### 3. Experimental results and discussion

Tensile creep was calculated by subtracting the initial elastic strain and the shrinkage strain (measured on an identical companion specimen) from the total strain recorded on each loaded specimen. Creep coefficients were calculated by dividing the creep strain by the initial elastic strain. Due to the fact that the initial stress applied to the concrete specimens (50% of the tensile strength) is low, the initial elastic strain was small. As the shrinkage strain was predominant, the total strains recorded on the loaded specimens changed from positive to negative in less than a day. Figure 3 shows a comparison between the development of total strain recorded on the specimens loaded at an age of 2 days and the shrinkage strain recorded on the companion specimens. Also shown are the initial elastic strain and the calculated tensile creep strain. The curves are the average of the responses all three specimens loaded at age 2 days.

**Figure 3. Development of strains in the specimens**

### 3.1 Effect of loading age on tensile creep

Figure 4 shows the tensile creep coefficients measured at different loading ages. As expected, the specimens loaded at day 1 had the highest creep coefficient, reaching a value of 1.9 after 21 days of loading. For a loading period of 15 days, the creep coefficient of specimens loaded at the age of 1 day was 1.85 (i.e. at age 16 days), while for the specimens loaded at the age of 7 days the creep coefficient after 15 days under load (i.e. at age 22 days) was 0.51. Clearly, the age at first loading has a very significant effect on early-age tensile creep, particularly for concrete loaded in the first one or two days. This is the case for many concrete structures, where tensile stresses begin to develop due to restrained shrinkage soon after the concrete sets.

Figure 4. Creep coefficients at different loading ages

The specific creep  $C$  is defined as creep strain  $\varepsilon_{cc}$  per unit stress. For a specimen subjected to a constant stress  $\sigma_0$ :

$$C = \frac{\varepsilon_{cc}}{\sigma_0} \quad (1)$$

Figure 5 shows the specific tensile creep versus time after loading. A relatively high creep response is observed when concrete is loaded at either 24 hrs or 48 hrs after casting and a significantly stiffer response is observed when the concrete is a few days older when loaded. These observations are in accordance with earlier findings of Østegaard et al. (2).

### 3.2 Comparison of compressive creep and tensile creep

Figure 6 shows a typical comparison between the compressive creep coefficients and tensile creep coefficients for similar test conditions and the same age at first loading.

Early age tensile creep is more prominent than early age compressive creep for same the concrete mix under similar loading conditions. These results are contradictory to earlier findings by Briffault et al. (7) and Rossi et al. (5). Briffault et al. found similar basic creep behaviour for normal concrete under compression and tension when specimens were loaded at the age of 5 days. Rossi et al. found that basic compressive creep was significantly greater than basic tensile creep while compressive creep and tensile creep under drying conditions were equivalent when specimens were loaded at 64 days.

Figure 5. Specific Creep at different loading ages

Figure 6. Compressive and tensile creep coefficient

### 3.3 Autogenous and total shrinkage

In order to draw comparisons between the total shrinkage strains measured on both types of specimens, i.e. the dog bones and cylinders, the hypothetical thicknesses  $t_h$  as defined in AS3600-2009 (10) have been calculated for both specimens as follows:

$$t_h = \frac{2A}{u} \quad (2)$$

where  $A$  is the cross-sectional area of the specimen and  $u$  is the perimeter of the specimen exposed to the atmosphere. Excellent agreement between the total shrinkage strains measured on the dog

bones and those measured on the cylinders is obtained if the cylinder strains are modified using Eq. (3). This comparison is shown in Figure 7.

$$(\epsilon_{cs})_{\text{dogbone}} = \frac{(t_h)_{\text{cylinder}}}{(t_h)_{\text{dogbone}}} * (\epsilon_{cs})_{\text{cylinder}} \tag{3}$$

**Figure 7. Total shrinkage strains in dog bones and cylindrical specimens**

Autogenous shrinkage was measured on the dog bone specimens only. Autogenous shrinkage is a volume change resulting from chemical reactions in the concrete and is not associated with drying. Autogenous shrinkage is measured on specimens where there is no moisture transfer to the surrounding environment. The autogenous shrinkage specimens were wrapped in self-adhesive aluminium foil soon after demoulding, as shown in Figure 8.

**Figure 8 Specimen wrapped in self-adhesive foil to eliminate drying.**

Figure 9 shows the total shrinkage and autogenous shrinkage strain versus time curves measured on the dog bone specimens. After 20 days of exposure to laboratory ambient conditions, the contribution of the autogenous shrinkage to the total shrinkage was 19% for a concrete mix of w/c ratio 0.55. This is consistent with Tazawa & Miyazawa (9) who found that for w/c ratios of 0.40, 0.23 and 0.17, the autogenous shrinkage was 40%, 80% and 100% of the total shrinkage.

**Figure 9. Total shrinkage and autogenous shrinkage**

#### 4. Conclusions

An experiment program has been carried out to quantify early age tensile creep of OPC concrete with a water-cement ratio of 0.55 and to examine the effects of age at first loading. It was found that early age tensile creep is strongly affected by the loading age, with tensile creep decreasing as the age at first loading increases. Early-age tensile creep was found to be significantly greater than early age compressive creep.

These experiments are part of a major research program to quantify the early age properties of concrete. These results, together with the results of future experiments, will be used to accurately model the early-age cracking of concrete.

<sup>3</sup>Assistant Professor Materials Engineering, Missouri University of Science and Technology

<sup>4</sup>Full Professor Concrete Technology, Ghent University

**Abstract:** In order to avoid durability problems caused by an inadequate consolidation of concrete, self-compacting concrete (SCC) has been developed. The mix design of SCC aims at balancing a minimum flowability allowing air bubbles to escape and a maximum flowability in order to avoid segregation. Because of the higher demands on mix design and additional requirements related to casting, SCC mixtures are in general more sensitive to small variations in its mix composition compared to conventional vibrated concrete. Besides improving the robustness of SCC with admixtures like Viscosity-Modifying Agents (VMAs), it is also important to find out why certain mixtures are more robust than others. This paper investigates the influence of the paste volume and the water-to-powder ratio (volumetric) on the robustness of fresh SCC mixtures. Nine SCC mixtures with a paste volume of 350, 375, and 400 l/m<sup>3</sup> and a volumetric water-to-powder ratio of 0.75, 0.90, and 1.05 were subjected to a variation of  $\pm 8$  l/m<sup>3</sup> water. The robustness of the produced mixtures was quantified measuring the slump flow, V-funnel time, L-box ratio, and sieve stability.

**Keywords:** Robustness, Self-Compacting Concrete, Rheology, Paste Volume, Water-to-Powder ratio

## 1. Introduction

### 1.1. Self-compacting concrete

After investigating many durability problems of post-war Japanese concrete structures, Okamura and his team found that a majority of problems originated in a poor consolidation of concrete during the casting process. As a solution to avoid similar problems, a new type of concrete was developed for which external vibration was no longer needed to assure a good compactation: self-compacting concrete (SCC) [1, 2]. In order to combine sufficient fluidity – allowing air-bubbles to escape and complete formwork filling – and sufficient stability to avoid segregation, the high fluidity concrete contains higher powder content compared to conventional vibrated concrete, superplasticizer(s), and sometimes a viscosity-modifying admixture (VMA). However, because the target range for sufficient fluidity, sufficient segregation resistance, and to avoid an excessive stickiness is much smaller than the optimum range of conventional vibrated concrete, self-compacting mixtures are generally more sensitive to small variations in the mix proportions, materials properties, and casting circumstances.

To counter this larger sensitivity to small variations, also referred to as reduced robustness, a more severe quality control and better trained workers are needed. The use of SCC is nowadays still limited to cases where all conditions are well-controlled and situations in which an external compaction would cause great difficulties. To facilitate the use of SCC in general and especially for applications with specific requirements for fresh concrete, it is necessary to investigate the origin of the robustness of concrete.

### 1.2. The origin of the robustness

Although many parameters such as material characteristics [3-11], temperature [12-14], and shear history [15-18] affect the fresh behaviour of self-compacting concrete, most robustness studies focus on the influence of small changes in the material proportions [11, 19-42]. Of all changes in material proportions, inaccuracies in the water amount are responsible for the largest variations of the fresh behaviour of SCC [43, 44]. Therefore, many studies on the robustness of fresh SCC focus on the influence of small variations of the water content ( $\pm 5$  to 10 l/m<sup>3</sup>). According to these publications, the sensitivity to small variations of the water content decreases as:

- A surplus of fine aggregates is included in the aggregates grading curve, preventing the coarse aggregates from becoming dominant [19-21, 45].
- The powder content increases [20, 21, 23].
- Part of the cement is substituted by silica fume or fly ash [22, 24].
- A VMA is added to the mixture [20, 28-39, 46].
- Certain types of superplasticizers are used [25-27].
- Opposing conclusions are drawn about the influence of the water-to-cement and water-to-powder ratio [19, 38]

The mechanisms and combination of influences of the powder content, the water-to-powder ratio, mineral additions and admixtures on the robustness are still unknown. Some authors indicate the importance of the paste volume, the paste density, and the paste viscosity [20, 21, 23], while others focus on the excess water in the concrete mix design [38] or make a link between the thixotropy and robustness [47, 48]. This paper attempts to determine the causes behind the influence of paste volume and volumetric water-to-powder ratio on the robustness of SCC.

## 2. Experimental work

### 2.1. Materials and mixing sequence

All mixtures are made with the same raw materials: Rhine sand 0/5, river gravel 2/8 and 8/16 (with a density of respectively 2630 kg/m<sup>3</sup>, 2670 kg/m<sup>3</sup>, and 2660 kg/m<sup>3</sup>), Portland cement CEM I 52.5 N (with a density of 3126 kg/m<sup>3</sup> and a Blaine fineness of 370 m<sup>2</sup>/kg), limestone filler (with a density of 2685 kg/m<sup>3</sup> and a specific surface area of 424 m<sup>2</sup>/kg, based on the particle size distribution), and a PCE superplasticiser with a solid content of 35%. The grading curve of the aggregates is illustrated in

Figure 1 and the chemical composition of the cement as determined by an XRF analysis is given in Table 1. After premixing the cement, filler, and dry aggregates for one minute in a planetary pan mixer, water was added to the mixer and mixing continued for another minute. Finally, the superplasticizer was added and the concrete was mixed for two more minutes.

Figure 1. Grading curve of the aggregates

Table 1. Chemical composition of the cement

	Cement [%]

### 2.2. Mixture compositions

The robustness of nine SCC mixtures was determined by measuring the slump flow, V-funnel time, L-box ratio, sieve stability, air content and density of the mixtures subjected to a variation of  $\pm 8$  l/m<sup>3</sup> water. The mixtures, given in Table 2, have different paste volumes (350, 375, and 400 l/m<sup>3</sup>) and volumetric water-to-powder ratios (0.75, 0.90, and 1.05), keeping the water-to-cement ratio constant. These paste volumes and volumetric water-to-powder ratio's correspond with the 20%, 50%, and 80% fractals of a database summarizing the properties of SCC mixes used in more than 175 papers [49,

50]. The superplasticizer dosage was always determined such that the Sieve Stability Index (S.S.I., tested according to EN 12350-11) of the reference mixture is between 8 and 12%.

**Table 2: Mix proportions of reference SCC mixes**

Paste volume / water-to-powder ratio (by volume) [l/m <sup>3</sup> ] / [-]	Sand 0/5 [kg/m <sup>3</sup> ]	Gravel 2/8 [kg/m <sup>3</sup> ]	Gravel 8/16 [kg/m <sup>3</sup> ]	Cement I 52 N [kg/m <sup>3</sup> ]	Limestone filler [kg/m <sup>3</sup> ]	Water [kg/m <sup>3</sup> ]	SP dosage [l/m <sup>3</sup> ]

### 3. Experimental results

Table 3 and Table 4 summarize the fresh properties of the nine reference mixtures. In Table 4, for each workability test, the values for the reference mixtures are listed together with the change of the test response per liter water of the parameter (eg.  $\Delta SF / 16 \text{ l/m}^3$ ) and the ratio of the interval divided by the mean value (eg.  $\Delta SF / SF_{ref}$ ). All workability tests except the L-box ratio gave a good picture of the impact of fluctuations of the water content on the fresh behaviour of the mixtures.

**Table 3: Fresh state properties of nine reference SCC mixes**

Paste volume / water-to-powder ratio [l/m <sup>3</sup> ] / [-]	Slump flow [mm]	V-funnel time [s]	L-box ratio [-]	S.S.I. [%]	Density [kg/m <sup>3</sup> ]	Air content [%]

### 3.1. Variations of the slump flow

Because the superplasticizer dosage was always adjusted in order to have a S.S.I. of  $10\% \pm 2\%$ , the slump flow of the nine mixtures is not related to their paste volume or water-to-powder ratio (Table 3). However, as shown in Table 4 and Figure 2, the sensitivity of the slump flow to changes in the water content depends on the paste volume: the robustness of the flow decreases as the paste volume increases. Table 4 shows that the water-to-powder ratio of the mixtures has no clear influence on the robustness of the slump flow.

Figure 2a: Influence of the paste volume on the slump flow

Figure 2b: Influence of the paste volume on the slump flow

Figure 2c: Influence of the paste volume on

Figure 3a: Influence of the volumetric water-to-powder ratio on the V-funnel time

Figure 3b: Influence of the volumetric water-to-powder ratio on the V-funnel time

Figure 3c: Influence of the volumetric water-

**3.2. Variations of the V-funnel time**

When the paste volume increases, the V-funnel time of the mixtures decreases slightly (about 3 sec difference between 350 and 400 l/m<sup>3</sup> for the same water-to-powder ratio); the sensitivity of the V-funnel time to variations in the water content also seems to be independent of the paste volume of the mixture. Mixtures with a higher water-to-powder ratio have a significant lower V-funnel time than mixtures with a lower water-to-powder ratio (see Tables 3 and 4). Especially, mixtures with a water-to-powder ratio of 0.75 are very sensitive to a decrease in the water content, making them very sticky and not easy to process. The robustness determined by changes in the V-funnel time therefore increases when the water-to-powder ratio increases (Figure 3).

**3.3. Variations of the L-box ratio**

Table 4 reveals no clear influence of the test responses on the L-box ratio results. The results are also difficult to interpret because of the poor flowability of the mixtures with 8 l/m<sup>3</sup> less water, a paste volume of 400 l/m<sup>3</sup> and volumetric water-to-powder ratios of 0.75 and 1.00, which have a slump flow of respectively 525 and 515 mm.

**3.4. Variations of the sieve stability**

As shown in Table 4 and Figure 4, an increase in the paste volume increases the sensitivity of the S.S.I. to variations in the water content. The paste volume has a larger effect than changes in the water-to-powder ratio.

Figure 4a: Influence of the paste volume on the sieve stability

Figure 4b: Influence of the paste volume on the sieve stability

Figure 4c: Influence of the paste volume on the sieve stability

#### 4. Discussion of influence parameters

Mixtures were designed to show a specific level of sieve stability, regardless of the fluidity of the mixture. As static segregation must be avoided in all cases, the S.S.I. was chosen as “reference mix design parameter”. The conclusions of this study may therefore deviate from other results in literature.

##### 4.1. Workability tests for the robustness

Variations induced by changes in the water content affect the filling ability, the passing ability, and the segregation resistance and may result in a rejected mixture. Because a lack of robustness of an SCC mixture is most often not caused by the three key characteristics of SCC at the same time, it is not evident to grasp the variations of the slump flow, V-funnel time, L-box ratio, and sieve stability index into one global ‘robustness value’. A better approach is to judge robustness of each mixture based on its most critical parameter: a poor flowability or a too viscous and sticky mixture when the mixture contains 8 l/m<sup>3</sup> less water; or a severe segregation of the coarse aggregates or extreme bleeding occurring when 8 l/m<sup>3</sup> water in excess is added to the mixture.

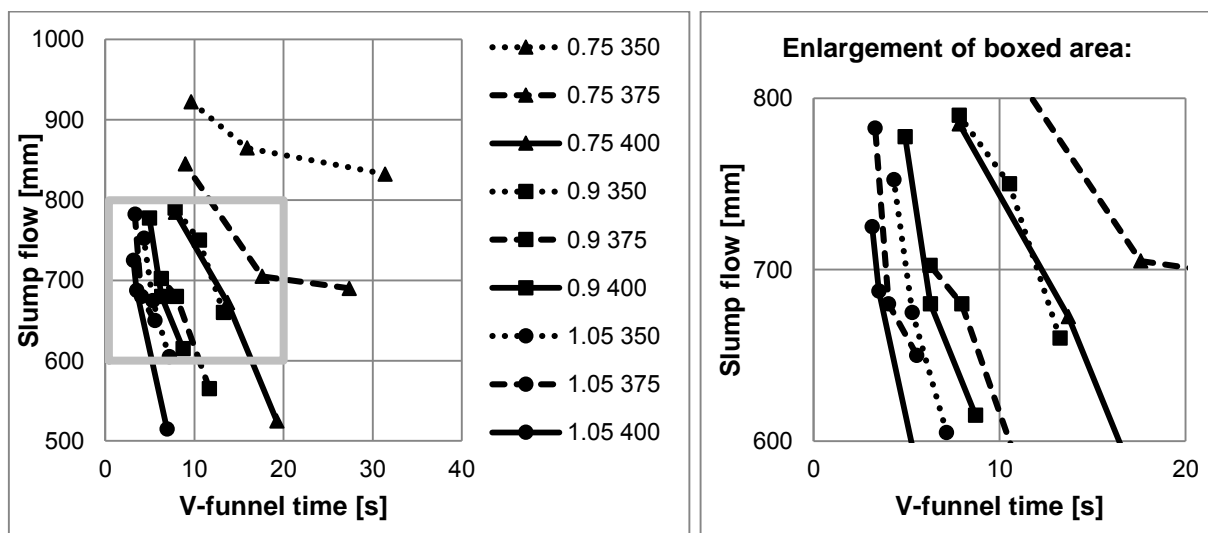

Figure 5: The robustness of all mixtures illustrated in a workability box

##### 4.2. Influence of the paste volume

When the paste volume increases, the robustness to variations in the water content of the slump flow and S.S.I. decreases while the sensitivity of the V-funnel time is constant (Table 4 and Figure 3 to 5). As shown in Figure 5, the SCC mixtures with a higher paste volume (full lines) have a lower slump

flow to achieve similar stability and are thus more sensitive to a poor flowability when the water dosage is decreased by 8 l/m<sup>3</sup> or have a more than proportional increase in S.S.I. when 8 l/m<sup>3</sup> water is added to the mixture.

#### **4.3. Influence of the volumetric water-to-powder ratio**

The robustness determined by changes in the V-funnel time increases when the water-to-powder ratio increases (Table 4, Figure 3, and Figure 5, lines with circles). Because the superplasticizer dosage added to the mixtures decreases with a higher water-to-powder ratio to achieve similar stability, the resulting effect on the sensitivity of the slump flow and S.S.I. is rather limited. Mixtures with a higher water-to-powder ratio have a lower plastic viscosity, making them more dependent on the yield stress to assure a stable mix design. Therefore, the robustness of these mixtures should be assured by increasing the aggregates volume and thus reducing the paste volume. When the water-to-powder ratio of a mixture is rather low, the plastic viscosity might become too high when reducing water by 8 l/m<sup>3</sup> and the robustness should be guaranteed by a larger paste volume. The paste volume, however, should also not be too high, since this increases the sensitivity of the slump flow of the mixture.

### **5. Recommendations**

Every application of SCC imposes specific demands towards the mix design of the concrete [24]. In order to combine specific workability demands with a sufficient robustness, the following is recommended regarding the paste volume and water-to-powder volume combination while assuming the stability of the mixture, summarized in Table 5.

**Table 5: The recommended paste volume and water-to-powder ratio depended on the application**

<b>Application</b>	<b>Recommended paste volume</b>	<b>Recommended volumetric water-to-powder ratio</b>
Large horizontal elements (floors and plates)	Low	High
Long horizontal elements (reinforced beams)	Low	Intermediate
Long vertical elements (walls)	Intermediate	Low
Slender vertical elements (columns)	High	Low

#### **5.1. Large horizontal elements (floors and plates)**

To facilitate the casting of large horizontal elements, SCC mixtures with high volumetric water-to-powder ratios should be used. Because the stability of such a mixture is provided by its high yield stress, the robustness can be improved by decreasing the paste volume of the mixture.

#### **5.2. Long horizontal elements (reinforced beams)**

A slow, but far flowing SCC mixture with a low paste volume and low water-to-paste ratio should be applied. In such a mixture, the stability is achieved by the high plastic viscosity. With a sufficiently high but not too high volumetric water-to-powder ratio, the needed robustness concerning changes in the water content is achieved.

#### **5.3. Long vertical elements (walls)**

In order to flow slowly and without segregation in between the reinforcement of long vertical elements, mixtures should have a low yield stress and a high plastic viscosity for its segregation resistance. The high plastic viscosity can be achieved with a low volumetric water-to-powder ratio. A maximum robustness is achieved by a higher paste volume, which should not be too high preventing the yield stress from becoming dominant and thus increasing the sensitivity to an too low flowability.

#### 5.4. Slender vertical elements (columns)

In columns and slender walls, the mixture should have a high plastic viscosity and without specific demands towards the yield stress. Because the stability to segregation can be provided by a combination of an intermediate plastic viscosity and yield stress, the mixture needs a low volumetric water-to-powder ratio to obtain the required plastic viscosity and a relatively high paste volume.

### 6. Conclusions

An experimental program including nine SCC mix compositions with different paste volumes and volumetric water-to-powder ratio's demonstrates that the robustness of SCC should be tested with several workability parameters in order to determine the most critical parameter of the mixture for a specific application. Because the L-box ratio does not always provide clear trends, the analysis in this experimental program is based on the slump flow, V-funnel, and sieve stability measurements. For all mixtures, the superplasticizer dosage was adjusted to achieve a specific stability level (S.S.I. =  $10 \pm 2\%$ ).

The robustness of the slump flow increases when the paste volume decreases, because mixtures with a lower paste volume depend mainly on their larger aggregate volume in order to obtain sufficient segregation resistance. The paste volume only has a minor influence on the V-funnel time and its sensitivity. A lower volumetric water-to-powder ratio increases the V-funnel time and increases the risk for the mixture of becoming too viscous when a small decrease of the water content occurs. The limited influence of the water-to-powder ratio on variations of the slump flow is probably caused by the lower superplasticizer dosage of the mixtures with a higher water-to-powder ratio.

**Abstract:** One of the developments in concrete technology is Self-Compacting Concrete (SCC). SCC refers to highly flowable, non-segregating concrete that can be spread into place, fill the formwork, and encapsulate the reinforcement without the aid of any mechanical consolidation. In this study, cracking in reinforced SCC and Fibre Reinforced Self-Compacting Concrete (FRSCC) slabs with particular emphasis on the development of flexural cracking have been investigated both experimentally and analytically. Two series tests were conducted on the one-way reinforced SCC and FRSCC slabs to study the development of short-term and long-term flexural cracking under monotonically increasing loads and caused by the combined effects of constant sustained service loads and shrinkage, respectively. Deflections, crack patterns, crack widths, steel strains and concrete surface strains at the steel level were recorded 'in the instantaneous cracking and post-cracking range for short-term tests' and 'both immediately after loading and up to 240 days under sustained loads for long-term tests'. Analytical models were developed to simulate SCC and FRSCC instantaneous and time-dependent flexural cracking. Also, available tension chord models for CC and FRC were modified and used in the proposed model to study the SCC and FRSCC tension zone of a flexural member and the effect of creep and shrinkage with time. Moreover, the crack width and spacing calculation procedures of the available codes of practice were assessed and some deficiencies in the existing approaches exposed. Finally, a comprehensive parametric study for the instantaneous and time-dependent behaviour of the slabs by FEM analyses has been conducted.

**Keywords:** self-compacting concrete, fibre reinforced self-compacting concrete, flexural cracking, crack control, time-dependent.

## 1. Introduction

Developments in concrete technology provide engineers, designers, suppliers and contractors with new methods of approaching engineering problems. Many of these developments are engineered solutions to technical and commercial problems, by either improving the current practices or overcoming limitations in the existing technology. One of the developments is Self-Compacting Concrete (SCC). SCC refers to 'highly flowable, non-segregating concrete that can be spread into place, fill the formwork, and encapsulate the reinforcement without the aid of any mechanical consolidation' as defined by the American Concrete Institute (1). SCC is regarded as one of the most promising developments in concrete technology due to significant advantages over Conventional Concrete (CC). Many different factors can influence a decision to adopt SCC over CC ranging from structural performance to associated costs. These decisions should be well informed and based on a sound understanding of such factors. Recently, SCC has gained wider use in many countries for different applications and structural configurations. SCC can also provide a better working environment by eliminating the vibration noise. Such concrete requires a high slump that can be achieved by superplasticizer addition to a concrete mix and special attention to the mix proportions. SCC often contains a large quantity of powder materials that are required to maintain sufficient yield value and viscosity of the fresh mix, thus reducing bleeding, segregation, and settlement. As the use of a large quantity of cement increases costs and results in higher temperatures, the use of mineral admixtures such as fly ash, blast furnace slag, or limestone filler could increase the slump of the concrete mix without increasing its cost (2).

In addition, Fibre Reinforced Self-Compacting Concrete (FRSCC) is a relatively new composite material which congregates the benefits of the SCC technology with the profits derived from the fibre addition to a brittle cementitious matrix. Fibres improve many of the properties of SCC elements including tensile strength, ductility, toughness, energy absorption capacity, fracture toughness and cracking. FRSCC can mitigate two opposing weaknesses: poor workability in Fibre Reinforced Concrete (FRC) and cracking resistance in plain concrete (3).

Generally, strength and serviceability are the two main criteria to be satisfied in the design of reinforced concrete structures. Strength is the ability of the structure to carry the design ultimate loads without collapsing. The strength of a structure may usually be determined with reasonable accuracy because reinforced concrete structures are commonly designed to provide ductile failure, i.e., yielding of the reinforcement before failure of the concrete. Serviceability refers to the behaviour of structures at working loads, with particular reference to cracking and deflection. Both cracking and deflection are primarily dependent on the properties and behaviour of the concrete but are more difficult to predict because of the non-linear, inelastic and time-dependent nature of the concrete. If structural designers do not adequately account for this non-linear behaviour, serviceability problems may result. Therefore, crack control is an important aspect of the design of reinforced concrete structures at the serviceability limit state (4). Because concrete is low in tensile strength, cracks are inevitable in reinforced concrete structures. Therefore, studying the cracking behaviour and controlling the width of cracks in reinforced concrete members are absolutely necessary.

For a structure that is made by SCC and FRSCC (e.g. bridges and tall buildings) to remain serviceable, crack widths must be small enough to be acceptable from an aesthetic point of view, small enough to avoid waterproofing problems and to prevent the ingress of water that may lead to corrosion of the reinforcement. Despite its importance, building code provisions for crack control mostly have been developed from laboratory observations of the instantaneous behaviour of reinforced SCC and FRSCC members under load and fail to account adequately for the time-dependent development of cracking. In this study cracking caused by external loads in reinforced SCC and FRSCC elements is examined experimentally and numerically (5).

## **2. Research Significance**

Limited researches have been undertaken to understand cracking and crack control for SCC and FRSCC members. Also, the time-dependent mechanisms and interactions are still not completely understood. In addition, a reliable and universally accepted design procedure has not been developed. There exists a need for both theoretical and experimental research of the critical factors which affect time-dependent cracking of SCC and FRSCC. The major objectives of this study were:

- (a) To gain a better understanding of the mechanisms associated with SCC and FRSCC flexural cracking of slab, and the influence of those factors that affect the spacing and width of flexural cracks under short-term and long-term loading.
- (b) To obtain benchmark, laboratory-controlled data to assist in the development of rational design-oriented procedures for the control of cracking and the calculation of crack widths on the short-term and long-term response of one-way slabs made by SCC and FRSCC.
- (c) To develop analytical models those accurately predict hardened mechanical properties of SCC and FRSCC.
- (d) To develop analytical models for flexural cracking that describe in appropriate detail the observed cracking behaviour of the SCC and FRSCC flexural one way slabs tested.
- (e) To effectively model CC, SCC, and FRSCC slabs under short-term and long-term loading. The Finite Element Method (FEM) was used to model the slabs with the aid of a computer program to process the finite element model. The models will be critiqued on their ability to properly replicate real cracking and deflection behaviour in practice models. There are multiple methods for determining the deflection of slabs as well as calculating crack spacing and crack width with regard to short term loading and under sustained load.

## **3. Experimental Study**

In this study, (a) short-term flexural load tests on eight reinforced SCC and FRSCC specimens slabs were conducted to study the development of flexural cracking under increasing short-term loads from first cracking through to flexural failure and (b) long-term flexural load tests on eight reinforced SCC and FRSCC specimens slabs were monitored for up to 240 days to measure the development of cracking and deformations under service loads. For this purpose, four SCC mixes – two plain SCC (N-SCC-a, b), two steel fibre (D-SCC-a, b), two polypropylene fibre (S-SCC-a, b), and two hybrid fibre (DS-SCC-a, b) FRSCC slab specimens – are considered in the test program. In this study, all testing and measurement requirements are based on the Nejadi (4) research study and we aimed to compare SCC and FRSCC slab series experimental results with CC (4) slab series experimental results. Deflections at mid-span,

crack patterns, crack widths, steel strains and concrete surface strains at the steel level were recorded 'in the instantaneous cracking and post-cracking range for short-term tests' and 'both immediately after loading and up to 240 days under sustained loads for long-term tests'. Detailed material properties, mix proportions, and fresh and hardened properties can be found in Aslani (5).

### 3.1 Mechanical properties, shrinkage and creep tests

Specimens for testing the hardened properties are prepared by direct pouring of concrete into moulds without compaction. The compressive and tensile strengths, modulus of elasticity and modulus of rupture specimens are tested at 3, 7, 14, 28, 56, and 91 days. Also, shrinkage and creep are monitored up to 240 days.

### 3.2 Short-term SCC and FRSCC slabs tests

Eight singly reinforced SCC and FRSCC slab specimens were cast and moist cured for 28 days. The slab specimens were each nominally 3500 mm long by 400 mm wide (see Figure 1). In all slabs the nominal distance from the soffit to the centroid of the main reinforcement was 25 mm and distance among bars is 103 mm. Slabs series were each reinforced with 4N12. All the specimens were tested to failure to investigate the distribution and extent of primary and secondary cracking under short-term loading using two equal point loads applied at the third points on the span, at ages greater than 28 days. Crack widths were monitored on the side face of the specimens from initial cracking up to a load sufficient to cause the tensile steel to yield. The schematic diagram of the test set-up is shown in Figure 2. Two identical specimen "a" and "b" were constructed for each SCC mix.

Figure 1. Dimensions and reinforcement details for slab specimens.

Figure 2. Short-term flexural test arrangement for all specimens.

### 3.3 Long-term SCC and FRSCC slabs tests

A total of eight SCC and FRSCC slabs with the same cross-section and details were monitored for up to 240 days to measure the time-dependent development of cracking and deformations under service loads. Details of the cross-sections and reinforcement layouts for slab specimens are shown in Figure 1. A general view of the test specimens is shown in Figure 3. All slab specimens were subjected to different gravity loads, consisting of self-weight plus superimposed sustained loads via carefully constructed and arranged concrete blocks supported off the top (of the specimens). To provide the sustained loading, rectangular concrete blocks of predetermined size and weights were cast and weighed prior to the commencement of the test. The blocks were suitably arranged on the top surface of each specimen to achieve the desired sustained load level. Two sustained load levels were considered, namely 50% and 30% of the ultimate design load, and designated load conditions “a” and “b”, respectively. The slab specimens were subjected to uniformly distributed sustained loads, UDL + self-weight. All measurements were taken within the high moment region, i.e. the middle third of the span for beams and for slabs where  $M \geq 90\% M_{max}$  (5).

Figure 3. General view of flexural long-term tests under load.

## 4. Experimental Results

The compressive and tensile strengths, modulus of elasticity and modulus of rupture results are presented in Table 1. The measured shrinkage strain and creep coefficients for SCC loaded at age 14 days is presented in Tables 2 and 3. Also, the results from short-term and long-term flexural tests are presented in Tables 4 and 5.

## 5. Numerical analysis

### 5.1 Short-term and long-term bond shear stresses

The force in the bar is transmitted to the surrounding concrete by bond shear stress  $\tau_b$ . Due to this transfer, the force in a reinforcing bar changes along its length. The transfer of forces across the interface by bond between concrete and steel is of fundamental importance to many aspects of reinforced concrete behaviour. Under service conditions  $\sigma_s < f_{sy}$  and according to Marti et al. (6),  $\tau_b = 2 f_{ct}$ . To investigate the influence of the assumed short-term bond shear stress on the predicted crack width, four different values for bond shear stress ( $\tau_b = f_{ct}$ ,  $\tau_b = 1.5 f_{ct}$ ,  $\tau_b = 2 f_{ct}$  and  $\tau_b = 3 f_{ct}$ ) have been considered. Moreover, following the CEB proposal which accounts for the breakdown of tension stiffening under long-term, each value was reduced by a factor of one half ( $\tau_b(t) = 0.5 f_{ct}$ ,  $\tau_b(t) = f_{ct}$  and  $\tau_b(t) = 1.5 f_{ct}$ ) for time-dependent behaviour. For each assumed bond shear stress, the crack widths were calculated and compared with the measured crack widths for each load increment. Instantaneous and time-dependent crack width calculations for concrete reinforced with bars are different from concrete reinforced with bars and fibres. Detailed calculation procedures have been presented in Aslani (5). The proposed bond shear stress models for short-term behaviour which have been applied in the crack width and spacing calculations can be presented as follows:

$$\text{N-SCC: } \tau_b = \begin{cases} 1.50 f_{ct} & \sigma_{s,max} < 180 \text{ MPa} \\ 1.50 f_{ct} & f_{sy} > \sigma_{s,max} \geq 180 \text{ MPa} \end{cases} \quad (1)$$

$$\text{D-SCC: } \tau_b = \begin{cases} 1.25 f_{ct} & \sigma_{s,max} < 180 \text{ MPa} \\ 1.30 f_{ct} & f_{sy} > \sigma_{s,max} \geq 180 \text{ MPa} \end{cases} \quad (2)$$

$$\text{S-SCC: } \tau_b = \begin{cases} 1.50 f_{ct} & \sigma_{s,max} < 180 \text{ MPa} \\ 1.70 f_{ct} & f_{sy} > \sigma_{s,max} \geq 180 \text{ MPa} \end{cases} \quad (3)$$

$$\text{DS-SCC: } \tau_b = \begin{cases} 1.50 f_{ct} & \sigma_{s,max} < 180 \text{ MPa} \\ 1.60 f_{ct} & f_{sy} > \sigma_{s,max} \geq 180 \text{ MPa} \end{cases} \quad (4)$$

The proposed bond shear stress model for long-term behaviour which has been applied in the crack width and spacing calculations can be presented as follows:

$$\tau_b = 1.5 f_{ct} \quad (5)$$

### 5.2 Instantaneous and time-dependent flexural cracking models

To control the crack width at the flexural member tension surface, designers can use the guidelines prescribed in various design codes. These guidelines are based on certain analytical solutions to crack width for CC that were developed by various researchers. There is no study about analytical models for instantaneous and time-dependent flexural cracking of reinforced SCC and FRSCC one-way slabs. The crack width and crack spacing calculation procedures outlined in five international codes, namely Eurocode 2 (7), CEB-FIP (8), ACI318-99 (9), Eurocode 2 (10), and fib-Model Code (11), are presented and crack widths and crack spacing are accordingly calculated. Then, the results are compared with the proposed analytical models and the measured experimental values, and discussed in detail separately. The proposed crack width and crack spacing models in this study for prediction of instantaneous and time-dependent crack widths for SCC and FRSCC are based on the Leutbecher (12) models. The Leutbecher (12) models include crack widths for initial crack and stabilized cracking phases. These models are proposed for Conventional Reinforced Concrete (CRC) and CRC with fibres. The flexural cracking modelling of fibre reinforced concrete is very complicated but the proposed models by Leutbecher (12) are very convenient and effective. The proposed models of Leutbecher (12) are more suitable when they are combined with the proposed effective tensile area of concrete by Nejadi (4) and the calculated results are more in agreement with the measured experimental results. Proposed SCC and FRSCC flexural cracking models are presented through Table 6. In these equations, the proposed these bond shear stress models, equations (1-5), should be used. Detailed calculation procedures and notations have been presented in Aslani (5). In order to make a comparison between the models, crack width and crack spacing were also

calculated in accordance with Eurocode 2 (7), CEB-FIP (8), ACI318-99 (9), Eurocode 2 (10), fib-Model Code (11), Nejadi (4), Leutbecher (12), and proposed model in this study. Comparison between the experimental results, proposed analytical model and international codes are presented in Figure 4.

**Table 6. Proposed SCC and FRSCC flexural cracking models.**

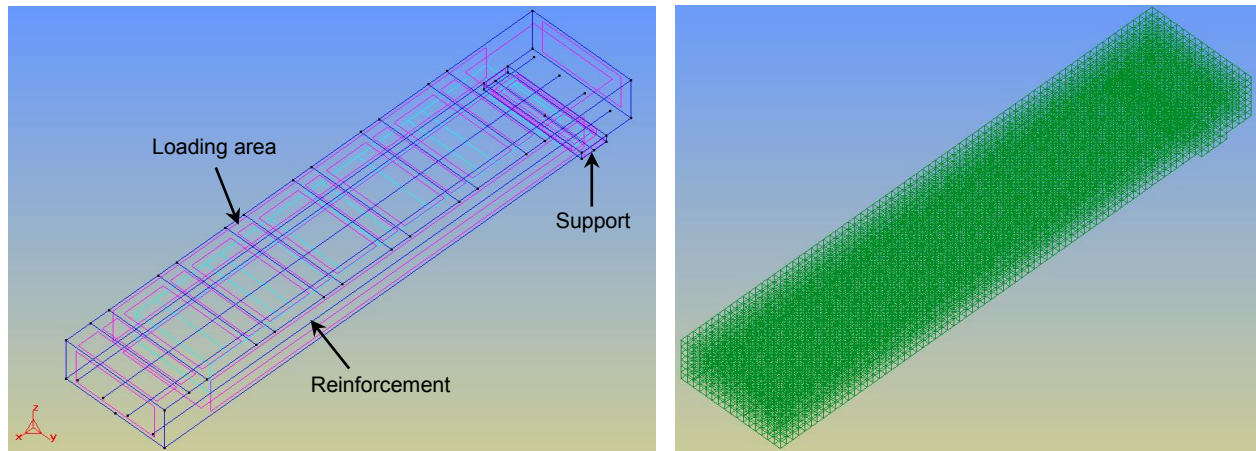

Proposed models	Equations
instantaneous crack width initial crack phase - SCC	$w = \frac{0.25 f_{ct}^2 d_b}{E_s \tau_b \rho_s^2} \left( 1 + \frac{E_s}{E_c} \rho_s \right)$
time-dependent crack width initial crack phase - SCC	$w = \frac{0.25 \left( \frac{\sigma_s}{1 + \frac{E_s}{E_c} \rho_s} - \varepsilon_{s,shr} E_s \right)^2}{E_s \tau_b} d_b \left[ 1 + \frac{E_s}{E_c} \rho_s \right]$
instantaneous crack width stabilized cracking phase - SCC	$w = \frac{s_r}{E_s} \left[ \sigma_s - \frac{s_r \tau_b}{d_b} \left( 1 + \frac{E_s}{E_c} \rho_s \right) \right]$
time-dependent crack width stabilized cracking phase - SCC	$w = \frac{s_r}{E_s} \left[ \sigma_s - \left( \frac{s_r \tau_b}{d_b} + \varepsilon_{s,shr} E_s \right) \left( 1 + \frac{E_s}{E_c} \rho_s \right) \right]$
instantaneous crack width initial crack phase - SCC	$w_s = \frac{0.25 \left[ \sigma_s - \frac{\sigma_{cf,cr}^i \frac{E_s}{E_c}}{\gamma} \right] d_b}{E_s \tau_b} (\sigma_s)$
instantaneous crack width initial crack phase - FRSCC	$w_s = \frac{0.25 \left[ \sigma_s - \frac{\sigma_{cf,cr}^i \frac{E_s}{E_c}}{\gamma} \right] d_b}{E_s \tau_b} (\sigma_s)$
time-dependent crack width initial crack phase - FRSCC	$w_s = \frac{0.25 \left[ \sigma_s - \varepsilon_{s,shr} E_s \left( 1 + \frac{E_s}{E_c} \rho_s / \gamma \right) - \frac{\sigma_{cf,cr}^i \frac{E_s}{E_c}}{\gamma} \right] d_b}{E_s \tau_b} (\sigma_s - \varepsilon_{shr}^* E_s)$
instantaneous crack width stabilized cracking phase - FRSCC	$w_s = s_r \left[ \frac{\sigma_s}{E_s} - \left( \frac{s_r \tau_b}{d_b E_s} \left( 1 + \frac{E_s}{E_c} \rho_s / \gamma \right) + \frac{\sigma_{cf}}{\gamma E_c} \right) \right]$
time-dependent crack width stabilized cracking phase - FRSCC	$w_s = s_r \left[ \frac{\sigma_s}{E_s} - \left( \frac{s_r \tau_{sm}}{d_b E_s} \left( 1 + \frac{E_s}{E_c} \rho_s / \gamma \right) + \frac{\sigma_{cf}}{\gamma E_c} - \varepsilon_{f,shr}^* \frac{E_f}{E_c} \eta \rho_f \right) - \varepsilon_{shr}^* \right]$
instantaneous and time-dependent crack spacing	$(s_r)_{max} = \frac{f_{ct} d_b}{2 \tau_b \rho_{ef}}; (s_r)_{min} = \frac{1}{2} (s_r)_{max}; (s_r)_{ave} = \frac{(s_r)_{max} + (s_r)_{min}}{2}$

### 5.3 Finite element modelling

This section deals with the finite element analysis of the flexural time-dependent behaviour of SCC and FRSCC slabs. A new finite element model procedure is developed using the commercial FEM program ATENA based on the proposed material properties, bond-slip, and creep and shrinkage constitutive models (proposed models can be found in Aslani and Nejadi (3, 13-14) and Aslani (5)) for SCC and FRSCC. In the FEM parametric study, mentioned proposed models for SCC and FRSCC are used together with the default ATENA models, to simulate and analysis of instantaneous and time-dependent cracking behaviours SCC and FRSCC one-way slabs. General and mesh views of slabs modelled in ATENA are presented in Figure 5.

**Figure 5. General and mesh views of slabs modelled in ATENA.**

The parametric study methods are as follows:

1. Using the default models of ATENA program (i.e. CC3DNonLinCementitious2 for material, CCModelB3Improved for creep and shrinkage, and bond-slip).
2. Applying default ATENA's CCModelB3Improved creep and shrinkage model then using the CC3DNonLinCementitious2User by utilizing the proposed models presented in Aslani and Nejadi (3), and default ATENA's bond-slip model.

3. Using default ATENA's CCMoelB3Improved creep and shrinkage model then using the CC3DNonLinCementitious2User and bond-slip model by utilizing the proposed models presented in Aslani and Nejadi (13, 3).

4. Using proposed creep and shrinkage models by utilizing the proposed models in presented in chapter 4 and using the CC3DNonLinCementitious2User and bond-slip model by utilizing the proposed models presented in Aslani and Nejadi (3, 13-14).

The results from parametric study have been presented in Tables 7 and 8. The results show that by using each proposed model (e.g. material properties, bond-slip, and creep and shrinkage), accuracy of the crack widths and deflections prediction increased. Also, when the analysis is combined with the proposed models the accuracy of the crack width and deflection prediction is in the best agreement with the experimental results. Typical FEM analysis result is shown in Figure 6.

## 6. Conclusions

In this study, cracking in reinforced SCC and FRSCC slabs with particular emphasis on the development of flexural cracking due to the combined effects of constant sustained service loads and shrinkage have been investigated both experimentally and analytically. The results have been compared with the CC slabs flexural cracking behaviour available in the literature. Also, this study provides a rational method for designers to control flexural cracking in reinforced SCC and FRSCC slabs and thereby improve the serviceability of concrete structures.

The crack widths calculated in accordance with proposed models and FEM at steel stress levels up to 250 MPa shows that predicts crack widths which are in good agreement with the measured experimental results at all steel stress levels. Also, long term deflections were accurately modelled with a maximum error of about 5% and the models showed appropriate flexural cracking behaviour.

**Abstract:** This paper describes the initial steps towards the development of a foam concrete-aerogel composite for thermal insulation in lightweight sandwich facade elements. Fire safety is an important issue pertaining insulation materials. Therefore, the need for low-density inorganic, non-flammable materials is rapidly increasing. Foam concrete is a lightweight material with good thermal characteristics; densities as low as 400 kg/m<sup>3</sup> and thermal conductivities as low as 100 mW/m·K can easily be achieved. The main advantage when compared to typical inorganic insulations (e.g. autoclaved aerated concrete or mineral wool) is that foam concrete has a much lower embodied energy, in particular due to the simplicity of the manufacturing process. However, in order to be competitive as an effective insulation material, the thermal conductivity needs to be drastically reduced which can be achieved by reducing the density and by incorporating silica aerogels (both measures affecting the compressive strength).

**Keywords:** Foam concrete, aerogel, insulation, facade, fire safety.

## 1. Introduction

The redirection of the construction sector towards Sustainable Construction is the core of the EU 2020 strategy, mainly through increased energy savings in buildings. The major goal is that by 2050, new buildings shall become energy neutral and have zero CO<sub>2</sub> emissions.

The building stock in Europe is around 160 million buildings, 70% of which built after 1945, thus with major potential for retrofitting applications. Residential buildings represent about 80% of the total building stock, where multifamily houses and high rise buildings account for 47% of the total number of building stock in EU25.

In a building, it is assumed that about 20% of the total embodied energy is associated with materials and transportation whereas the remaining 80% is consumed at the user stage. Thus, it is important to consider the user stage when considering the total energy use. This means that the buildings shall have low embodied energy, low weight of construction materials and enhance thermal properties. Breakthroughs will be in the area of the application of nanomaterials for the development of multifunctional products and components in order to address energy efficiency, fire resistance and living comfort aspects with processes that are more robust and cost-effective.

The most important part of a building from an insulation perspective is the building envelope. One way to decrease the energy consumption in buildings and thus increase the energetic efficiency of the building envelopes is by improving the thermal insulation. Better insulation materials in terms of performance, durability and embodied energy are therefore required. This concerns both new buildings as well as refurbishment applications.

### 1.1 Project concept

Facade elements made of concrete have a long tradition in the built environment. Typical pre-fabricated concrete sandwich elements are very heavy and thick; they consist of an outer panel (80-100 mm thick) made reinforced concrete, an insulation layer (100-200 mm thick) in EPS or mineral wool and an inner load-bearing panel (100-150 mm thick) made of reinforced concrete.

There is a huge and growing demand for new solutions concerning the energetic retrofitting of buildings made of this type of prefabricated sandwich elements. Such solutions should not only be energy efficient, but also fire safe as well as promoting a healthier indoor environment.

The SESBE project (*Smart Elements for Sustainable Building Envelopes*) aims to develop new lightweight façade elements that are energy efficient, non-combustible and have multifunctional properties. The new sandwich elements totally based on inorganic cementitious materials, use carbon fibre reinforced reactive powder concrete as structural material and aerogel modified foam concrete for the insulation layer. In addition, the project proposes cost-effective use of nanomaterials and nanotechnology as a tool to custom design functional and performance properties such as easy-to-clean/self-cleaning surfaces, increased heat reflectivity by a heat reflective layer and moisture control in the insulation using nano-clays.

## **1.2 Foam concrete: a fire-safe insulation material**

Foam concrete, also known as cellular lightweight concrete (CLC), can be defined as a cementitious material with a minimum of 20% by volume of mechanically entrained air in the fresh cement paste or mortar [1]. It differs from autoclaved aerated concrete (AAC) in which the spherical voids are chemically generated by the reaction between aluminium powder and the alkali hydroxides in the cement.

The basic components of foam concrete are cement, sand, water and foam (water, air and a surfactant). Typically, the air content varies between 40 to 80% of the total volume with void sizes ranging from 0.1 to 1.5 mm in diameter, although coalescence can produce larger voids, especially at lower densities [2]. Although the composition of the cementitious matrix and air void content influences the properties of the material, there is a good correlation between the dry density and compressive strength, typically varying between 400 and 1600 kg/m<sup>3</sup> and from 1 to 10 MPa, respectively. Due to the low density and highly porous structure, foam concrete presents good functional properties such as fire resistance, thermal conductivity and acoustic performance; for example, at a density of 400 kg/m<sup>3</sup>, the  $\lambda$ -value is approximately 100 mW/(m·K).

Due to its pumpability and self-compacting behaviour, foam concrete is majorly used as filling material for sealing sewage pipes, wells, mines, storage tanks and tunnels. Other applications include: soil stabilisation; bridge abutments; floor and roof screeding; road sub-bases; insulation of foundations in industrial and domestic housing; sandwich fill for precast units and concrete blocks [2].

So far, in building applications, the use of foam concrete is limited to social housing projects where a large number of units need to be produced in a short time and where densities of around 600 kg/m<sup>3</sup> constitute an affordable and sustainable alternative when both structural and insulation characteristics are required. To our knowledge however, the use of foam concrete as a high performance insulation material has not been proven.

The reason for using foam concrete in the SESBE project is to increase the fire-safety of the sandwich elements by developing a non-flammable inorganic insulation material. Standard insulation materials present several disadvantages: organic materials such as polystyrene (EPS/XPS) and polyurethane (PUR) are highly flammable and release toxic fumes during fire; inorganic materials such as mineral wool, although non-flammable, have a large embodied energy due to the high temperatures during the production process; state-of-the-art vacuum insulation panels (VIP) are expensive and require cautious handling and installation in order not to be perforated leading to the potential loss of their insulation properties.

As mentioned previously, the  $\lambda$ -value of foam concrete with a density of 400 kg/m<sup>3</sup> is around 100 mW/(m·K). In fact for such low density cementitious foams nearly all data available in the literature reports to the thermal performance of chemically generated foam concrete. Proshin et al. [3] reported thermal conductivities in the range of 60 to 160 mW/(m·K) for foam concretes, partially filled with polystyrene beads, with densities between 200 and 650 kg/m<sup>3</sup>. Akthar and Evans [4] reported values of 110 and 135 mW/(m·K) for cement foams with densities of 193 and 220 kg/m<sup>3</sup>, respectively. Finally, Zheng and Chung [5] reported thermal conductivity of 46 mW/(m·K) for a density of 152 kg/m<sup>3</sup>.

Silica aerogels are nano-porous heterogeneous solid materials, with pore diameters in the range of 1 to 100 nm. Aerogels consist of approximately 90 to 95% air in volume and therefore have low densities (80 to 150 kg/m<sup>3</sup>) and very low thermal conductivities (12 to 25 mW/(m·K)). Due to its nano-porous structure, they possess a very high specific surface area (up to 800 m<sup>2</sup>/g). Typically, aerogels are produced via a super-critical drying process meaning that they are often quite expensive. However, in the SESBE project, aerogels produced via the ambient pressure drying method [6] will be used contributing to the competitiveness of the final insulation product.

The incorporation of aerogels into the foam concrete is expected to significantly decrease the thermal conductivity. In a study by Serina et al. [7], the  $\lambda$ -value of a UHPC formulation decreased from 2300 to 310 mW/(m·K) when 80% in volume of aerogel was used (the density of the UHPC-aerogel composite was around 800 kg/m<sup>3</sup>). In another study by Hub [8] a cement paste containing 75% in volume of aerogel showed a  $\lambda$ -value of 61 mW/(m·K) (the density of the composite was around 370 kg/m<sup>3</sup>).

The main goal of the SESBE project is to develop a foam concrete-aerogel composite insulation material with a thermal conductivity around 30-35 mW/(m·K) at a density of about 150 kg/m<sup>3</sup>.

## 2. Material development

At present, the material development consisted on the selection of the type of cement most appropriate for the production of very low density foam concrete, design of the basic mix (w/c ratio, superplasticizer) and incorporation into the foam. The main goal was to characterize the state-of-the-art foam concrete (to be used as a reference) as well as the new formulation, with regards to the following fresh and hardened properties: density ratio, i.e. fresh density/design density (as an indicator of the homogeneity of the final mix); stability (tendency to collapse); compressive strength and thermal conductivity.

There are two main types of foaming agents used for the production of foam concrete; protein-based and synthetic. Protein-based foam is in general more stable than synthetic foam; however, protein-based foaming agents have a foul smell and dark brown colour, leaving a sticky residue after drying. The resulting foam has a pale yellow colour; the odour is present in the foam and can linger in the foam concrete for a long time after production, subject to drying conditions and ventilation. Because proteins are organic substances, foam concrete made with protein-based foam has a greater tendency to facilitate mould growth and other microorganisms and for that reason should be avoided in residential and commercial buildings. Synthetic foams on the other hand are odourless, bright white and dissolve easily in water without leaving any residue. For this reason, in this project, only synthetic foam was used.

In the first stage of design of the basic mix, a multi-binder system based on CEM I 52.5 R and incorporating high volume of mineral additions was tested. Table 1 lists the materials and mix proportions for the foam concrete developed. Most of the foam concrete mixes collapsed within the first 2 to 4 hours after casting and only 2 out of 16 could be tested for compressive strength. In most cases, the plastic density was below the design density. A number of possible reasons for the behaviour of the mixes tested are pointed:

- Due to the high viscosity of the cementitious matrix, homogenization of the foam concrete becomes difficult resulting in segregation. Depending on the level of segregation of the mixture, this leads in the first place to lower densities than design and eventually collapse as the cell structure is not able to support itself (not enough binder);
- The fact that some of the mixes didn't harden means that there is an unbalance between the amount of cement and the volume of mineral additions in the mixture. When water is added to the cement, the main products from the reaction are calcium hydroxide (CH) and calcium-silicate-hydrates (CSH-gel). Additionally, other alkali-hydroxides are formed; these are important to activate the pozzolanic reaction and contribute to the strength gain (setting and hardening) of the concrete;
- Silica fume, metakaolin and quartz filler have a higher specific surface than cement requiring more water. This water can be taken from the foam leading to segregation and eventually collapse;
- The high volume of mineral additions (mainly fly ash and metakaolin) and quartz filler negatively influences the stability of the foam concrete since it increases the setting time, thus increasing the tendency to collapse.

**Table 1. Mix proportions for foam concrete based on multi-binder system (in kg per m<sup>3</sup> of foam concrete).**

Material	CEM	SF	FA	MK	QF	Sand	Acc	SP	w/c	Foam (l)	Design Density
(kg/m <sup>3</sup> )	44-148	14-37	22-59	22-35	28-71	129-318	2.8-5.6	0.4-7.1	0.3-0.5	690-910	250-700

SF, silica fume; FA, fly ash; MK, metakaolin; QF, quartz filler; Acc, accelerator; SP, superplasticizer

Given the unsucceeded first stage, a second approach was based on a single-binder system. For that, 4 different cements were selected and tested. Table 2 lists the materials and mix proportions for the foam concrete developed. For each cement, at least 3 different series, i.e. 3 different densities within the range shown in Table 2, were produced. The results clearly indicated that some of the cements were not suitable for the formulation of low density foam concrete. Except for CEM I 52.5 R SR3-LA, all other cements led to collapse of the foam concrete, presumably due to the following reasons:

- Despite the fast setting time, CEM I 52.5 R is not suitable for the production of foam concrete mainly due to its high alkalinity which interacts with surfactant leading to the collapse of the foam;
- CEM I 52.5 R SR3-LA is also a rapid hardening cement but with a much finer particle size distribution and lower  $d_{50}$  (4-5  $\mu\text{m}$  as opposed to 15-16  $\mu\text{m}$ ) when compared to CEM I 52.5 R. This fast setting associated with the low alkalis content enables the production of low density foam concrete;
- CEM II/A-LL 42.5 R and CEM II/A-V 52.5 N are not suitable for the production of very low density foam concrete. Both cements include around 16% mineral additions (limestone and fly ash, respectively), with prolonged setting time which might lead to collapse of the foam.

**Table 2. Mix proportions for foam concrete based on single-binder system (in kg per  $\text{m}^3$  of foam concrete).**

Material	CEM I 52.5 R	CEM I 52.5 R SR3-LA	CEM II/A-LL 42.5 R	CEM II/A-V 52.5 N	SP	w/c	Foam (l)	Design Density
( $\text{kg}/\text{m}^3$ )	278-299	155-300	153-296	152-175	0.4-1.5	0.3-0.4	800-890	250-450

### 3. Material properties

Based on the results from the second stage of development of the mix design, CEM I 52.5 R SR3-LA was selected for further studies of material properties. The w/c ratio was set to 0.35; the superplasticizer to 0.5% by mass of cement and, for lower densities, the use of accelerator was set to 5% by mass of cement. The objective was to evaluate the dependency of the compressive strength and thermal conductivity with density. Table 3 shows the mix proportions for foam concrete of different densities.

**Table 3. Mix proportions for foam concrete of various densities (in kg per  $\text{m}^3$  of foam concrete).**

Material	Design Density ( $\text{kg}/\text{m}^3$ )					
	800	600	500	400	300	200
CEM I 52.5 R SR3-LA	572	413	338	266	186	109
Superplasticizer	2.8	1.9	1.6	1.3	0.9	0.5
Accelerator	x	x	x	x	x	5.4
Water	200	145	118	93	65	34
Foam (l)	615	722	773	821	875	926

#### 3.1 Compressive strength

The compressive strength was measured on foam concrete cubes 150 x 150 x 150 mm at the age of 28 days, according to EN 826 [9]. As expected, the results in Figure 1 indicate a clear dependency of the compressive strength with the density of foam concrete. Although foam concrete is intended to be used as insulation material and therefore serves no structural purpose, it is still important to quantify the compressive strength because during manufacturing, transportation, assembly and usage, the material will be subject to some mechanical loads. The apparent linear relation between compressive strength and density is, in the present case, the result of a common base mix for all the densities tested.

Yet some scatter can be observed, as a result of the manufacturing process, e.g. differences in the mixing time between foam concrete of different densities. Similarly low values were obtained by Tonyan and Gibson [10] who reported compressive strengths of 0.04 and 0.12 MPa for foam concrete with densities of 160 and 224 kg/m<sup>3</sup>, respectively, while higher values were reported by others: Zheng and Chung [5] reported values of 0.5–0.9 MPa for densities between 130 and 190 kg/m<sup>3</sup>; Van Deijk [1] reported a value of 0.6 MPa for a density of 240 kg/m<sup>3</sup> and in ACI 523.1R [11], 0.48 MPa were obtained for a density of 240 kg/m<sup>3</sup>.

Figure 1. Compressive strength of foam concrete as a function of the density.

### 3.2 Thermal conductivity

Thermal conductivity measurements were performed in foam concrete plates 400 x 400 x 50 mm, according to EN 12667 [12]. The results in Figure 2 show that there is a fairly good linear correlation between  $\lambda$ -value and density. Note that, without the aerogel, the thermal conductivity of the foam concrete with a density of 130 kg/m<sup>3</sup> is 46 mW/(m·K). These results are in line with those reported in the literature (see section 1.2). Naturally, there is some variability of the results which is associated to the mixing process and the air-void size and distribution. Depending on the density, there is a dominant pore size, which increases as the density decreases (see Figure 3) due to the higher quantity of foam used. In addition, other factors such as coalescence voids (mainly at low densities) and degree of hydration (note the presence of large unhydrated cement grains in Figure 3 middle) will have an impact on the thermal properties of the foam concrete.

As a first trial, 50% in volume of aerogel was also incorporated into a cement paste. The thermal conductivity of the aerogel particles is approximately 20 mW/(m·K). The result in Figure 2 show a reduction of more than 60% in the  $\lambda$ -value when compared to the reference and that this value lies clearly below the  $\lambda$ -value versus density trend line.

Figure 2. Thermal conductivity of foam concrete as a function of the density.

Figure 3. Pore sizes in foam concrete of various densities.

#### 4. Conclusions

The present paper reports the preliminary results towards the development of a foam concrete-aerogel composite material to be used as thermal insulation in lightweight sandwich façade elements.

A multi-binder system based on minimization of cement clinker and replacement by high volumes of supplementary cementitious materials was tested without success. It was found that such systems are not suitable for very low density foam concrete due to increased specific surface area which increases the water demand and delayed setting.

A formulation for very low density foam concrete was developed, based on single-binder system, using a commercial cement of the type CEM I 52.5 R SR3-LA. For a design density between 200 and 300 kg/m<sup>3</sup>, the cement content ranges from 110 to 190 kg/m<sup>3</sup>.

At a density of 130 kg/m<sup>3</sup>, the compressive strength is around 0.2 MPa and the thermal conductivity around 46 mW/(m·K). Preliminary experiments with aerogel incorporated into ordinary cement paste showed a reduction of the  $\lambda$ -value by more than 60%, for a degree of replacement of 50% by volume.

## 5. Future work

The work so far demonstrated that it is possible to produce very lightweight foam concrete with acceptable mechanical performance and good thermal characteristics. The incorporation of aerogels is expected to further enhance the thermal conductivity of the foam concrete, representing a competitive and safer alternative insulation material. However, the incorporation of aerogels is not expected without challenges.

Firstly, the mixing method must be optimized to ensure that the aerogel becomes part of the skeleton structure of the foam concrete rather than being entrapped in the air voids. Then, it is important that the aerogel maintains its physical and chemical integrity and is not destroyed (partially or totally) during mixing (shear action).

Secondly, the amount of aerogel needs to be optimized towards maximum performance at minimum level of incorporation, i.e. in a cost-effective way. This implies that modifications to the basic mix (in terms of w/c ratio, superplasticizer) might be necessary.

Thirdly, to achieve such low densities, the basic mix is composed only by cement (and aerogel). This means that the foam concrete is prone to chemical shrinkage and eventually cracking, as it is restrained by the inner and outer reactive powder concrete layers as well as mechanical connectors. In order to reduce the stiffness of the material, PVA fibers will be incorporated, the amount of which needs to be optimized with regards to the mechanical performance but without compromising the thermal performance.

Finally, acoustic performance and fire resistance tests will be carried to assess the suitability for use; aerogels are nanoporous materials which may significantly influence the sound transmission/absorption properties.

# Prefabricating in Unusual Environments

Marco Menegotto<sup>1</sup> and Luciano Marcaccioli<sup>2</sup>

<sup>1</sup>Professor of Civil Engineering, Sapienza University of Rome, Italy

<sup>2</sup>General Manager, Construction Division, Piccini Group, Perugia, Italy

**Abstract:** Three building projects were realized in environments that, given the local economic and natural conditions, were theoretically not fit for industrialized construction. Prefabrication, although not common in any of the respective contexts, turned out to be the key solution and, perhaps, the only way in which the projects could have been carried out, given the requirements in terms of quality, cost and timeframe. Completing the projects with traditional construction methods would have been, if not impossible, much more lengthy and costly, with lower quality results.

**Keywords:** Prefabrication, Environment, Climatic conditions, Concrete structures, Prestressing, Cellular concrete (non-autoclaved).

## 1. Introduction

The feasibility of structural prefabrication is commonly believed to be limited to industrialized areas, where it can offer its typical advantages in meeting construction needs. However, applications can be valuable and convenient also in areas that are far from any industrial environment, in particular when large projects are to be developed and insufficient traditional construction facilities are available nearby. In such conditions, prefabrication can prove more appropriate in meeting projects' requirements and in making the best use of the local technical and logistic means as well as of the local human and natural resources.

This paper aims at showing how the above can be put in practice by presenting three case studies in which the authors were involved from the conceptual stage and throughout the planning, design, production and construction, and where optimum solutions were developed for both the building features and the construction processes.

In all these cases, the final option was precast concrete; structural systems and production procedures customized for the individual cases were conceptualized, and "unconventional" prefabrication plants reflecting the needs of each specific environment were installed. All projects were completed successfully.

Since then, the buildings in object have been in use, showing how the solutions adopted in the different cases proved to be successful, not only with respect to their structural features.

## 2. Self-construction housing

### 2.1 Needs to meet

A housing project in the Costa Rican highlands, Central America, planned for low-cost self-construction by private individuals, was launched by the Government of Costa Rica in the early 1980s. At the time, the country was not industrialized and had practically no experience in prefabrication.

The project framework required that the local applicants owned a piece of land and that the government would contribute to construction expenses by providing "coupons" to people with lower incomes. The government's contribution was approximately US\$ 4,000 per low-income family and was directed at supporting procurement of required materials.

Requirements were rather specific and directly related to the social and natural environments in which the projects were to be developed. While realizing a low-cost self-construction system for individual family houses was considered to be the main goal, security was also a requirement, including protection from the intrusion of small animals. With temperatures ranging always within 22-27 °C, climate conditions posed no problems for thermal insulation, but protection against the very intense daily rainfall was needed.

The devised design was based on very light load-bearing precast concrete wall panels, which constituted the core part of the solution through realizing inner and outer partitions with the required structural performance and protection functions.

## 2.2 The construction system

The construction system was composed of precast pre-stressed concrete panels with a very thin ribbed cross-section (30-60mm). The structure was made of those panels, clamped in a channel to the foundation, also made of U shaped small precast concrete units, and linked together on top by a wooden rod. Moreover, wooden truss-beams supported a light roof as well as forming a horizontal diaphragm. The light weight structural elements allowed their movement, handling and erection by a small number of unskilled persons, without the need for machinery or lifting equipment. A complete single-family house could then be easily built by the end-users with some external assistance in the shortest possible period.

The main features of this system are: safety, dimensioned against wind and seismic actions (in fact, resistance to both vertical and lateral actions is distributed along the whole base, yet continuous, contrary to most systems); security (concrete walls); flexibility of layout and ease of adding rooms for enlarging the house; economy (self-construction); last but not least, pleasant look.

The system consists of a series of precast prestressed concrete elements, the dimensions of which are shown in fig. 1. The production system was a purpose made long line pre-tensioning bed. The industrial components are panels and clamping rails, embedded into a cast-in-situ raft foundation, quite simple and easy to build, thanks to the lightweight construction. The other building elements were the roof, normally made of timber trusses with metal sheathing (according to local customs and abilities) and complementary finishes (doors, windows, floor finishes, false ceiling, piping), all items that could be handled and installed by the end-users themselves, with the help of craftsmen, possibly available within their community.

**Figure 1. Plan cross section of a typical wall panel (mm) and edge dry connections schemes**

Typical elements have a standard height of 2.6 m, with part heights used to create openings (fig. 2).

**Figure 2. Plan and isometric view of assembled walls**

Concrete is added with propylene fibers, allowing very thin sections with high level of resistance to cracking and failure, pre-stressed with 2x4mm + 2x3mm indented wires and reinforced with steel bars. It is designed to develop sufficient early strength to release the wires at 12 hours after casting under summer conditions, without use of heat. During winter, 2-4 hours of heat is used, to ensure a daily production cycle.

Panels are divided into five types, with sub types, allowing for a very large number of choices for internal distribution of areas as well as window positions.

The joints between the panels are dry type; expanded bitumen polyurethane band can be placed between the joints, to prevent any seepage. The connections to the foundation, by filling the channel with mortar, are structural, as well as those with the top rod and realize fixed end restraints (fig. 3).

**Figure 3. Assembly sequence of a house**

The precast panels offer smooth finishes on both sides, ready for painting, which allows to give the finished house a pleasant aesthetic appearance, as shown in figure 4.

**Figure 4. A typical house built according to the system: a) structure completed; b) finished**

More than 1,200 houses were built using this very effective system for low-cost housing, under the umbrella of the mentioned government grant program.

### 3. In the desert

#### 3.1 Boundary conditions

Gas fields located in the middle of the Sahara desert in Algeria, where exploitation was mobilizing in the early 1990s, needed dwelling, social and service buildings for large worker settlements. Surroundings were lacking access roads or basic facilities; materials and supplies including natural coarse aggregates for concrete, were only available at locations over one thousand kilometers from the sites.

The main requirements included resistance to wind and seismic actions, thermal insulation, construction speed. The work was not limited to personal dwelling but also included social buildings and workshops.

The ideal structural solution would involve loadbearing walls, for providing stiffening elements and acting as cladding, partitions at the same time. Ultimately, a design solution was devised to use precast concrete loadbearing panels and solid slabs.

At first stage, two villages (one of them appearing in fig. 5) were built, with forty dwelling buildings, six social buildings (for meetings, healthcare, religious functions, shopping, restaurants, ...) and ten workshops were built using lightweight cellular (foamed) non autoclaved concrete for walls and slabs. On the other hand, for a limited number of additional elements in areas requiring ample and unobstructed free space, standard precast concrete frames with columns, beams and roof elements were used. Throughout, the panels performed an important structural function, either providing both bearing and lateral resistance, in one or two-story buildings, or being only large cladding wall panels for lateral stiffening of the R/C frames. Moreover, foamed concrete was used for the foundations, sensibly reducing their cost.

Figure 5. Workers' settlement near gas fields in the Sahara desert

Given the lack of coarse aggregate, concrete was made with local sand (sieved and washed), cement, superplasticizer and foam, with the great advantage of achieving a low density product. This generated two decisive features: low self-weight of the elements, making the application possible for slabs as well, and very good thermal properties (mass and conductivity combined), making additional insulating material unnecessary. It is worth noting that temperatures in the area reach up to 55 °C.

Figure 6. a) The prefabrication plant; b) oversized units

As the performance proved to provide optimum results, a prefabrication plant was first built (in steelwork) on the site (fig. 6a), followed by a quick start in precast element production. It should be noted that the transport of the precast elements was possible without problems on the existing desert tracks, including the transport of oversized elements (fig. 6b).

### 3.2 Structural system

The use of foamed concrete as a structural material was not in the scope of structural standards and codes at the time. Therefore, ad hoc rules were agreed with the authorities and the client. In fact, the system was to be used for one- and seldom for two-story buildings with short floor spans, making the solid panels subject to low-level stresses in service. Specific tests were made to assess properties like strength, elastic modulus, behavior under long term loading and bond with rebars.

Foundations of dwellings were 0.30 m deep rafts with a similar concrete, of a density of  $1800 \text{ kg/m}^3$ , cast in-situ.

Precast elements were made of cellular concrete of  $1600 \text{ kg/m}^3$  with a compressive strength (cubic) of  $15 \text{ N/mm}^2$ . External walls were precast panels 3.2 m high and 250mm thick, providing a coefficient of thermal conductivity of  $K = 1.4 \text{ kcal / m}^2 \text{ h } ^\circ\text{C}$ ; internal partitions are 160mm thick. Upper floor or roof are made of 200mm deep solid slabs of the same concrete, simply supported on four sides by internal and external wall panels, with spans less than 4m; roofs were in some cases sloped as well as the top of their bearing panels (Fig. 7)

Figure 7. Scheme of a typical house and plan of the roof with the points of connection to walls

Figure 8. Finished houses, and a foundation raft for an additional one

Connections were specially devised for maximum simplification, taking advantage of the low level of stressing. Vertical joints between panels were continuous recesses of 25 x 80 mm on both sides, without keys for vertical shear, filled with mortar and relying on adhesion only. In fact, they are not required to perform a structural function, i.e., walls do not need to be connected to form **T** or **I** cross-sections. Joints were finished and closed with sealants. Supports of wall and slab panels rested on a thin layer of mortar and they interacted as a whole in a boxed system behavior that was ensured by vertical pin rods protruding from the wall panels into holes of the slabs, wide enough to account for all tolerances and again filled with mortar. Verifications against wind and seismic actions showed that the walls did not need to be anchored to the foundation, in the absence of tensile resultant forces. Joints between slab units, welded in two points and filled with mortar, ensured the compatibility of deflections. For two-story buildings, the rods continued throughout the slab and into the upper wall panel.

**Figure 9. Typical panel-to-panel connections (1-6: horizontal cross-sections) and panel-to-roof connections (7: vertical cross section; 8: plan view)**

In this way, a typical “non-emulative” system was built up, with elements connected to each other by means of linear hinges.

Panels were also molded with decorative reliefs depicting local architecture and then painted, as shown in the figures below.

**Figure 10. Examples of houses built with cellular concrete precast wall panels**

The system proved to be effective from all standpoints: construction speed, economy, quality and overall efficiency. Further settlements were then constructed.

## 4. In the equatorial rain forest

### 4.1 The environment

The project was a large conference center and hotel compound, located within the African rainforest in Equatorial Guinea, about 200 km from any town or even road, at the moment.

It was the first ever construction to take place in an region where the completely new metropolitan area of Oyala was planned to be built.

The site, a river peninsula, was previously fully covered by a dense rainforest jungle, making the work on the final layout only possible after site clearing (fig. 11).

**Figure 11. General plan of the compound with hotel, conference center, park and villas**

Temperatures in the area are not extreme but rainfall is, with 3,100 mm per year, which may be critical for the works planning and invites to reduce outdoor operations.

To cater for the Project's size, installing a prefabrication plant in the vicinity, in spite of the difficult and adverse surrounding conditions, was identified as a sound and ideal investment.

Firstly, the presence of source of natural aggregates needed to be identified and, fortunately enough, optimum quality and abundant granite was found in a nearby location. A quarry was established as well a high capacity crushing plant, producing fine and coarse aggregates.

As for the project in the Sahara desert described above, short range transportation was rather easy and oversize was not a problem for the units' transport to the working site, whereas long range transport was problematic.

The compound comprises a five-star-luxury hotel with 450 rooms, suites, restaurants, roof gardens, shops, fitness center and SPA, business center, underground car parks and all related services, as well as a congress hall, a medical clinic, and outdoor resort amenities like a 18 holes golf course, swimming pools and tennis courts, with a built up area of 150,000 m<sup>2</sup>, within an area totaling 250 hectares.

Fifty high-standard two-story individual "villas", 700 m<sup>2</sup> each, are also part of the compound.

## 4.2 The buildings

Figure 12. The five-star luxury hotel and conference center – front view

Figure 13. Plan of the hotel and conference center

Regarding the structures, the production of high quality precast concrete, with a compressive strength of  $50 \text{ N/mm}^2$ , was made possible by the mentioned conditions and the design was performed together with the study of the elements required.

For the hotel, the foundations were a grid of surface beams, cast in place, as well as the columns of the underground garage and the first level. The upper part is divided in blocks, up to 8-story high, made of precast frames and cast-in-place stairs-elevators shafts. The latter provided most of the resistance to lateral forces of the whole construction. All floors were constructed using precast pre-stressed hollow-core slabs.

All connections were of a wet type, with overlapped or welded reinforcement, in order to achieve a continuous “emulative” concrete structure, i.e., matching the behavior of fully cast-in-situ structures. The façade was also made of precast concrete elements. Only the hall’s roof and its inner flyovers were in steelwork.

Structures of the villas (fig. 15) were also made of precast load bearing wall panels.

**Figure 14. Hotel's structural 3D model and a construction phase**

**Figure 15. One group of the villas, built with precast concrete panels,**

Most interesting is the construction of the prefabrication plant itself. Contrary to the previous case, this was built with precast concrete elements. In fact, it is an example of self-prefabrication, within the jungle (fig. 16). After installing a crushing plant for the aggregate, a concrete mixing plant and the prestressing beds, pocket foundations, columns, pre-stressed beams and pre-stressed joists were produced for mounting the plant's 10,000 m<sup>2</sup> hall itself.

**Figure 16. The plant during its own "self-prefabrication"**

What was called “self-prefabrication” of the plant was chosen for two main reasons: (i) the high local cost of steelwork compared with concrete produced on site and (ii) the possibility of training local unskilled personnel with the prefabrication techniques.

**Figure 17. The 10,000 m<sup>2</sup> prefabrication plant in full operation**

Thereafter, the plant became operational for the construction of the compound (fig. 17). Later on, it has been used for other projects nearby.

## **5. Conclusions**

Structural prefabrication has been thought often as a means for selling closed systems. In fact, little of this remains at that stage. Through research and application, concrete prefabrication, has significantly advanced over the decades and has succeeded in overcoming many challenges, being adopted in the rarest and most difficult environments, too.

In this respect, the cases presented above show how it has been possible to build concrete structures with special requirements in unusual environments, that could have hardly been met using traditional means. The case studies illustrated in the paper are examples of the ability to adapt to local resources, which is a way of transforming imagination and theoretical research into actual and practical realizations. This without forgetting the typical advantages of prefabrication, such as the quality of the final product and the speed of construction.

In the examples shown above, prefabrication made the projects feasible, where traditional construction techniques would have encountered overwhelming obstacles, making such undertakings extremely difficult and perhaps even unachievable.

Paradoxically, in a non-industrialized context, prefabrication can be by far the best if not the only solution for uncommon construction. The authors keenly await further opportunities for getting involved in other unusual environments in which, by facing different conditions and challenges, they could once again test and confirm this statement.

# Paddington Rail Station

George Jones

Member of *fib* Commission 6

Director, Commercial Design Concepts Ltd (CDC Ltd)

**Abstract:** The Paddington Rail Station is at the London end of the First Great Western Line from Bristol. The station is presently undergoing major renewal and expansion as part of the Crossrail project. It is one of the largest and most significant infrastructure projects being undertaken in Europe.

Part of the Station extension involves the installation of precast concrete ceiling panels then the use of “top down” construction from ground to track level, enabling work at ground level to be carried out as excavation proceeds.

The Station has significant geometrical complexity and the use of BIM modelling was essential to achieve the satisfactory coordination of services within the concrete envelope. The complex, but regular, ceiling profile favoured the use of precast concrete to achieve the required consistency of finish and profile, and to maximise the benefits of repetition.

**Keywords:** Railways, Precast Concrete, Top Down, BIM

## Project Background

A new station is being constructed and integrated with the existing Paddington Station as part of the Crossrail project across London. The mainline Paddington Station was at the eastern end of the First Great Western Line, undertaken by Isambard Kingdom Brunel and opened in 1854. The existing station is a central London railway terminus and London Underground station complex served by four underground lines. It is also the London gateway for international passengers arriving from Heathrow.

**Figure 1: Architect's section through new station**

## Selection of Precast Concrete for Ceilings

The ceilings to the main platforms and concourse areas are formed as curved coffers with lighting at the top of the curve of each coffer. The coffers are of consistent profile and are set out in regular patterns. Fair and consistent finish for the ceilings is a contract requirement. This could only be achieved economically using precast concrete.

In order to limit the amount of mouldage and to achieve consistency the coffers were cast individually through repeated use of the same moulds, and installed in the required patterns. Each coffer had a plan area of 2.5m square and depth of 160mm. A total of 1132 precast ceiling elements were supplied as part of the contract, of these 286 were coffered units. The original cast in place scheme required 180 coffer moulds to meet both programme and quality targets. The precast solution used only four glass fibre coffer moulds.

**Figure 2: View of part of ceiling from platform**

The trackside platform is over 250m long and the coffered ceiling fully covers the platform area. Cast in place concrete is provided over the tracks themselves.

The precast concrete coffers act as permanent formwork to a structural slab of varying depth between 1500 and 1800mm. The coffers are designed to withstand the construction loading from cast in place concrete and also the possibility of blast loading during service.

In order to accept precast concrete as a solution for the ceilings Crossrail required a full size mock-up of a typical bay to be constructed at the Contractor's precast production facility. The mock-up had to take account of construction conditions and incorporate all the service conduits required. The Contractor was using "top down" construction (See later section also). Therefore, to reflect the site conditions each precast slab spanned between temporary supports onto white neoprene bearing strips to provide an even bearing surface and minimise marking from the bearing medium. A slab of 1800mm depth was cast onto the precast concrete permanent formwork.

The mock-up result was considered satisfactory by Crossrail and precast concrete coffers were accepted as the solution for achieving the specified ceiling finish and profile.

## Use of BIM Modelling for Precast Coffers

Close coordination between the precast concrete arrangement and the architectural layout was required to achieve the building form required by Crossrail.

It was decided at an early stage that the precast arrangement would need to be developed first, in line with general architectural and service parameters, and the finer detail relating to services and finishing was then integrated into the precast arrangement. The Architect's early 3D model was used as a basis for the precast arrangement. A 3D model of the precast arrangement was then developed in close collaboration with the Architect and the Services Engineer, with the precast team taking the lead role at this stage. Services requirements were added to the precast model by the Design team to achieve a fully integrated solution.

Figure 3 below is an extract from the model and shows a top view of the precast concrete elements only, forming the ceiling above the station platforms, with all other building elements removed. Precast concrete vertical elements were also used to form the finished wall face alongside the main station escalators to achieve uniformity of finish. An intermediate level of coffered slabs above the Concourse is also shown in Figure 3.

**Figure 3: Precast model extract at platform ceiling/concourse level**  
(Top of coffered slabs shown at Concourse Level before receiving insitu structural slab concrete)

The formwork requirements were challenging, and a model of the individual coffer was prepared and issued to the mould supplier. A master glass fibre mould was then produced by the supplier from his own 3D software, and thereafter three further identical moulds delivered to achieve profile consistency through the project.

Reinforcement detailing also became part of the BIM process with 3D versions of the coffer bar arrangement produced for fabrication by the precast producer. Structural design of the coffers was carried out using finite element software.

**Figure 4: 3D Model of Coffers Reinforcement**

Factory production rates exceeded site delivery requirements and project programme and budgetary targets were satisfied. Quality control and supervision had to be of the highest order to meet both aesthetic and technical requirements.

## **Top Down Construction**

Many projects in London now use “Top Down” as part of the construction process to avoid open excavations and allow other construction activities to run in parallel, which would be impossible using traditional methods.

“Top Down”, as its name suggests, involves firstly constructing at ground level and above, with work below ground following either later or in parallel.

To enable use of this method a temporary supporting system for the superstructure has to first be installed. In this case steel piles were driven to act as temporary columns (See exposed temporary steel piles penetrating the concrete ceilings in Figure 8 below). At permanent column locations the steel piles will be encased in insitu concrete forming an elliptical visual section. At other locations the temporary columns are removed once the permanent concrete columns are constructed and the slab penetrations closed with custom made precast concrete cover slabs matching the general ceiling finish.

The top surface level structure was then constructed onto the ground surface. Once the ground structural slab had reached a satisfactory strength the strata below was excavated to expose the ceiling. This approach involves greater risk with regard to achieving the required surface finish as an extra digging operation is introduced. Also, the surface is not exposed to view until many weeks after installation. Use of precast concrete minimises these risks as each element surface can be inspected before delivery and corrective action taken at an early stage before it becomes critical.

The main precast concrete ceiling is above platform level. Excavation was completed from Ground to Concourse Level and temporary concrete strip footings then poured to support the precast ceiling panels as shown in Figure 5. The panels were landed onto neoprene strips (See mock-up reference earlier), joints sealed, and then the main structural slab reinforcement cage fixed on top of the precast ceiling as shown in Figure 6 below. The structural slab was then poured.

**Figure 5: Section through a Precast Concrete Coffered at Concourse Slab Construction Phase**

Once the Concourse structural slab had acquired its design strength excavation beneath Concourse resumed. The temporary footings were removed as part of the excavation operation. The precast concrete ceiling was now mechanically anchored to the structural slab via vertical tie bars that had been coupled to the reinforcement in the precast ceiling elements; see projecting vertical anchor bars in Figure 4.

Distribution of the precast elements at underground levels had been achieved through use of a crane gantry system. Elements were delivered to a designated distribution point at ground level alongside a "mole hole". "Mole holes" were located along the station as points for vertical delivery and removal of materials from the underground site. After delivery below ground by tower crane the elements then had to be distributed horizontally to their individual locations using the crane gantries. A gantry can be seen in the background in Figure 6.

Following completion of the Concourse structural slab an intermediate ceiling above was installed using traditional methods supported from the completed structural slab below.

**Figure 6: Structural slab reinforcement being fixed on precast concrete ceiling panels**

An excellent result was achieved with the ceiling finish. The temporary supporting system along the panel edges had resulted in minimal panel deformations and surface blemishing.

**Figure 7: Exposed Coffers Slabs**

**Figure 8: Exposed platform ceiling**  
(Note temporary steel piles penetrating the concrete ceiling)

## **Conclusions**

A challenge arose to provide a high quality fair faced concrete ceiling at the new underground station at Paddington, London. There were a number of other constraints that included a pattern of coffered elements forming the ceiling, the integration of complex services and finishes, the production of a cost effective and risk reduced formwork system, and the accommodation of “top down” construction in the process.

Precast concrete was chosen to provide a high and consistent standard of finish, certainty of profile and minimal, highly repetitive, cost effective formwork. BIM modelling achieved the technical end result required through close collaboration with the Design Team. Finally, a highly professional team foresaw potential problems at an early stage, solved them and achieved a commendable result.

# PCI Design Awards Program

Jason Krohn, Precast/Prestressed Concrete Institute

Daniel Roman, Southern Illinois University

Karla Vazquez, Southern Illinois University

For over 50 years, the PCI Design Awards program recognizes design excellence and construction quality using precast concrete. The program has helped the design and construction community innovate and advance by showcasing ideas that push the envelope, overcome challenges, and improve upon existing concepts. The program demonstrates how designers are continuing to utilize high performance precast/prestressed concrete to achieve sustainable, more cost-effective, aesthetically-pleasing, and quickly-constructed projects. All winning projects are showcased at the PCI Convention and National Bridge Conference, as well as included in summary articles published in the PCI Journal, Ascent and Aspire magazines. Together these publications reach more than 60,000 industry stakeholders. There are entries from across the country and even international entries. In 2014 a couple international entries won and received honorable mentioned. The following winners are selected from the 2014 competition results.

The winner for the category of “The Best Government or Public Building” was Salas Regionales del Golfo, located in Veracruz, Mexico. The architect was Tribunal Federal de Justicia and the precaster was Pretecsa. The building is the legal system headquarters for the state government. The façade was made up of 373 architectural

**White architectural precast panels**

precast panels. The architect opted for the white and beige marble aggregates and light acid etched finished. It took approximate 60 days

to erect all 373 precast panels (5873.5 m<sup>2</sup>). Along with the precast panels, the structure also has large curtain walls that look over the exceptional surrounding views. The precast manufacturing started late May of 2012 and installation was completed in July 2012. By using precast concrete, the project was able to maintain a clean working environment and not allow pollution to spread to local areas. The quickness of the erection of the precast allowed for a quick closure, which aided against the bad weather that the site is prone to receiving.

Another successful project that took place in Mexico, this time in Mexico City, was the Kinder Monte Sinai, which won “The Best K-12 School”, the architect was LBR&A and the precaster was Pretecsa. A

**Precast panel wall installation**

grade school with many of the basic amenities but with a modern touch, it houses a library, main courtyard, and 18 classrooms that are elevated 11m from the parking lot. Out of the 18 classrooms, 12 are whitewashed

precast concrete panels with drippers, perfect round window cuts at various

**Main entrance of Regionales del Golfo,**

**The Kinder Monte Sinai with window cut outs on its façade**

elevations. To allow for this stacking effect, the architect needed a material that was light. Glass-reinforced precast concrete panels reduced the weight to about one-third in comparison to the competing material. The cubes required 285 very slim precast panels, which contained white marble aggregates and were hand polished. It took approximately two months to erect the precast.

From schools to malls, internationally precast is being utilized and is being pushed to new grounds, as in the following project. Fiber optics were taken into consideration when designing this precast structure. La Maison Simons is a mall located in Montreal, Quebec, Canada. Designed by LEMAYMICHAUD Architecture Design and the precast provided by BPD L Beton Prefabrique. Requiring a material that allowed the flexibility to install fiber optics into the walls, designers quickly looked into precast concrete. The fiber optics light up the structure throughout the day. A total of 140 white double wythe insulated panels were used. The molds were created with recesses in various locations. They had to be designed to accommodate rain and other inconveniences. The fiber optics were woven into the panels to activate the eye catching effect. A challenge that was encountered was that each mold had around 600 recesses. With different variations of the panels along with the recesses, different molds had to be made to accommodate for the design. The project had to be efficient and appealing to the client.

LED illumination of La Maison

An honorable Mention under the Multi-Family Housing was awarded to the Hotel Staff Accommodation in Dubai, UAE. The structure houses 320 residential units for employees for a local corporation. The whole structure was precast, from load-bearing walls to hollow-core slabs, and cladding. The cladding is insulated sandwich wall panels, with no thermal bridges. The 21,368 m<sup>2</sup> structure is located in a developing zone of the city. Precast is even more cost effective when designing in a modular manner. The designer took advantage of that and was able to reuse a lot of the same structure and aesthetics throughout the design. To make the living complex more visually pleasing, greenery was added along with a pool and a green terrace. The precast erection took place from March 2013 to August 2013.

Top: Main entrance to Boeing Center  
Bottom Right: Boeing Center corner condition

particular project, which in fact is able to withstand hurricane forces. At approximate 30.5 m tall, it is the tallest building in the museum campus. They needed to enclose the building quickly to continue working on what the interior

The winner of the Government or Public Building was the U.S. Freedom Pavilion/The Boeing Center at the World War II Memorial. This project is part of an addition to an ongoing expansion to the museum in New Orleans, Louisiana, USA. The designer, Voorsanger Mathes LLC, used interlocking precast concrete elements which allowed an interesting corner condition. Gate Precast Co, provided the precast for this

was going to house, actual aircraft that would hang from the interior structure. The erection time was from September 2012 to October 2012. The precast panels were designed without any 90 degree angles. Horizontal joints align but are tapered, and the vertical joints are offset. The flexibility of precast made for these aesthetically pleasing details to be created. In total 253 gray, light sandblast finish panels were used in the project. The typical height of the panels is 2.4 m, about 23 panels were over 12m long. One panel was over 15m long.

The Sanford Heart Hospital in Sioux Falls, South Dakota, USA, was the winner under the category of Healthcare/Medical Structure. Designed by AECOM and precast provided by Gage Brothers, the owner of Sanford Heart Hospital primarily wanted the building to be constructed of masonry. Due to its tight location and possible disturbance that a full crew of masonry workers would have to the area, the designers had to look for an alternative. Precast was the solution for such conflict. The use of thin-brick-clad precast concrete panels allowed for a close resemblance to the buildings in the area. By using precast, the owner was able to save over \$1 million US dollars and the building was completed about 3 to 4 months quicker. A couple months were taken in the manufacturing of the precast, but it only took a little over 20 days to erect all of the precast. There was about 936 pieces that covered about 11982 m<sup>2</sup>

Finish perspective of thin brick cladding of Sanford Heart Hospital's clock tower

Z parking structure, close to being done

Car parks have been constructed out of precast concrete for a very long time. Some architects are taking the design aspect and are having fun with the limitless possibilities that precast concrete can offer. The Z in Detroit, Michigan, USA, won the Parking Structure category. It is a multipurpose 10 level structure that holds 1282 cars with retail and restaurant space in the lower level. The exterior façade uses repetitive formwork to create a frame pattern. The pattern was designed to reduce the scale of the 10 level building. The precast was manufactured from January 2013 to November 2013 and the erection of the precast was from April 2013 to November 2013. Since a lot of the manufacturing is being done indoors, the winter exposure that workers had to endure was really low. In total there was about 2,385 pieces from columns, double tees, to architectural finish panels.

North East view of Brigham Temple

3D model utilized for construction planning and coordination.

The Religious Structure award was awarded to the Brigham Temple. The Architects from FFKR Architects were asked to design a temple with a stone façade. After calculating the cost and time frame it would take, they knew they had to go with precast concrete. With precast, they were able to obtain the look and quick construction all at a much lower price. The structure is clad entirely in sparkling white dolomite aggregate-based precast concrete panels. A total of 337 precast pieces were used: seven large panels were used to make the base; 100 panels were used for different ornamentation along the building site; and 230 panels were used on the main temple. The temple's spires are 45.7 m tall, that makes the temple visible from other local landmarks. "The architectural versatility and plasticity of concrete to accommodate several integral design features and create a complex façade of dramatic depth and bold character was

taken as an advantage" as one judge commented. The amount of detail that was integrated into the project would have been really hard to replicate with other materials or methods. There are about 40 different cornice details that were able to be reproduced to use again. A challenge, that was encounter during construction, were the steeples. Comprised of architectural precast "wedges", the tower was supported with interior steel framing and pre-assembled at the precast plant. When it was delivered they were lifted and attached to the structural. A 3D Bim modeling program was used to make sure all the design work

Ohio State University Chiller Plant located in Columbus, Ohio, USA, won the award for Best Custom Solution. The architecture firm Champlin Architecture worked with High Concrete group, the precasters, on this 10 story 5011 m<sup>2</sup> plant. Precast Concrete was utilized for its ability to be reproduced in

Shadows casted due to glass fins

such number of forms. There were 11 different forms that were used to produce about 200 different panels that went into constructing this building. These panels were arrange in such manner that allowed for fenestrations to view them inside but still able to keep the interior temperature consistent and the energy use regulated. The façade is more than just a concrete box, it also has a high polish finish and "fins" of diachronic glass. These "fins" cast different colors on to the concrete, and it varies on the time of day, season, and

Erection of custom sized precast panels

location of whoever is looking upon it. 3D modeling was used at different times during the project. In one occasion in which it was helpful was during the design of the connection between the steel and precast cladding. Over 100 of the connections were pre-connected to the steel frame as it was fabricated, which saved a lot of time during erection. The erection took from December 2011 to January 2012. According to the architect, “By using such a small number of panel types, a significant reduction in precast cost was realized because the manufacturer was able to utilize these forms multiple times, in lieu of constructing new forms.” The design team also wanted to design the largest size panels in order to accelerate the installation process. Transportation criteria dictated the final panel sizes. The size of the panels are 3.75 m x 9.1 m, with the top panels being 10.6 m tall to enclose the cooling towers. The precaster’s involvement during the design was key to the success of the precast work on this project.

Not all projects are meant to last forever; the G8WAY Pavilion in Washington, DC, USA, is a temporary structure that is a great example of how to utilize ultra-high performance concrete (UHPC). With Gate Precast providing the precast and Architect Davis Brody Bond as the designer, this pavilion with sloping canopy and rooftop terrace won the Best Custom Solution Award. A total of 181 light weight precast ultra-high performance panels that measure 45mm thick were used to construct the pavilion. As the result of increasing the size of the precast panels to match the structural steel, the architect was able to minimize the number of extra reinforced steel members. It took roughly 19 days to make 181 UHPC panels and the erection was completed in one month. The roof structure is about 122 m long by 7.6 m high by 18.2 m wide and an impressive 44.45 mm thick. The strength, durability, and aesthetics that UHPC offered helped in multiple functional benefits and creative design possibilities. The panels and the supplemental hollow structural section attached to the back of the panels were incorporated into the structure, which created an appealing, yet structurally safe pavilion. The architect was able to eliminate the need for additional steel framing to support the architectural roof panels by using lightweight UHPC. No waterproofing system was required below the panels because of the UHPC roof system. This saved more money for the owner.

Elevation view of G8Way Pavilion

UHPC being installed on G8Way Pavilion

Various number of bridges were entered into the competition. The PCI Design Awards program divides the bridges into many different categories; a few categories are Best Bridge with Span over 46m, Best Non Highway Bridge, Best Rehabilitated Bridge, and Best Transportation Special Solution. The winner for Best Bridge with Main Span over 46m was the Foothills Parkway Bridge No. 2, located in Wears Valley, Tennessee, USA. The engineer was Corven Engineering, Inc while the precaster was Ross Prestressed Concrete Inc. The bridge is 241 m long.

Since the site is on an uneven mountain terrain, a temporary work trestle was used. It granted access along the entire bridge alignment and could be reconfigured as work shifted from foundation and precast concrete segmental piers to superstructure segment erection. The winner of the Best Non Highway Bridge was the North Milliken Avenue Underpass value Engineering Redesign, in Ontario, Canada. The precaster, Oldcastle Precast, worked closely with the Engineer, T.Y. Lin International, to be

Segments of precast being placed

Rehabilitation of New York Avenue bridge  
Permanent concrete girder system

able to create this bridge. The underpass measures at 52 m long by 16 m wide. The use of precast saved about \$900,000 US dollars over the original plan of using steel. I-5 Bridge over the Skagit River in Burlington/Mount Vernon, Washington, USA, won the award for best Rehabilitated Bridge. The rehabilitation came after a crash caused a 49 m long part of the bridge to collapse. Precast concrete was chosen for its time and cost effectiveness. This precast option would minimize the need to close the interstate. The Rehabilitation of New York Avenue Bridge in Washington, DC, USA, won the Best Transportation Special

Solution. The project engineer was T.Y. Lin international, and the Precaster was The Fort Miller Co. Inc. This particular bridge spans and connects Maryland and Washington DC. Being a major transportation outlet, it is used by over 87,000 cars a day. The design used precast, post-tensioned concrete deck panels that cantilever 4 m over the exterior girders. Rehabilitation and repair of the existing substructure to sustain the multi-beam superstructure systems was accomplished by constructing post-tensioned pier caps that rest on the retrofitted pier columns. The deck replacement was achieved through the innovative erection of longitudinally and transversely post-tensioned precast concrete deck panels.

Foothills Parkway Bridge Completed

West elevation of Terracotta finished panels

Some Buildings are awarded multiple awards such as the following entry, the University Of Missouri Henry W. Bloch Executive Hall Of Entrepreneurship and Innovation. It was awarded the Harry H. Edwards Industry Advancement Award and Best Higher Education Building. The precaster on the project was Enterprise Precast Concrete, Inc. and the Architects were BNINM Architects and Moore Ruble Yudell Architects & Planners. This project took a material which has been used in architecture for many years. With

the help of the precaster and the innovations of precast, they were able to take terra-cotta to a whole new level.

Erection of terracotta panels

Terra-cotta was used in the large 3.65m wide, fully insulated precast panels. It was quickly realized that by choosing set wall conditions, other factors were going to work out perfectly, such as the wall system supplying a great rain barrier without the intricate fabrication of a rain screen system. In reward to its great thermal performance, it was awarded LEED Gold Registered. A lot of research and tests were conducted. Everything was explored from the coefficient of thermal expansion to the amount of precast bowing that the tiles could withstand before cracking, the optimal thickness of the tile, reaction of the panel during freeze-thaw cycles, and much more. The terra-cotta company is given a lot of credit for being hands on when it came to testing and answering any questions the architects or precasters had. “Once the building became thermally stable, it allowed us to bridge the budgetary objective together in one solution,” noted the senior project architect. The structure was comprised of 159 pieces (total of 5,852 m<sup>2</sup>). The panels were 3.65m wide and about 280 mm thick.

The University of Kentucky Albert B. Chandler Hospital Pavilion A won the Sustainable Design Award. Located in Lexington, Kentucky, USA the hospital was designed by GBBN Architects and the precast was provided by Gate Precast Co. The precast concrete panels consisted of 75 mm front wythe of concrete with another 16 mm layer of thin brick, a 50 mm center of polyisocyanurate insulation with ship-lapped edges, and interior 100 mm structural wythe. The nominal panels are 2.03 m tall and 11 m long. The main concern when completing the project was enclosing the interior as quickly as possible so that the complex interior could be worked on as soon

as possible. This requirement went hand in hand with having the building all continuously insulated without any cold spots. No thermal bridge was allowed at the connection points, because it was crucial to meet energy requirements. The insulated panels came into perspective in a great manner later on when it was realized that it had other benefits such as; inherent mold and mildew resistance, excellent indoor air quality due to the lack of off-gassing or other chemical interactions, noise dampening from exterior sources due to its high mass and elimination of air penetration, fire resistance due to

Finished perspective of The University of Kentucky Albert B. Chandler Hospital Pavilion

Pre-insulated thin brick precast panels

concrete inorganic composition, and reduced trades on site during construction. A total of 1,758 panels were erected.

The Rich street Bridge in Columbus, Ohio, USA won the All-Precast Concrete Solution & Bridge with Main Span from 23-45 m. The Project engineer, Burgess and Niple, Inc and precaster, Prestress Services Industries, LLC were in charge of constructing this bridge. The modern ribbed bridge spans 717 m, it is constructed of semi-lightweight precast, post-tensioned concrete arch ribs. The primary design called for cast-in-place arches, but it was realized that it would take more time and more money to accomplish. Using precast instead allowed the project to be completed approximately 7 months earlier and reduced the cost by about 10 million US dollars. The modern arch structure uses precast beam, arch rib, and arch apex segments stitched together with a combination of pre-stressing and field post-tensioning to create a fully continuous frame, eliminating intermediate expansion joints and spandrel columns. The bridge has five spans and three lanes, utilities integrated in the bridge railing and sidewalks for use during festivals and community events. The bridge also has an open design that provides more transparent views and reduces flooding impacts.

# Sustainability of Structures with Precast Elements

D. Fernández-Ordóñez<sup>1</sup>, B. González-Rodrigo<sup>1</sup>, J. Ramírez<sup>1</sup>, R. Valdivielso<sup>1</sup>

<sup>1</sup> Universidad Politécnica de Madrid (Technical University of Madrid), Madrid, Spain

**Abstract:** Prefabrication has evolved in depth and breadth from its beginnings, bringing many of the advantages of industrialisation to construction, while solving some of the problems that arose in the early years. Today prefabrication, compared to traditional construction methods, and concrete as a material, feature a number of beneficial characteristics.

As prefabrication makes optimal use of materials, its potential for savings is much greater than in cast-in-situ construction. Structural performance and durability are also enhanced through design, modern manufacturing equipment and carefully planned working procedures.

This paper deals with the very interesting subject of Sustainability of building structures and taking a close look at precast concrete structures. It reviews the specific aspects of industrialized construction in enclosed factories. These factories make possible that production conditions are controlled for the quality point of view of the precast elements. Also the conditions that make possible a better quality control than the normal on site work make possible that sustainability conditions are better met. Sustainability conditions take into account from the simple control of emissions, the working conditions of the workers to the possibility of recycling and reuse.

**Keywords:** prefabrication, thermal mass, sustainability, concrete technologies, environmental production.

## 1. Introduction

The production of precast concrete elements normally takes place under controlled climatic conditions in enclosed factories. This makes control of waste, emissions, noise levels, etc. easy compared to the same process at a traditional building site. Working environment is also easily controlled.

Moreover the use of new technologies like self-compacting concrete (SCC) can significantly reduce the noise and vibration in the production process. The use of high performance concrete (HPC) enables design and production of more reliable and more durable structures with optimized shape. The potential for savings in structural material consumption and consequently natural resources is evident.

The environmental burden of prefabrication is mainly the impact caused by the raw materials of concrete (especially production of cement and steel) which is similar as other concrete construction structures but in a reduced way because of the reduced use of materials in comparison with in situ construction. The environmental burden caused by raw materials is approximately three times larger than that caused by the production process of the elements, as indicated by the examples of environmental product declarations.

The thermal inertia of heavy materials is well known for both in warm and cold climates. Most people have experienced the comfort of coming into a comparatively cool stone building on a hot day in a warm climate. In precast structures several constructive systems have been developed using this characteristic.

## 2. Precast structures

### 2.1 Service Life

In the First International Conference on Sustainable Construction in 1994, sustainable construction was defined as the creation and the responsible maintenance of a healthy constructed environment, based on ecological principles and with an efficient use of resources. (Hendriks, 2000)

This definition resumes most of the essential functional characteristics, as the use of energy, internal ambience conditions and flexibility. A very important aspect for sustainability, and for the life cycle assessment for the construction of a building, consists of taking into account a design life for different structures and systems that are in the building following the principles life cycle analysis, and this means as follows:

- Primary System= External facades and structural design > 80 years
- Secondary System = main interior load bearing partitions > 30 years
- Tertiary System = interior non load bearing partitions > 10 years

Therefore, both durability and recycling possibilities are two very important aspects of life cycle design as can be observed in Figure 1.

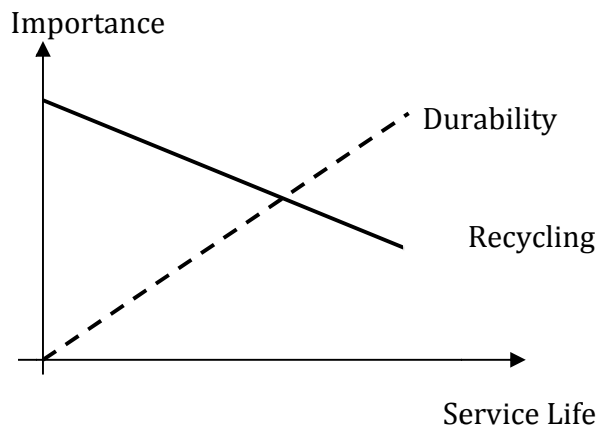

Figure 1. Principles for optimization in service life (Óberg, 2000)

## 2.2 Structural Systems

Some examples there have been compared the structures of buildings with several heights for buildings of both homes and office. The functional unit is one square meter of ground used by the building for the life of the building, including both horizontal and vertical structural components and supplementary materials, i.e., the total environmental load of the building. Lifetime expectation was taken as 50 years. Several schemes for handling the demolition debris were investigated. Differences can be seen in Figure 2

Figure 2. Relative Costs of different kind of decks for housing. (CIMbéton, 2002)

The example is basically a revision of the environmental contributions of each kind of structure to a given number of ambient hazards, like the greenhouse effect or acidification. The example has been developed in the Netherlands, and can be adjusted according to local conditions. The different effect categories are weighted according to local political environmental goals and regulations.

In the production of the structure of the load bearing components, it is generated from 75 to 95% of the environmental burden. Total Cost is set as the sum of the environmental burden and economic integral cost. Loads are calculated in two environments that must be articulated in monetary terms.

This is done by calculating or estimating the costs necessary to restore the environmental impact caused by the use of raw materials, energy, water, etc. These effects could be further normalized according to the ISO 14041 normative. In any comparison, it is of great importance that the functional unit always includes the same parameters, in this case regardless of soil type. The functional unit may include a selection of parameters such as structural performance, safety, comfort, etc.

### **3. Durability and flexibility**

The production of precast elements, under climatic controlled conditions, allows a precise control of the outcome, such as tolerances and concrete quality. Usually, there are higher design concrete strengths in precast concrete structures than in ordinary in situ structures. These two facts, high strength and controlled curing of concrete, have the potential to produce very dense and durable concrete.

The most common damage in concrete structures is reinforcement corrosion. In the production of precast concrete cover this damage is easy to secure and therefore, durable components are created. Furthermore, concrete used in precast elements has usually high resistance and therefore, it is a dense material that inhibits or delays deterioration.

These improved properties of high-quality concrete allow it to be used with minor requirements for a useful life span or with improved lifetime while maintaining the same cover. The utmost symbol of durability is to be able to use for longer time old structures. In sheltered from the weather concrete, for instance in all building structures., expectancy life is a hundred years.

If the structure is made so that the building can be changed without major demolition process, no doubt the building itself may have a long life, it will only need to adapt its inner architectural layout for new uses. Lately the practice of reusing concrete structures with old concrete removed for new buildings has become more and more frequent, as well as detaching existing structures and reassemble them again. Several examples are well known in the Netherlands, Sweden and Norway.

Precast structures are flexible in many respects. First, when using prestressing, design spans are usually long, so it is easy to adapt the building to future needs of change or forthcoming use demands. After then, life design for the structure and external walls is at least 50 to 100 years, while for the inner partitions is just about 10 years. After those 10 years the experience is that the building has to be redesigned for a change in use.

Connections are an essential part of the design and the construction of precast concrete buildings. With regard to durability, it is necessary to consider the risk of corrosion of reinforcing steel and cracking and spalling of concrete with due attention to the actual environment. Steel exposed to aggressive environment should be provided with a permanent protection. This can be achieved by applying a layer of

epoxy, rust proof paint or bitumen, or by casting-in with concrete or mortar. In many cases the connections cannot be inspected or maintained after the building has been completed. In such a case the connection, without maintenance, should have life expectancy that exceeds that of the structure.

In the secondary buildings that have structures built with precast elements, such as mezzanine floors in industrial buildings, structures can be installed or removed at request. When buildings are designed as demountable, in can be advised to use bolted connections that are demountable and provide immediate fixity. Several systems that are fully demountable are in use for precast buildings. However, to overcome constructional deviations, tolerances in three-dimensional space must be accommodated.

#### 4. Thermal Mass

Thermal inertia of precast concrete deck elements can be used to reduce the energy used for cooling and heating the whole structure. Heating capacity of reinforced concrete is about  $2.20\text{-}2.50\text{MJ/m}^3\text{K}$ . With an average volume of  $30\text{ m}^3$  concrete per apartment, this energy of about  $70\text{ MJ}$ , is stored in the concrete structure for each degree as the temperature rises. This energy can be released and can contribute to heating when the temperature decreases. An example of this system of using thermal mass is the Elizabeth Fry Building, University of East Anglia 1998.

To get an idea of how much energy it is about, it can be compared with the total energy required to heat an apartment in a modern building on a Nordic country. On an annual basis the energy needed it is up to  $150\text{ kWh/m}^2$ , which is  $45\text{GJ}$  in an apartment of  $80\text{ m}^2$ . Therefore daily energy consumption in the cold season will be at least  $250\text{ MJ}$ . (Obergh, 2000).

It is well known that in a life cycle perspective, energy consumption while using the building is essential. Hence, any measure that would reduce energy consumption when the building is in use will have a significant effect on the environmental record of the construction. It is this aspect that makes visible the energy savings potential of all systems that use the thermal mass of concrete that are important from the environmental point of view, in addition to the economic benefit for the owner of the building.

**Figure 3. Example of the use of thermal mass in precast decks**

Another important benefit is that the concrete mass also provides excellent properties for acoustic insulation and is ideal as exterior walls for the houses overlooking the roads with heavy traffic, as well as isolation between different areas of a building, and as noise barriers along railways and roads.

Several systems have been developed in precast structures by using this characteristic. There is a representative system of these solutions in which the air is distributed in the voids of the hollow core slab elements.

This system minimizes the installed power and generates energy savings in both heating in cold weather. It also allows cooling in the warmer months. This system can achieve an energy heating saving of about 35% and a reduction in cooling power consumption of 40%. (Environmental Aspects of Concrete, 1998)

To maximize benefits of concrete precast structures, surfaces on roofs should be exposed. Eliminating false ceiling systems allows great savings in the overall height of the building that can provide 5% to 7% of construction cost savings. The concrete slabs behave as a normal steel duct. There are reports done by independent agencies confirming this. Thus the ducts can be used and maintained just the same as normal steel ducts.

Comfortable indoor temperature improves productivity of people working in the building. Another possibility is to use false open ceilings elements to allow air exchange between the upper part and lower part. Figure 4 offers an example about the use of thermal mass in reinforced or prestressed precast concrete floors at night time conditions on summer.

On summer nights, fresh air is blown through the roof with hollow core slabs using mechanical ventilation fans. This air cools the concrete slab and acts as a cold store space for the next day. Thus, intensive energy air conditioning demand can be reduced to a great extent or even eliminated. Another advantage is that cooling elements can operate with cheap electricity rates at night, while the traditional electric cooling is required during peak hours during the day.

**Figure 4. Example of the use of thermal mass in decks during summer: a) night and b) day**

In summer daytime conditions, with warm days, cold from the previous night stored in the hollow core slab roof improves comfort in two ways:

- It absorbs the heat produced by people and machinery.
- Cool air goes through the roof slab and cools before entering the room

The use of thermal mass instead of other cooling methods saves energy and allows more freedom for the occupants because if necessary, they can open the windows.

On the other hand, in winter night time situations as seen in Figure 5, the building is closed at night to keep heat gains, produced by people and machinery during the day. Anyhow in very cold climates additional heating may be required.

Therefore ventilation heating will start two hours before the working hours to ensure that the room temperature is suitable at the beginning of the working day. If the building cools at night below the preset limits, air conditioning equipment will initiate air recirculation, and a slight warming will start. There is no fresh air ventilation when the building is empty. There will be no fresh air ventilation in an empty dwelling.

With regard to winter conditions, even though in daylight conditions, the heat generated by the occupants and machinery will be radiated to the hollow core slabs and it will be also recuperated from the exhaust air, which goes again through the slab across the rooms. This design using these systems reduces ventilation needs for heating and cooling ducts or ventilation, and hence reduces cost and improves space utilization. It also uses very efficiently the available thermal mass.

**Figure 5. Example of use of thermal mass in decks during Winter: a) night and b) day**

There is no additional capital cost as the use of thermal mass doesn't add any extra material or equipment. In fact, since the installed AC-equipment is small-sized, generally about half of a conventional installation, the installation cost is lower than in a conventional system.

- 20-50% Lower Energy Consumption and thus lower CO<sub>2</sub> Emissions.
- 70-90% savings in power demand during peaks
- The building height is also reduced as no false ceilings are needed (lower construction costs)
- The system is silent and there are no draughts. The hollow cores act as efficient silencers which make the system completely silent. Since the supply air is warmed or cooled when passing through the slabs before entering the room, the temperature of the supply air is very similar to the room temperature.

There are benefits in Hot Climates as experiences from several buildings in the Middle East show a 50% reduction in installed cooling capacity required for the thermal mass systems compared to conventional air-conditioning systems. This results in reduced capital costs for air-conditioning by 15-30% due to much smaller dimensions on chillers, fans, etc. Also, the total energy costs will be 30-50% lower compared to an identical building due to lower energy consumption (the ambient air is cooler at night, which increases the efficiency of the chiller & night cooling can be used during parts of the year). The reduced installed power means lower electrical connection and distribution charges.

There are also benefits in Cold and Temperate Climates as in milder climates, such as Sweden and UK, the slabs are primarily cooled during night with the outdoor air. Small chillers, if any, are needed. Heating will also be reduced since the heat accumulated in the slabs during daytime can be used to warm the building during cold nights. The energy savings will therefore be very high, up to 50 %.

### 3. Conclusions

This paper emphasizes the importance of sustainability in precast concrete buildings taking into account the full life of the structure, even with the consideration of reuse and recycling. Taking into account these aspects, the contribution of thermal mass specific uses in precast concrete are considered.

- (1) The use of industrialization or prefab in construction provides the advantage of applying industrial methods for construction.
- (2) The use of available resources in industry provides materials optimization and means of implementation for structures. It can be either because they minimize work at site, or because structures can be performed with less materials and higher quality.
- (3) The greatest impact that involves industrialized elements transfer at site is compensated by the advantages of industrial means within controlled premises.
- (4) Thus environmental impact of industrial structures implementation is less than with traditional means directly on site.

# Christchurch Art Gallery Foundation Strengthening and Building Re-Level

James O'Grady<sup>1</sup>, William Lindsay<sup>2</sup> and Russell Deller<sup>3</sup>

<sup>1</sup>Sales Manager, Mainmark Ground Engineering,

<sup>2</sup>General Manager, Mainmark Civil & Mining

<sup>3</sup>General Manager, Mainmark Ground Engineering NZ

**Abstract:** The four-storey Christchurch Art Gallery was badly shaken by the 2010 and 2011 earthquakes. The 6500 square meter basement slab sank unevenly and was out of level by up to 182 mm. A global tender was called for the remediation of the foundation ground and re-leveling of the building. Mainmark Ground Engineering (trading as Uretek Ground Engineering at that time) was the successful tenderer. The re-level contract held many challenges; an occupied building housing priceless artworks needed to be raised and leveled from the basement which was located below the water table. Mainmark Ground Engineering installed a reaction platform with jet grout columns. Over 1800 tonnes of cement were used in the jet grout column formation. A computer controlled cement grout leveling system was then used to level the building by lifting off the reaction platform. The movement of the basement slab and structure was monitored in real time using wireless Trimble S8 Robotic Stations and prisms. The consultants and building owner were able to monitor the movement in real-time, with the basement contours being updated every 45 minutes during the lifting process. The foundation ground of the structure was strengthened and the building restored to its original level across the 6500 square meter slab. A value-added consequence of the re-leveling work is the reaction platform and leveling grout has strengthened the ground beneath the gallery, providing the existing building with improved behaviour under seismic loads.

## 1. Christchurch

Christchurch is located on the Canterbury plains on the east coast of New Zealand's south island, and is well known for its historic timber houses and stone churches. The Avon River winds through the centre of the city.

In 2010 and 2011 a series of earthquakes struck Christchurch, New Zealand's second largest city. In the four years from 4 September 2010, 4,558 earthquakes of magnitude 3 or higher were recorded in the Canterbury region. The earthquakes destroyed almost one third of the buildings within the CBD. There were four major earthquake events; 4 September 2010, 22 February 2011, 13 June 2011 and 23 December 2011.

The initial earthquake event occurred on 4 September 2010 and was centred 40 kilometres west of Christchurch at a depth of 11 kilometres. The peak ground acceleration at the epicentre was 1.25g, however at Christchurch the acceleration had reduced to 0.37g (2). The 7.1 earthquake was the largest in New Zealand since 1931. Severe building damage occurred in Christchurch; however there was no loss of life.

The 22 February 2011 earthquake event occurred 10 kilometres south east of the Christchurch CBD and was much shallower, only 5 kilometres deep. Peak ground accelerations of up to 2.20g were measured in Christchurch suburbs. Severe building damage occurred and 185 lives were lost. Liquefaction was extensive, particularly in the eastern suburbs, with approximately 400,000 tonnes of silt being forced to the surface, burying streets and properties and damaging essential services such as water, sewerage and electricity.

The third earthquake event occurred 10 kilometres south east of Christchurch on 13 June 2011 and the fourth occurred 20 kilometres east of Christchurch on 23 December 2011. The peak ground acceleration was 0.68g and 0.44g respectively.

## 2. Christchurch Art Gallery Building

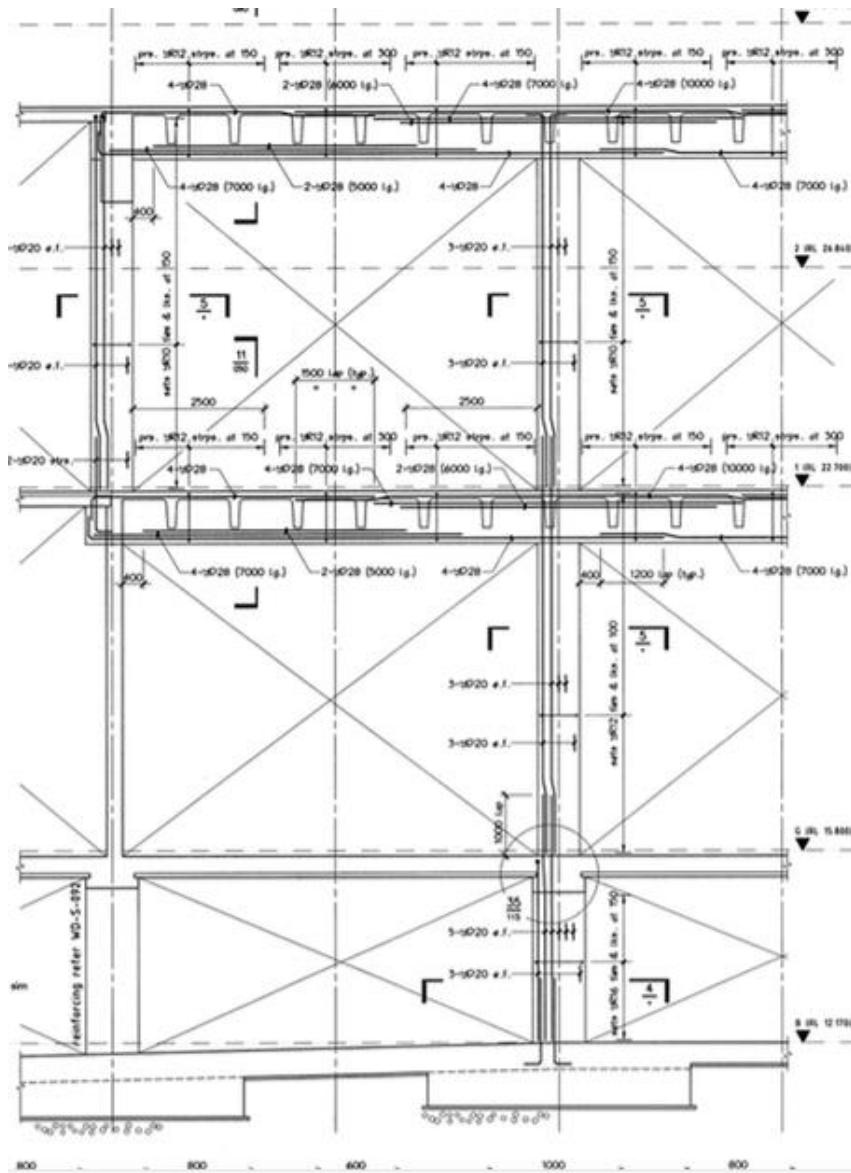

The Christchurch Art Gallery is located in the heart of Christchurch, approximately 100 metres from the Avon River. The public art gallery houses one of New Zealand's finest art collections and hosts major international exhibitions. The Christchurch City Council owns the gallery.

The art gallery building, with its distinctive curved glass façade, was opened in May 2003.

The four-storey building weighs 30,000 tonnes and has a 6500 square metre basement slab. Due to the earthquake risk, the gallery was designed as a raft slab to evenly distribute earthquake forces through the structure.

**CHRISTCHURCH ART GALLERY**  
FOR  
**CHRISTCHURCH CITY COUNCIL**

frame elevation grid C & D

Figure 2. Basement Plan

The Art Gallery is a reinforced concrete structure. As the basement slab is approximately 1 metre below the level of the water table, it was designed as a water retaining structure. The basement slab is typically 400 mm thick with N20 bars at 350 centres each way top and bottom. The column pads are typically local thickenings beneath the basement slab. Included in the basement slab is the 150 mm thick car park entry ramp to the East of the site,

Although the basement slab had subsided and the building was over 180 mm out of level as a result of the 2010 and 2011 earthquakes, the structure of the gallery survived the earthquakes remarkably well, sustaining only secondary damage. After the earthquakes, the gallery was used as the Emergency Operating Centre for the recovery effort.

**3. Contractual Requirements**

Jenny Harper, Director of Christchurch Art Gallery, stated “It is essential for the gallery to have ‘a gold-plated engineering certificate’ so international and local galleries will be confident enough to lend works and bring exhibits to the city”.

The re-level of the Art Gallery was an international tender; to restore the building to its original level and, as a value add, to provide additional earthquake stabilization work. The requirements to submitting a conforming tender included:

- All level correction works to be carried out from within the basement level of the building.
- No impact to the external landscape, including car park toppings, footpaths and roads.
- Guarantee a maximum 25 mm settlement under static load.
- The back up power and computer servers servicing the adjacent Civic Building (Christchurch City Council Main Administrative Centre) were located in the Gallery basement and were not to be interrupted.
- An 11,000 KVA Zone Sub Transformer Station servicing Christchurch’s CBD and surrounding residential population was located in the lowest level of the basement, power supply was not to be interrupted
- The Art Gallery Structure was anchored in place with 73 No. 12m long post tensioned grouted tendons, required to resist hydraulic uplift as a result of a seasonally high water table due to glacier melt and the proximity of the Avon River

- The site had a history of hydrocarbon and high levels of organic volatile contamination
- There was to be no vibration and dust particles were to be minimised.
- All existing art was to remain on site.
- The Art Gallery was to remain occupied by management and tenants.

Following a long design process, Mainmark Ground Engineering was the successful tenderer to perform the lifting and level correction works at the Art Gallery.

### **3.1 Site Challenges**

The site conditions provided several challenges.

As gallery staff and tenants were to occupy the building during the works, all services had to be maintained for the duration of the works. Electricity, water, sewerage and data services could not be interrupted during work hours. The zone substation and council computer back up servers located on the site had to stay in operation at all times.

The gallery building services, surrounds and environment had to be protected during the works. The basement extends under the large forecourt in front of the gallery. However the forecourt was not designed for vehicle loads and could not be used as a staging area for the works.

Access to the basement was via a vehicle ramp with only 2.1 metre head height. Only compact machinery could be mobilised and used in the basement. The head height of the access ramp meant trucks could not deliver into or pick up from the basement. The head height within the basement itself was as low as 2.25 metres.

The basement slab is approximately one and a half metres below the water table.

The ground water flow through the site was to the Avon River, about 100 metres from the site. Real time monitoring of the pH was required, both of the ground water and of water in the Avon. If water sampling revealed pH outside the range 5.5 to 8.5, work had to stop immediately.

There was a requirement that minimal reinforcement be disturbed by the works, consequentially all slab and wall reinforcement was required to be located using ground penetrating radar. Before any reinforcement was cut, approval had to be obtained from Aurecon, the engineers for the Art Gallery. Every penetration through the slab had to be approved, annotated and documented prior to drilling or coring.

There were seventy-three ground anchors, approximately twelve meters in length, tied into the basement raft slab. These anchors were required to resist upward floatation forces due to variable ground water levels. It was not known if the earthquakes and subsequent settlement had compromised the integrity of the anchors. Each of these anchors had to be located and the concrete about the anchor heads excavated. The tension in the anchors had to be controlled, requiring the anchor heads to be backed off at the same rate as the level correction of the adjacent slab. Upon completion of the project the anchors were required to be tested, re-tensioned and locked off,

The artwork stored in the gallery had to be protected from construction dust. A custom dust extraction and filtration system was designed and constructed to ensure there was no risk of cement dust entering the Art Gallery ventilation system.

## **4. Mainmark's Solution**

The objectives of the Mainmark solution were:

- To raise the gallery building back to its pre-earthquake design levels.
- To release the tension stresses caused by the differential settlement of the foundation.
- To complete all work from the building basement.
- To ensure zero business disruption to the gallery staff and tenants.
- To maintain the structural integrity of the superstructure throughout the level correction exercise.

To achieve this Uretek proposed a combination of 124 JetGrout columns with 350 JOG integrated computer levelling locations monitored by 6 Trimble robotic stations in real time.

The Mainmark solution was modelled by KGA Geotechnical Investigations Christchurch and Geotecnia Lisbon. The modelling determined that in addition to providing a platform to level the structure, the proposal also improved the building's ability to withstand future earthquakes and improved the performance of the footing system to meet the new New Zealand building code earthquake requirements. "The relevel solution of the Christchurch Art Gallery provides a non-liquefiable crust of at least 6.5 m below foundation, which is considered to minimize the manifestation of liquefaction damage at foundation level."(3)

The solution presented for this landmark project was the first of its kind in the world, utilizing these combined technologies.

#### **4.1 Jet Grout Columns**

In order to guarantee lift of the structure, a reaction platform had to be constructed beneath the structure. This reaction platform was constructed with 124 Jet Grout soil mix columns of 3 and 4 metre diameter.

The 3 and 4 metre diameter Jet Grout columns were placed through 200 mm diameter cores through the slab onto a gravel layer approximately 6.5 metres below the basement slab. The cement paste was injected into the soil through rotating horizontal jets. The force of the jets cut through the soil and enveloped the gravels, mixing with the soil to form soil-cement columns. The gravel lenses encountered across the site consisted of cobbles up to 300 mm in diameter. Excess soil cement slurry was extracted from the core and pumped to a basement holding tank, before being pumped from the basement to an external tank before being removed from site. The JetGrout columns extended from the gravel layer at 6.5 m below the top of slab to 2 metres below top of slab.

Over 1,800 tonnes of cement were used to install the 124 JetGrout columns. The JetGrout columns were installed on a triangular grid at 7,500 mm centres. The columns about the perimeter of the structure were 4 metres diameter and the internal columns were 3 metres diameter.

The 124 Jet Grout columns were installed within 52 working days.

#### **4.2 JOG Integrated Computer Levelling**

Once the Jet Grout columns were installed, cement grout was injected into the soil beneath the slab, levelling the building and providing a load transfer layer between the Jet Grout columns and raft slab, using JOG integrated computer grouting technology.

The JOG process provided a hydraulic lift of the building, gradually and gently lifting the building back to level. The building was lifted to its original position by injecting a variable mobility laminar cement grout beneath the building basement slab at 350 locations contemporaneously. All 350 injectors were connected via eight kilometres of delivery hoses back to injection pumps located within a temporary batch plant constructed within the basement car park.

The purpose-made batching plant was constructed to guarantee grout quality. The five colloidal mixers and ten high-pressure grout pumps were linked back to the computer controllers.

The injection array was designed considering the building loads, degree and distribution of lift required, and mitigation against any new stresses being imposed on the structure during the lifting process. Injection ports were installed through 40 mm diameter cored holes in the raft slab.

The lifting process was computer controlled. The basement was divided into 10 zones, with up to sixty-four injectors in a zone. A network of five computers controlled the rapid succession in which the injections took place, the amount of modified cement grout that was injected at each location, the delay between injections and the delivery time of each injection. During each sequence, only a very small volume of cement grout was injected at each location.

Over 16,500 25kg bags of cement were used in the lifting of the art gallery slab. A total of 1.5 million litres of grout was injected during the levelling operation. The levelling of the building was completed in 44 working days.

**Figure 3. Initial Slab Contours**

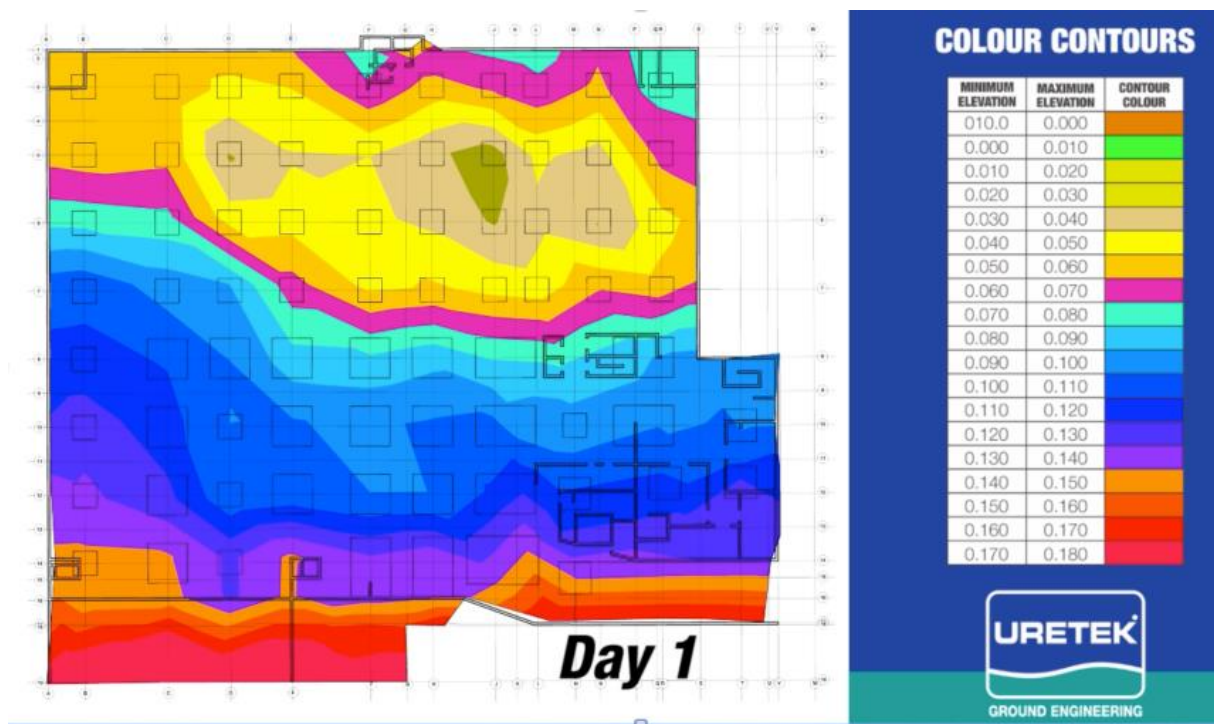

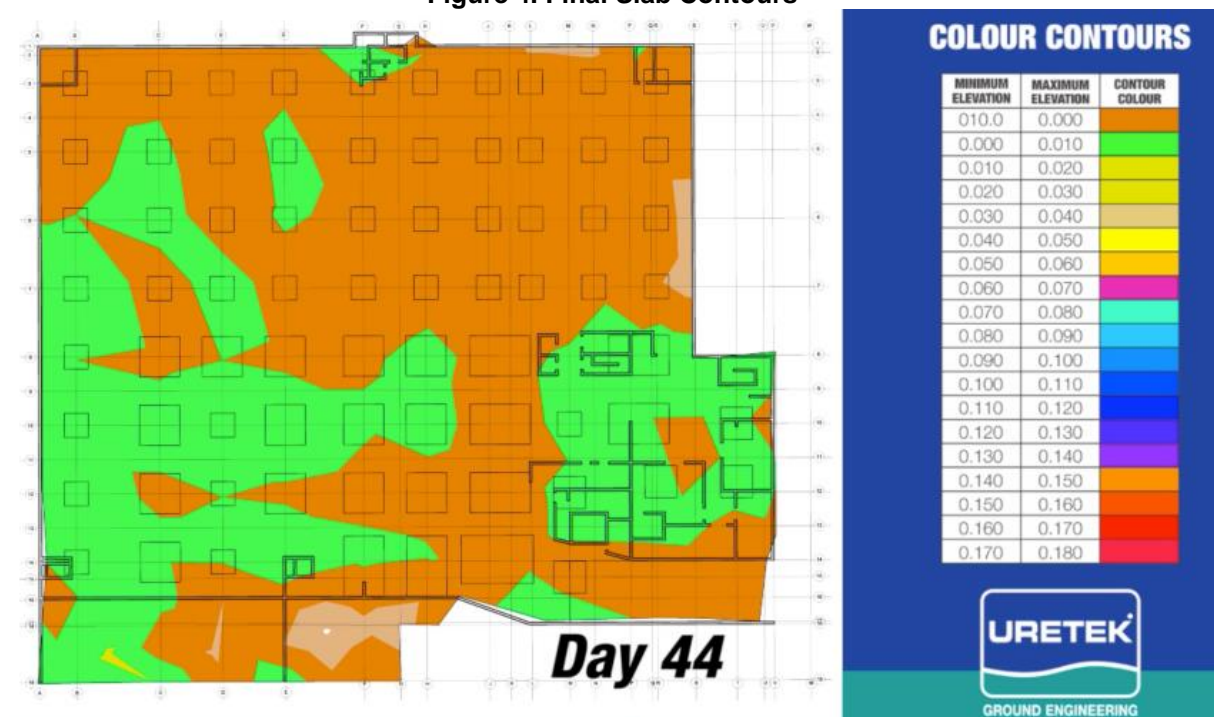

Figure 4. Final Slab Contours

#### 4.3 Trimble Total Station Monitoring

Prior to commencement of the correction works, a 3D laser scan of the basement, building interior, external façade and surrounding properties was undertaken to determine the exact location of the structure. This scan, with over one billion points, provided a virtual building model that could be entered at any time to determine the condition and location of the building prior to the work commencement. The building model was used to confirm the degree of settlement and to examine existing and potential new stresses on the structure.

A network of 5 Trimble S8 robotic stations placed in the basement and 1 Trimble S8 external to the building was used to monitor the building 24 hours a day during the lifting process. The Trimble S8 stations continuously monitored the movement and rotation of over 400 locations throughout the

basement and building exterior. Over 300 prisms were mounted in the basement. Every column, the centre of each beam and the upper surface of the basement slab were monitored.

The external station was required to transfer true levels from outside the building back to the stations located in the basement. As the entire building was being lifted, there was no internal zero point that could be used as a reference during the works.

The data from the S8 stations was fed back to the control room computers by wireless MOXA communication equipment. The real time monitoring of the movement of the building provided feedback to the JOG injection sequence, allowing the technicians to slow down or speed up the lift of discrete parts of the structure. This ensured the building was lifted smoothly and prevented additional stresses being applied to the building during the process.

The complex output of the Trimble S8 stations was used to provide contour maps of the basement slab every 45 minutes. These contour maps were loaded onto a web site where the Art Gallery, Council, Aurecon and Trimble could monitor the progression of the building lift during the work.

The basement slab was levelled to within +/- 10 mm.

## **5. Conclusions**

From possession of the site in August 2013 to completion in January 2014, the project took a total of five months. The project was completed on time and on budget. The 6500 square meter floor plate was levelled to within +/- 10 mm.

Mainmark's solution was a surgical approach, installing the lifting columns and lifting the structure through penetrations of 200 mm diameter and smaller. The structural integrity of the building was not compromised. All work was completed from within the basement level of the building.

The work was completed with zero business interruption to the art gallery, and all artwork and art gallery personnel remained on site. All building services were maintained throughout the process.

## **6. Acknowledgement**

Uretek acknowledge the support and assistance of the Christchurch Art Gallery Te Puna o Waiwhetu, The Christchurch City Council, Aurecon, KGA Geotechnical Investigations, Geotecnia Lisbon, Kevin O'Connor and Associates, Geosystems New Zealand and Trimble in the delivery of the re-leveling of the Christchurch Art Gallery.

# Design of Berthing Dolphins on Curtis Island LNG Jetties

Jesper Jensen<sup>1</sup>, Peter Kastrup<sup>2</sup> and Matt Hodder<sup>3</sup>

<sup>1</sup>Engineer, Arup

<sup>2</sup>Queensland Maritime Leader and Senior Engineer, Arup

<sup>3</sup>Senior Engineer, Arup

**Abstract:** The demand for energy in South East Asia and the Pacific region has seen vast growth in gas exploration across the continent of Australia. With the approval of a number of liquefied natural gas (LNG) export facilities across the Australian seaboard, Arup Australasia has put its multi-disciplinary capabilities to full use in the delivery of a number of LNG Jetties in Gladstone, Queensland in a design and construct collaboration with contractor John Holland Group (JHG). One of the most vital elements of an LNG Jetty, both from a design and construction point of view, is the berthing dolphins. While the structural form may vary considerably across various project sites, this structure is consistent in functionality which is to resist the lateral forces associated with berthing and mooring of vessels. With the world's energy demands growing and sea going vessels increasing in size and volume for coal and LNG transportation, berthing dolphins are growing both in size and complexity in design. This paper presents the design and construction of berthing dolphin structures accommodating berthing and mooring of vessels of up to 220,000 m<sup>3</sup> in capacity, which is the result of close collaboration between JHG and Arup.

**Keywords:** LNG Jetty Design, Constructability, Pile Group Analysis, BIM, Maritime Construction

## 1. Introduction and Project Background

In 2010, the Queensland Government approved the Queensland Curtis LNG (QCLNG), Gladstone LNG (GLNG), and Australia Pacific LNG. The project partners across the three projects are (at the time of writing):

- QCLNG – QGC(BG), China National Offshore Oil Corporation (CNOOC)
- GLNG – Santos, PETRONAS, Total, KOGAS
- Australia Pacific LNG – Origin, ConocoPhillips, Sinopec

Bechtel was awarded as the engineering, procurement, and construction contractor of the three jetties. JHG was awarded the marine subcontracts, including procurement, fabrication, construction and commissioning of the structural, mechanical and electrical components of the product loading facility. JHG appointed Arup in a Design and Construct (D&C) collaboration for the permanent works design of the three LNG jetty facilities. Arup was also the engineer of record during construction, certifying that the works met the design intent.

With three different project stakeholders, the projects are considered as three separate projects. As such, each project required an individual assessment of the project-specific design requirements, geotechnical profile, and environmental conditions. The three LNG plants are located on the south-western shoreline of Curtis Island and are only accessible by water. The three project sites are illustrated in Figure 1.

Early collaboration with the client to understand the ancillary functional requirements of the dolphins such as furniture, early Arup input during fender selection and involvement with the contractor to understand the constructability needs, was key to a successful scheme development.

**Figure 1. Top left: Overview of the Curtis Island LNG plants (from the bottom; Australia Pacific LNG, QCLNG and GLNG). Top right: GLNG. Bottom left: Australia Pacific LNG. Bottom right: QCLNG. ©Bechtel**

Concerns over positional tolerance of the driven piles from a floating barge meant that a reinforced concrete pile cap was adopted as the contractor's preferred solution. This was seen as the most efficient method to accommodate the large bending moments resulting from a significant cantilevering length between the fender unit load application level and design mudline level of up to 25m, including allowance for scour and over-dredge. Arup designed a complex reinforced concrete pile cap to accommodate the 4 no. driven tubular steel piles. Bored rock sockets were specified where the geotechnical axial tension capacity, provided by the driven steel tube shaft friction, was inadequate to resist the design axial pile tension.

The high variability of ground conditions in Gladstone Harbour and concerns over geotechnical risk governed the contractor's early decision to adopt a vertical pile solution. This was chosen over raking piles for the ease of installation and flexibility while the bored in-situ concrete rock sockets could be practically extended where required to counteract the ground condition variability and manage geotechnical uncertainty.

## **2. Key Design Inputs**

Before the dolphin design could be developed, a number of key design inputs were required. Of particular importance was the berthing and mooring analysis to determine an envelope of forces and angles for the range of operational vessels for input into the analysis. A metocean study was needed to determine the operational and ultimate limit state wind, wave and current conditions specific to Gladstone harbour and the subsequent loads for input into the analysis. The different design lives for each project had a significant impact on the metocean design criteria.

A geotechnical/geological assessment of the local ground conditions was also undertaken. The assessment included carrying out detailed geotechnical studies and development of site-specific ground models to inform pile types and installation methodologies, in addition to determination of geotechnical parameters for input into the structural and geotechnical analyses.

## **2.1 Berthing Analysis and Fender Selection**

Assessment of normal and abnormal berthing was carried out in accordance with PIANC Guidelines for the Design of Fender Systems (Guidelines for the Design of Fender Systems, PIANC, MarCom WG33, 2002) including factors for manufacturing tolerance, angle, temperature performance and velocity correction. Due to the non-linear energy performance behaviour, normal berthing proved to govern the loading from the fenders chosen on these projects.

The fender cone was inverted to minimise the height of the concrete dolphin cap and subsequent concrete volume. The fender type and size was also confirmed to be acceptable for the required fender thrust, determined as part of the mooring analysis.

## **2.2 Mooring Analysis and Mooring Hook Selection**

The objective of the mooring analysis was to confirm that the berth layout provides a safe and efficient mooring system. In the mooring analysis, the vessels at berth were subjected to a range of survivability and operational conditions. A large number of combinations of wind, wave and current input was varied in direction and intensity, hence an advanced software package was used. This included the metocean criteria specified by the Oil Companies International Marine Forum (OCIMF) (Oil Companies International Marine Forum (OCIMF), Mooring equipment guidelines (MEG3), 2008) applied to each design vessel moored port and starboard.

The movement outputs of the analysis were checked against project specific criteria as well as criteria from OCIMF (Oil Companies International Marine Forum (OCIMF), Mooring equipment guidelines (MEG3), 2008) the Society of International Gas Tanker and Terminal Operators Ltd (SIGTTO) and the World Association for Waterborne Transport Infrastructure (PIANC).

During the analysis, prismatic and spherical tank vessels were found to have noticeably different mooring characteristics. Spherical carriers tend to have large windage areas combined with offset manifolds. This resulted in notable yaw movements for some spherical vessels when the design metocean forces were applied.

Passing ship analysis was performed and demonstrated that while a passing ship does have an effect on the vessel at berth, the project specific effects were minimal and negligible when considered probabilistically.

The key dolphin design outputs from the mooring analysis were confirmation of line loads, hook size and load angle envelope.

## **2.3 Metocean Conditions and Loading (Water Levels, Wave and Current Loading)**

Each of the projects specified different design life requirements and hence different requirements for metocean condition design return periods. Joint probability was considered where possible, which provided optimized design basis for water level, wave height & period as well as current – which in turn optimised loading and structural design.

Wave and current loads on the piles were determined using Morison's equations. Stokes 5th order wave theory was used to determine the water particle velocities and accelerations. Fenton's Fourier approximations and stream theory were also used. Marine growth was prescribed as a design criterion, which also varied across the projects. Typically, an increased marine growth thickness requirement between Highest Astronomical Tide (HAT) and Mean Sea Level (MSL) meant that the typical wave load profile had a load spike in the HAT to MSL range.

Each project had different design wave crest and pile cap levels. This meant that wave loading on the dolphin pilecap had to be considered in some cases, but not others.

## **2.4 Geotechnical Assessment**

In order to inform foundation analysis and dolphin design, Arup undertook a detailed geological and geotechnical assessment to evaluate the site ground conditions.

During the initial site evaluation, the prevailing ground conditions on site were found to consist of alluvial soils overlying metasedimentary and deformed rocks; typically comprising mudstones, sandstones, siltstones and chert (scattered sporadically). It was identified that following deposition of the underlying geological formations as horizontal sedimentary layers during the Late Devonian to Early Carboniferous period, the region was subjected to intense metamorphism and deformation during the Late Carboniferous period. This is when fault bound tectonic blocks were thrust up against each other which resulted in the tilting of the underlying formations.

Critical to the selection of pile type and installation methodology was the identification of highly variable ground conditions and the underlying steeply dipping (typically between 60 and 80 degrees to horizontal) rocks beds. Tilting of the rock beds resulted in significant vertical and horizontal variations in stratigraphy and the variable strength and weathering resistance of the rock materials encountered at the site.

## **3. Pile Group and Structural Analysis**

One of the key stages during the detailed design process was the development of the analysis models to determine both the load effects on the structure and on the ground. Generally, the Arup in-house geotechnical analysis program, 'Oasys ALP' was used for lateral geotechnical analysis, however the dolphins were analysed using a pile group software. Soil-structure interaction analysis of the pile group was undertaken to design a number of key elements in the dolphin structures and also to check the ultimate limit state geotechnical lateral stability of the pile group. Seamless interface between the structural and geotechnical disciplines was crucial in the delivery of an efficient design approach. The geotechnical analysis of the dolphin structures was undertaken using numerical analysis incorporating non-linear lateral 'p-y' pile-soil interaction springs and group interaction factors to model pile group behaviour under applied loads. The pile cap was considered as a rigid body and the piles were modelled with a non-linear relationship between pile bending moment and curvature. The soil was specified in a series of horizontal layers of variable thickness. Input soil parameters were converted to non-linear springs and applied at the pile interface to represent the ground behaviour. Both upper bound and lower bound cases were analysed using models with corresponding pile toe levels derived from the pile driveability analyses, and with ground material strength representative of each dolphin characteristic ground profile.

Three types of pile group analysis were performed to satisfy the design requirements:

- SLS design action effect analysis performed to determine deflections and material stresses at serviceability limit state.
- ULS design action effect analysis performed to determine ultimate limit state pile design actions for structural and geotechnical design
- ULS geotechnical lateral stability analysis performed to check ultimate limit state geotechnical lateral stability of the pile group

In the ultimate geotechnical lateral stability analyses, both 'short' and 'long' pile failure mechanisms were checked. Ultimate geotechnical lateral stability was satisfied by ensuring that the lateral ground pressure (modified for lateral group effects) was not mobilised, and the number of plastic hinges required for the structure to form a mechanism had not formed. Non-linear pile bending moment-curvature relationships were adopted in the analyses, which allowed the redistribution of load throughout the system as the ultimate bending moment capacity of the piles is reached and plastic hinges are formed.

Structural modelling of the dolphin structures was undertaken using the Arup in-house structural analysis program, 'Oasys GSA'. In order to model the lateral pile-soil interaction within Oasys GSA, equivalent linear springs were derived from the non-linear p-y curves derived from the geotechnical analyses. The equivalent linear spring stiffnesses were derived considering loading magnitude and pile deflection in response to lateral loading, and for both upper bound and lower bound cases. For critical load cases, the

equivalent linear spring stiffnesses were iterated until similar pile deflections and structural actions were calculated using Oasys GSA and the geotechnical analysis software.

As part of the structural analysis and design of the dolphin structures, analyses were carried out to determine the deformations of the structure and the impacts on the design load effects, requiring the use of the rigorous method of analysis to AS5100.5 Cl. 7.4 (Australian Standard, AS5100-2004, Bridge Design). Staged Analysis was carried out to replicate the construction sequence and accurately account for locked-in stresses. The Arup in-house structural section analysis program, 'Oasys AdSec' was used for the reinforced concrete design.

#### **4. Pile Cap Analysis & Design**

The Arup in-house software Oasys GSA was used to create the structural analysis model. The ability to easily import and export data was crucial and the ease with which design actions can be managed was a factor in reducing the time required for analysis.

In determining the design actions for the pile cap the non-flexural pile cap was idealised by a truss consisting of compression struts and tension ties connected at nodes to form a load-resisting system. Early conceptual assessments indicated that vertical ties were required between the piles. Further refinements determined the spacing of the vertical ties to optimise the utilisation of the compressive struts.

Non-linear analysis was required to reach equilibrium between the applied external loads, the axial forces in the 3D strut and tie grid, and the pile reactions. This allowed determining the reinforcement requirements to limit serviceability limit states steel stresses and ensure adequate strength at ultimate limit state. Local confinement reinforcement was carefully detailed in the rupture zones near the piles.

Thermal modelling following the guidelines of CIRIA C660 (CIRIA C660, Early-age Thermal Crack Control in Concrete, 2007) was required to assess the deleterious effects due to the heat of hydration. This effect was controlled by designing surface reinforcement to control cracking associated with the anticipated differential temperature. The input to the thermal modelling is further discussed in section 7.

#### **5. Pile to Pile Cap Connection and Pile Design**

A challenge associated with using vertical piles is the relatively high design actions at the connection between the pile cap and piles, when the structure is subject to lateral loadings. The local effects at this load transfer zone require careful attention and detailing.

The design actions were of a magnitude exceeding the maximum capacity of the reinforced pile plug, which is used to transfer design loads between the pile cap and piles. Increasing the diameter of the steel pile liner was not desirable due to limitations on the lift capacity of the barge crane and would also increase the total steel tonnage. As such, Arup developed a solution with further embedment of the steel pile liner into the pile cap to provide the necessary strength to resist the combinations of design loads as well as meeting operational and serviceability requirements. Development of this solution was key to determining the reinforcement arrangement within the pile cap itself and the temporary works solution.

Relying on composite action of the steel liner and reinforced concrete pile plug introduce a requirement for weld beads to resist the associated interface shear stresses. Significant extents of the pile would have required weld beads to overcome the high ground variability, for which this option was considered not to be feasible. Instead, superimposed behaviour was investigated in collaboration with the Arup Advanced Technology and Research team. Studying the compatibility conditions of the two bodies led to a formulation of the load sharing under serviceability limit state and ultimate limit state conditions. Rigorous analysis was required to assess whether the steel pile liner had adequate strength, and in order to account for the buckling behavior. The anticipated long term corrosion varies dependent on the exposure classification, yielding a varying cross-section along the member. 6 mm corrosion was required for the splash zone. Marine grade coating and sacrificial anodes were adopted for corrosion protection for the steel liner, however the design criteria requirement for corrosion allowance was still applicable. Below For piles in compression, the modified member slenderness was therefore used when determining the nominal member capacity to AS4100 Cl. 6.3.4 (Australian Standard, AS4100-1998, Steel Structures) by use of a modal buckling analysis associated with each individual load case.

## 6. Reinforcement Clash Detection

As the projects were delivered in a high labour cost environment, pre-fabricated solutions were developed by Arup in collaboration with JHG. Adopting this type of modular construction had a positive impact on the critical path of the construction programme.

In addition to the coordination of temporary works and the reinforcement, it was also a priority to develop a solution maintaining a safe working environment. Particularly the positioning of vertical tension ties was optimised to allow for personnel access within the pile cap. In zones such as the pile to pile cap connection and where the fender unit cast-in bolts were located, a significant challenge was present in avoiding congestion and allowing safe placement of reinforcement.

The solution to overcome this challenge was the development of a fully coordinated and integrated 3D building information model (BIM) of the pile cap reinforcement, including cast-in items for the fender unit, mooring hook, walkway supports, ladder supports, cable ladder supports, rope rail guards, handrails and several types of electrical equipment. The immediate benefit was the visualization of the heavily reinforced structure aiding to undertake reinforcement clash detection and aiding drawing production. Beyond this, sharing the BIM model with JHG ensured a fully integrated design and construct relationship. This proved to be an extremely useful tool allowing JHG to further develop the temporary works solution by carrying out clash detection with the temporary works supports and cast-in items for the formwork, prior to procurement and construction. It furthermore allowed accurate construction sequence planning that, by use of visual effects, enhanced the understanding of the construction process and fixing sequence.

Additional benefits from the 3D design philosophy were identified during construction in being able to promptly react to changes, which ultimately yielded program savings. Furthermore, the as-built condition was incorporated in the BIM model at the final project stage using 3D laser scanning technology. An example of the BIM model and 3D laser point survey is shown in **Figure 2**.

**Figure 2 Top: Design BIM Model. Bottom: 3D Laser Point As-Built Survey. ©Arup**

An opportunity exists to create a 6D BIM model by including links to product data and details, maintenance/operation manuals, specifications, warranty data, maintenance requirements and

manufacturer information and contacts. This would further assist the project stakeholders and facilities managers in the operation and maintenance of the jetty throughout the life cycle.

## **7. Concrete Supply and Impacts on Design**

Arup undertook detailed assessments of the proposed concrete mix, placement methods, construction sequence and pour dates to ensure the concrete temperature was within the specified limits. This was coordinated closely with JHG to ensure full compatibility between aspects related to construction processes and the Arup design. Thermocouples were used to measure and record the concrete core and face temperature during the initial curing process.

Different methods and techniques were used for winter and summer concrete cooling and transport in order to satisfy placement requirements.

On one of the three project sites, the construction of berthing dolphins was started prior to completing construction of the access trestle and loading platform. As such, concreting of sockets, pile plugs, and pile caps was done by use of a barge mounted boom pump. On average 40 no. concrete agitators were delivered to the site on barges to complete an in-situ berthing dolphin pile cap pour. Each barge delivery would hold 7 no. agitators. A transportation time of minimum 90 minutes from the point of batching to the point of discharge led to an increase in placement temperature. Therefore, concreting had to be done during winter, to avoid excessive peak temperatures. The temperature development for a berthing dolphin pile cap poured in May 2014 is shown in Figure 3.

Another method adopted was to use a line pump to complete the in-situ pile cap pours where direct access to the dolphins was possible via the access trestle, loading platform and access walkways. This reduced the transportation time to 20 minutes. Where this placement method was applied, the construction programme required concreting during the summer months. Although the transportation time was reduced, the minimum achievable placement temperature was at a level such that, in combination with the expected adiabatic temperature rise, the peak temperature would reach an unacceptable level. The solution was to inject liquid nitrogen (LN) into the ready-mix truck immediately before the point of discharge. A fully automated and controlled setup was implemented in a secured area only accessible to trained operators. A test determined the efficiency of the LN injection as 7 minutes of injection to cool the mix by 10 °C. A target placement temperature was defined which controlled the active injection time for each delivery. By implementing the LN injection no peak temperatures exceeded the allowable limit.

**Figure 3 Top: Injection of liquid nitrogen to reduce concrete placement temperature during summer. ©Bechtel/Arup. Bottom: Temperature development for a berthing dolphin pile cap pour. ©Arup**

Arup defined the requirements related to the performance of the concrete during the early stages of the detailed design programme, which made allowance for preparation of the concrete mix and verifying performance by a test pour before commencing construction activities.

## 8. Conclusion

Achieving an efficient design that meets the environmental, metocean and vessel design criteria, while satisfying the challenging ground variability and construction constraints, was a testament to the positive collaborative relationship between the design team and contractor. Early engagement and an aligned understanding of the constraints helped in paving the way to designing efficient structures. In addition fluid communication between structural, geotechnical, maritime, and electrical design teams was paramount in achieving the design which produced holistically positive outcomes. The implementation of BIM modelling was useful during both design and construction stages to both Arup and JHG, yielding improved visualisation and construction planning.

First gas was shipped from Curtis Island on 5 January 2015 from QCLNG. GLNG and Australia Pacific LNG are expected to commence shipping later in 2015.

# Lady Cilento Children's Hospital

Ken Gallie<sup>1</sup> and Darryl Feodoroff<sup>2</sup>

<sup>1</sup>Structural Team Leader and Principal, Cardno

<sup>2</sup>Principal, Cardno

**Abstract:** The Lady Cilento is a new tertiary children's hospital, a state of the art health facility and an iconic building. Works commenced in 2007 and construction completed in 2014 at an overall project cost \$1.5 billion.

The Architects for the project were Conrad Gargett Lyons. Town planning, civil, structural and traffic engineering was undertaken by Cardno and services were by AECOM. Lend Lease were the Managing Contractor.

The building has four basement parking levels, eight main hospital levels, four ward levels and three upper levels for services. In order to achieve openness, light and connectivity within the large footprint, there are two central atriums with large radiating open spaces. The footprint and atrium size vary for each of the main hospital levels and have landscaped roof areas.

The varying footprint, voids and column grid created challenges which required an efficient structural system suitable for construction, operation, installation of complex building services and be adaptive in the long term. A band beam and slab system with post tensioned beams was adopted to minimise depths and control deflections. The slabs were designed with conventional reinforcement to maintain flexibility for the installation of services.

The ward level floors have a different column grid and were fully post tensioned to minimise weight at the transfer level.

The concrete specified for the project included shrinkage control mix in the slabs, strengths up to 80 MPa in columns and specialised concrete mixes for thick walls. Metal decking was used as permanent formwork for slabs.

**Keywords:** Concrete composite column, post-tensioned, reinforced

## 1. General Project Description

The Lady Cilento Children's Hospital is a tertiary healthcare facility serving paediatric clients in Queensland. It replaces the Royal Children's Hospital and the Mater Children's Hospital and is located on a brown field site in South Brisbane, adjacent to the Mater Hospital Campus.

The Lady Cilento Children's Hospital is the major component of a new health precinct which includes a separate energy building, a medical research building, and a multi-storey short term parent's accommodation facility. The energy and research buildings are linked to the main hospital building with tunnels for both services and pedestrians.

The new precinct was occupied by a variety of buildings and open spaces, including a multi-level car park and a telephone exchange. To allow for construction of the new hospital building, a new multi-level carpark had to be constructed on an adjacent site. Once the new carpark had been completed, it allowed the original carpark to be demolished.

The telephone exchange occupied a corner of the site which was key to the overall redevelopment of the precinct. Initial studies included relocating the exchange within the Lady Cilento Children's Hospital, however ultimately the exchange was decommissioned and the building demolished. The hospital construction had to be staged around the exchange building to allow sufficient time for all of the existing telephone services to be relocated.

The project brief was to provide a state of the art building that brought together all paediatric services in one location, providing a positive experience for patients and families, conducive to achieving healthy outcomes.

Photograph 1. The Lady Cilento Children's Hospital

The architectural design incorporates a 'trunk and branch' concept with two internal atria forming the *trunks*. Each trunk has large radiating public spaces or *branches* at different levels throughout the building which extend from the atria to the face of the building. The branches seek to open up the internal parts of the building and provide views of some of Brisbane's landmarks. The branches also cantilever through the façade of the building creating a distinctive feature of the building.

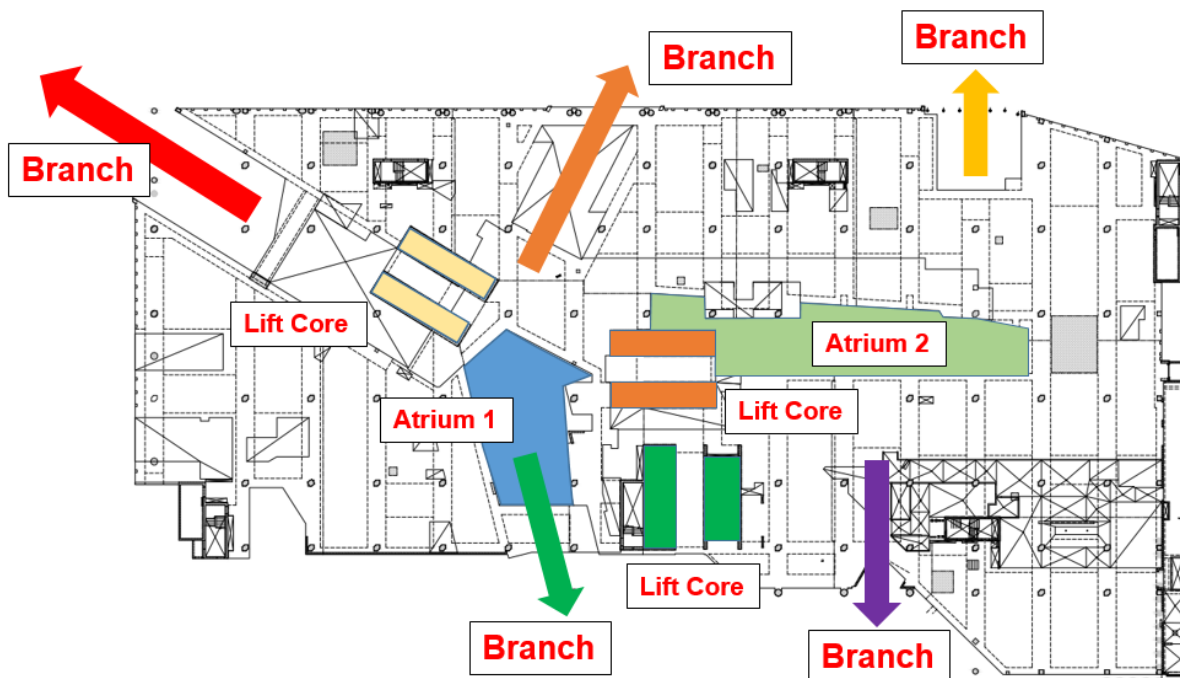

Figure 1. Trunk and Branch Concept

The Lady Cilento Children's Hospital has over 110,000 square metres of floor space, spread across eight main floors (Levels 1 to 8) which cater for clinical, administrative and other facilities. Each of the levels has a varying footprint with the atria and branches altering in size and orientation. The building form steps back progressively creating a series of landscaped rooftop spaces, which provide areas for patients and staff, as well as providing rest areas for families.

There are four ward floors which start at Level 9 and have a completely different footprint to the main floors of the building. Above the ward floors is an open rooftop area incorporating plant rooms and an elevated helipad. The helipad is supported by steel trusses which cantilever up to 13 m off concrete columns.

Externally the development included reconfiguring the adjacent road intersection and street improvements to improve traffic flows, plus the creation of landscaped open spaces which link to the nearby South Bank Parklands. An open children's play area and pet visiting area are located external to the hospital at Level 2.

Vehicle access is provided to the off-street drop off zones at the Stanley Street and Raymond Terrace entry points. Due to the complexity of the underground services and the heavy local traffic, tunnel boring was adopted as the only viable alternative to upgrading and relocating many of the services in the precinct including electricity, water, gas and telecommunications services.

Early construction works commenced on the site in 2008 and the hospital opened in late 2014.

## **2. Primary Structural Concrete Elements**

### **2.1 Foundations and Basement Floors**

The geotechnical site investigation revealed that the site was underlain by rocks of the Bunya Phyllite which is a weakly metamorphosed fine grained rock. Seven boreholes were drilled to depths of up to 18 metres during the geotechnical investigation. There were three weathered rock profiles encountered in the boreholes including phyllite, metasandstone and metagreywacke. The depths to the weathered rock increased in the north eastern corner of the site. Generally improving with depth, the rock strength varied from very weak to strong.

There are four basement levels of car-parking which allows for up to 650 vehicles. The excavation of the basements were completed in stages. Bored piers were installed and then anchors installed as the basement was excavated. Although 600 mm diameter piers were used in some areas, generally 750 mm diameter piers at approximately 2.5 m centres were adopted. In addition to the lateral earth pressures, the piers were also designed to support the loads from the building where required. To resist the retention loads, the bored piers were temporarily anchored into rock using 15.2 mm diameter stressed strands. 150 mm thick spray-crete walls were constructed between the piers prior to the next stage of excavation commencing.

Due to the proximity of the project to the South Brisbane Bus Tunnel (under Stanley Street), an extensive geotechnical study was required to satisfy the Department of Main Roads and Transport that the existing tunnel would not be adversely affected by the excavation of the basement including the construction of ground retention system and the building generally. Real time monitoring was carried out during construction to ensure that there were no movements within the tunnel structure.

High level pad footings were used to support the building internally and were sized on the basis of an allowable bearing pressure of 1500 kPa. To reduce the amount of rock over-break, a rock saw was used to cut the rock to suit the size of the footings.

While the lowest levels of the basement floors were slab on ground construction, upper suspended levels consisted of reinforced band beams and one way slabs. To allow for creep and shrinkage of the floor slabs, special details were required for the connection of the band beams and suspended slabs to the retention piers. The gaps between the slabs and the piers were later grouted allowing the temporary rock anchors to be de-stressed.

## **2.2 Typical Floors Levels 1 to 8**

The slabs at these levels have a large footprint and are interrupted by two atriums of varying size and three lift cores. The footprint varies floor to floor, with the western and eastern ends stepping back progressively to create a series of useable roof areas. The column grids vary to optimise floor planning and as a result, beams and slabs are required to have medium to large spans.

Hospitals are highly serviced and the floor structure needs to be able to maximise the ceiling space. To cater for changes in service delivery and technological advancement, hospitals also need to be able to adapt to changes over time. The floor structure needs to;

- Provide for the functional and technical aspects of the design brief
- Be serviceable, with appropriate vibration performance for the various functions, particularly in the operating theatre suites and diagnostic imaging areas
- Be economical, durable and provide adequate fire resistance
- Cater for a high level of services cores, risers and voids of varying sizes
- Allow flexibility for future re-planning, including provision for setbacks for wet areas and services installation
- Have provision for heavy loading and suit the installation of a wide variety of clinical and imaging equipment, data processing and mechanical plant
- Have medium to large spans to provide the most flexibility in planning
- Minimise depths to provide the maximum clear ceiling space for services runs
- Cater for column transfers
- Provide radiation shielding in radiography areas

A number of floor systems were investigated to satisfy these issues, including flat slab, flat plate and banded slab. Precast systems were discounted as they constrained flexibility needed to suit potential planning changes. A banded slab system was adopted as the preferred system. The slabs are generally conventionally reinforced with strategic use of post-tensioning to allow for future flexibility and installation of services.

Post tensioning was introduced in band beams to minimise depths and control deflections on the larger spans and to cater for transfer loads. Post tensioning was also introduced in some internal slab areas to suit heavy loadings and in some floors to suit construction programming and to minimise back propping. External slab areas were post tensioned to aid in waterproofing.

Flexibility for the provision of future wet areas was provided by topping the slabs at some levels. It was considered uneconomic to top all of the floors within the building. A study of possible future planning changes was carried out and particular floors were identified as requiring a topping. To reduce the impact on the construction program and to avoid issues with delamination, a topping integral with the slab was adopted rather than a separately applied topping or screed.

Conventional formwork was used for the beams, areas of varying slab shapes (in plan) and other particular zones. Metal decking was typically used as permanent formwork for the slab soffits between the beams.

During construction there were up to five tower cranes, six concrete placing satellite booms and three material and personnel hoists rising within the building. The large number of temporary voids necessary to suit these had a significant effect on the design and construction of the slabs. These were all ultimately closed in as the plant was removed.

The external roof slab areas created by the building setbacks have a variety of uses, from patient and staff areas to recreational and quiet spaces for families. These areas have surface falls to drainage outlets and have various surface finishes including turf and pavers.

Movement joints were provided in the slab to allow for the initial shrinkage of the concrete due to the large floor plates and the effects of the three internal lift cores. To avoid impacts on the construction program, a lockable dowelled joint system was used. These joints were left as long as possible before the dowels were locked and the joint gaps that had opened since casting the slab were grouted.

**Figure 2. Level 5 Slab Key Plan**

In this heavily serviced building there are a large number of slab penetrations for services. While as many as possible of these services had pipework or sleeves built in when the slab was poured, there were still a large number installed after the floor had been cast.

Late changes also occurred due to planning changes and some of the detailed services design lagging behind the construction program. To manage this and avoid inadvertent drilling and cutting causing structural issues, a permit system was introduced. The permit system required sign off by all parties and all services installers were required to follow this procedure.

### **2.3 Levels 9 to 12 - Ward Floors**

The ward areas are located in the upper four levels of the building. To suit the ward planning and overall form of the building, these floors have a completely different footprint to the building below.

The column layout is significantly different on the ward levels requiring a transfer floor at Level 9. The band beams are significantly deeper on Level 9 than the lower floors and are more heavily reinforced with an increased level of post tensioning.

A fully post tensioned banded slab system was used for the ward levels to reduce weight, minimise the transfer loads and to keep floor to floor heights to a minimum.

Generally 50 mm deep set downs were provided for wet areas in the ward levels. Level 12 was designed as a shell floor and incorporated extended set down areas to suit any planning changes that may occur in the future fitout.

**Figure 3. Level 11 Slab Key Plan**

## **2.4 Composite Structural Steel & Concrete Columns**

Early design studies for the building investigated a cantilevered building perimeter, however the depth of the supporting beams was found to be a constraint to providing sufficient clear ceiling space for services. An alternative solution of raking columns was adopted for the perimeter of the building. The geometry of the columns vary to suit the building form and are coordinated with vehicle access to the Raymond Terrace and Stanley Street patient drop off zones. The columns form a striking feature of the building.

The raking columns comprise an outer steel circular hollow section (CHS) with an inner universal column (UC) section encased in concrete. The inner core relies on composite action between the UC section and the concrete. As the CHS is sacrificial in the case of fire, it was assumed to not contribute to the overall structural capacity of the column.

The columns found on bored pier foundations and as the columns on the Stanley Street frontage rake outwards significantly, the foundations to these have tie beams back to the main structure to cater for the lateral forces that arise.

**Figure 4. Typical details of raking columns**

Some of the earliest construction using composite concrete columns was in Brisbane, Melbourne, Perth and Adelaide in the late 1980's and early 90's. There was no Australian Standard covering the design of composite columns in buildings when the raking columns were being designed for the Lady Cilento Children's Hospital. Our research indicated that composite columns in Australia have been designed using Eurocode 4: Design of Composite Steel and Concrete Structures - Part 1-1. This design code was adopted which satisfied the performance requirements of the BCA (rather than the deemed to comply requirements).

Due to the three dimensional geometry, the columns had to be temporarily propped with falsework to position them and maintain their stability, until they were cast in with the floor slabs. Differential deflections of the columns was also factored into the design.

**2.5 Vertical Elements**

The building has three main multiple lift cores and a number of stair cores. The columns range in shape and size up through the building. Walls and columns were designed as cast in-situ reinforced concrete. The column grid is fairly regular in the long direction of the building, but varies at end spans and across the short direction of the building to optimise planning. There are column transfers at various locations to suit planning and the atriums. Column and wall sizes have been minimised by the use of high strength concretes, particularly in the basement parking areas to optimise parking arrangements.

The lift cores terminate at different levels to suit the planning requirements and were constructed using a jump form system. The lift cores provide lateral stability to the structure for wind and seismic loading. Due to the complex shape of the building, a wind model study was carried out to provide more complete information than could be derived from Code provisions. Three dimensional computer modelling, including dynamic loads from seismic actions, was employed to analyse the building frame and optimise the structural wall sizes and layout.

An innovation, promoted by the Project Architect, was to shape the main building columns to suit the installation of services.

**Figure 5. Typical Concrete Column Shape**

Apart from the lift and stair cores, there are reinforced concrete walls for rainwater and potable water storage tanks and transfer walls. Some walls were also provided for shielding in radiography zones. Loadbearing walls were kept to a minimum to provide flexibility for future reutilisation. Loadbearing blockwork was generally avoided.

**2.6 Sloping Green Wall**

The sloping green wall is a significant landscaping feature of the building. Located on the western side of the building, the sloping green wall traverses two floors, starting at Level 6 and continuing to Level 8. The slope of the green wall is approximately 30 degrees which presented some challenges during construction. The main feature of the sloping green wall is the landscaping element which consisted of planting contained in *baskets*. The baskets were designed to hold the soil and planting in place on the slope.

During the early phases of design development, a number of options were considered including in-situ concrete, precast concrete, structural steel and composite/fiberglass. Fire, durability and waterproofing considerations eventually ruled out structural steel and the composite/fiberglass options. A moving stage would have been required to finish the concrete had a full insitu option been adopted.

**Photograph 2. Sloping green wall**

A combination of 3.5 tonne, 190 mm thick precast concrete slabs with in-situ concrete pour strips was adopted in conjunction with the Managing Contractor and the formwork sub-contractor. The precast slabs were laid on falsework and the infill strips were then constructed. The precast slabs allowed a safe zone for the steel fixers and the concreters to work from. The number of identical precast slabs was maximised to allow the panels to be stack cast adjacent to the green wall.

**Figure 6. Part Plan showing precast concrete slabs to sloping green wall**

Once the concrete operations had been completed and backpropping removed, a waterproof membrane was applied and the baskets were installed. Stainless steel straps were used to prevent the baskets from sliding down the sloping surface. Safety lines were installed at the top to allow abseilers to maintain the green wall.

**Figure 7. Typical cross sections of sloping green wall**

## **2.7 Use of Precast Concrete**

To minimise falsework, the lift motor room floors and roof slabs to the water tanks were constructed using precast panels with a cast in situ topping. The topped panels were designed to suit the elevator plant loads and to suit forming and pouring the roof slab over. Craneage requirements dictated the size of the precast slabs in some instances. The precast slabs were typically 180 mm thick and weighed up to 6 tonnes. The number, size and location of penetrations in the lift motor room precast slabs were a primary issue for the design. Steel beams were used to provide temporary support of the panels during construction.

## **3. Concrete Materials**

As expected for a project of this complexity, a wide range of concrete mixes were used. There was over 60,000 cubic metres of concrete placed, at an average of over 120 cubic metres per day during the building structure construction.

Mixes were developed to suit the various building components and the extensive surrounding paved areas. Concrete mixes supplied to the project included:

- 40 to 80 MPa strength in columns and walls. High strength concrete was used in the basement parking zones to minimise the column size and optimise parking arrangements
- Generally special class 32 MPa in slabs, with shrinkage control and high early strength to suit post tensioning
- 65 MPa concrete in thick water tank walls with temperature controls to reduce thermal effects
- Topping mixes
- 32 MPa special aggregate mixes for exposed aggregate paving
- A number of special mixes were also supplied for particular situations or where there were constraints on delivery and placing

Aggregate sizes and slumps varied to suit the particular situations, pumping and placing.

The site was very constrained on all sides, with insufficient area to establish a concrete delivery and pumping site close to the building. To overcome this problem, the Managing Contractor established a remote concrete delivery site on an adjacent street and the concrete was pumped to the site through

underground pipelines. Delivery to the satellite boom pumps on the site was controlled through a manifold system in the basement. Up to six boom pumps across the site were established to suit concrete placing.

#### **4.0 Structural Steel**

##### **4.1 Branches**

The branches offer a unique statement to the façade of the building form. The branches cantilever over the streetscape and are typically over two floors. The branches form a balcony that allow users of the hospital to view the city skyline. The side walls of the branches were designed as structural steel trusses enabling the structure to cantilever from the concrete columns at the building interface.

Concrete columns were specifically shaped to allow the structural steel from the branch to connect into the building fabric and also to provide an interface for the curtain wall. The branch walls, ceilings and roofs were clad with alpolic. Branch floors were constructed using in-situ concrete over steel formwork supported on structural steel framing.

The layout of the structural steel floor framing were set out so that the steel formwork did not require propping during construction.

**Photograph 3. Northern Branches**

##### **4.2 Atriums**

Two atriums were part of the living tree concept for the project. The first of these commenced at Level 2 and continued to Level 10. The walls of the atrium were multi-faceted with a significant number of inclined faces. The walls were framed using structural steel and light steel stud framing. Complexity of the architectural form, fire-rating, maintenance and cleaning were key issues during the design and documentation.

**Photograph 4. Atrium 1**

### **4.3 Helideck**

Located at Level 14, the Lady Cilento's emergency helipad measures approximately 27m x 23m. There are two components of the helipad being the primary support structure and the helipad deck. The primary support structure consisted on four structural steel trusses that were supported on concrete columns. Two of the trusses were required to cantilever up to 13 metres and were designed to support emergency services helicopters weighing up to 8.0 tonnes. The 3.0 metre deep trusses were fabricated using 273 x 9.3 CHS top and bottom chords with 168 x 4.8 CHS diagonal members.

**Figure 8. Typical cross section through Helideck structure**

## **5. Design Codes and Loads**

The various building uses were considered in determining the types of loads onto the structural elements. There are special load areas within the building to cater for uses such as medical imaging, records, plant and landscaping. Planning for the heavy equipment included defined load routes through the building for the installation and replacement of the same. Provision was also made for access points into the building, through the façade and via a hatch through the Level 2 slab. Provision for specific vibration sensitive functions was also made to suit operational requirements.

The structural design parameters were set by the Project Brief, the Building Code of Australia, Australian Standards and Regulations. International codes were adopted when there was no appropriate Australian Standard.

## 5.1 *Dead and Live Loads*

A Building Code of Australia Importance Level 4 was adopted for the building structure. Floor and general loadings were adopted in accordance with AS1170 Part 1. Loads in excess of AS1170.1 have been used in some areas to permit future flexibility. Special load cases apply in various parts of the building for plant, imaging equipment and landscaping. Generally, loads were as follows;

- Superimposed dead loads from partitions, etc, (excluding slab toppings) 1 kPa
- Live load generally 3 kPa; public areas 4 kPa; plant areas 5 kPa;
- Special loads as required for medical imaging and other equipment

## 5.2 *Wind Loads*

A wind tunnel study was commissioned to examine the wind pressures on the complex façade including branch structures. The wind study also provided advice on the effect that the operable louvres that occur at the branch ends would have on the internal walls and ceilings. The operable louvres automatically closed once the wind speed exceeds 10m/s.

The external walls (excluding the main façade), internal atrium walls and general internal walls were designed in accordance with the requirements of the design guidelines and the Building Code of Australia.

### 5.2.1 *Basic Wind Pressure*

The wind loads were assessed in accordance with the Building Code of Australia and AS 1170 Part 2. The wind speed was assumed to vary with the height of the building. For practical reasons the wind pressures were calculated in groups of three storeys above Level 1. The ultimate design wind pressure (at Level 13) was 3.20kPa.

Region	B
Importance Level (BCA)	4
Topographic Multiplier	Mt = 1.0
Shielding Multiplier	Ms = 1.0
Terrain Category	2.5

### 5.2.2 *Pressurised Internal walls*

Typically the pressurised internal walls bound the open spaces created in the centre of the building between Levels 1 and 4. These spaces have natural ventilation from the louvres in a number of the Branches that allow natural light to permeate through the building. Above Level 4, the atrium splits off into two smaller isolated atriums that extend to roof level.

## 5.3 *Earthquake Loads*

The building was designed to withstand a 1 in 1500 year seismic event (Seismic Design Category III) which required a dynamic assessment to be undertaken. As noted earlier, lateral loads were resisted by the lift and stair cores.

## 6. *Conclusion*

The Lady Cilento is a new tertiary children's hospital, a state of the art health facility and an iconic building, designed to serve Queensland. At an overall cost of \$1.5 billion, works commenced in 2008 and construction completed in 2014.

The building has four basement parking levels, eight main hospital levels, four ward levels and three upper services levels. In order to achieve openness, light and connectivity within the large footprint of the main floors, there are two central atriums with radiating branches which connect through to the façade.

The footprint and atrium size vary for each of the main hospital levels and have landscaped roof areas. The western façade includes a raking wall which supports specialised landscaping.

Reinforced and post-tensioned slabs and band beams were generally adopted for the floor structures as these were considered to be the most efficient and adaptable system.

# Documentation of Bridge Deck Construction Using Industrially Produced Internally Cured, High Performance Concrete

Timothy J. Barrett<sup>1</sup> Albert E. Miller<sup>2</sup> and W. Jason Weiss<sup>3</sup>

<sup>1</sup>PhD Candidate, Purdue University

<sup>2</sup>Graduate Research Assistant, Purdue University

<sup>3</sup>Jack and Kay Hockema Professor of Civil Engineering, Purdue University

**Abstract:** In 2013, the Indiana Department of Transportation (INDOT) commissioned the construction of four bridge decks using an internally cured concrete designed to achieve an increase in durability through reductions in ionic transport and reductions in the potential for cracking. In an effort to improve the durability, a blended cementitious system was used containing ordinary portland cement, fly ash or slag, and silica fume was specified for use at moderate water-to-cementitious materials ratios, of less than 0.43. Since higher performance concretes show an increased susceptibility for shrinkage cracking, the process of internal curing using a pre-wetted fine lightweight aggregate was used to reduce the potential for cracking. This paper presents a case study on the construction of these internally cured, high performance concrete bridge decks with a focus on its impact of implementation on practice. Basic testing results such as strength and stiffness will be presented with a focus on the lack of necessity for revisions to code equations or design practices due to the presence of internal curing. In addition, a new quality control technique for the rapid determination of lightweight aggregate moisture states will be reviewed while recommendations for the daily field implementation of internally cured concrete will also be presented. This research is intended to provide a succinct overview of the successful field implementation of internally cured concrete, which offers the potential to produce concrete that may have a lower susceptibility to cracking, leading to realized improvements in the service life of high performance concretes.

**Keywords:** Internal curing, high performance concrete, construction documentation, service life, shrinkage.

## 1. Introduction

The Indiana Department of Transportation (INDOT) constructed four bridge decks utilizing internally cured high performance concrete (IC HPC) during the summer of 2013. These decks are being considered as one method to reduce cracking and to improve the durability of the bridges [1]. While the laboratory results of internally cured concrete have shown great promise, few studies have documented field performance [2]. The objective of this research is to provide documentation of the construction of four IC HPC bridge decks that were constructed in Indiana during 2013 and to quantify the properties and performance of these decks from samples procured at each site. The data obtained from each of these mixtures will be compared with equivalent high performance concretes (HPC) that contained no internal curing for each respective mixture and contrasted with a typical bridge deck concrete that is used in Indiana (so-called Class C concrete) [3]. The purpose of this documentation is to provide data that can be used to quantify the performance of industrially produced internally cured concrete with the goal of developing recommended procedures to implement new technology and developing future strategies to determine if and where internal curing should be used. The documentation provided by this project will focus on three main areas:

1. Documentation of construction/measurement of the constituent materials, variability, and fresh concrete properties.
2. Documentation of the properties of the concrete used in these bridges
3. Documentation of the shrinkage cracking resistance with a comparison of IC HPC and reference (non-internally cured) concrete.

## 2. Specification Overview

As a part of this work, a new specification was developed and implemented which incorporated both prescriptive and performance based measures which were intended to produce a concrete of high durability, low permeability, and low cracking potential [4]. This section will review the specified measures intended to provide higher performance and internal curing using prewetted fine lightweight aggregates (LWA).

## 2.1 Higher Performance Specifications

The higher performance inherent to the IC HPC comes from three key specification measures. The first is through the use of two supplementary cementitious materials in combination with the portland cement which will result in a refinement of the pore network, consumption of calcium hydroxide, and a microstructure that is more dense overall [5]. The specification requires a minimum of 231 kg/m<sup>3</sup>, a content of 20 to 25% of Class F or C fly ash (by mass), and a content of 3 to 7% of silica fume (by mass). It is permitted to substitute ground granulated blast furnace slag (ggbfs) in an amount of 15 to 20% (by mass) in lieu of fly ash. An additional benefit of the use of supplementary cementitious materials is the net reduction in cement consumption for the production of concrete bridge decks. IC-HPC conforming to this specification may result in a net reduction in cement usage of 23 to 32% (18 to 27% using ggbfs).

The second aspect of the specification that improves the performance of the mixture is a limitation of total paste volume to 25% with a tolerance of  $\pm 1.0\%$  on batched quantities. This limitation was intended to limit the shrinkage potential of high performance mixtures, based on research presented in the FHWA/IN/JTRP-2008/29-2 report where it is recommended that a paste volume of less than 24% be targeted [6]. This report reflects previous recommendations from Schmitt and Darwin which studied 33 monolithically cast bridge decks constructed prior to 1994, where it was documented that measured cracking increased with increasing paste volumes [7]. The survey indicated that the volume of paste should not exceed 27%, based on a sample of 9 bridge decks at moderate w/c of 0.42 or 0.44. This data was then reproduced in 1999 [8], 2004 [9], and again in 2005 [10] with the culmination of these results being used as the basis of mixture proportioning for a low-cracking, high-performance concrete with a maximum paste content of 24% and performance being measured in relation to crack density alone [11].

This body of work recognizes the importance of paste volume, as shrinkage in cementitious systems is derived primarily through chemical reactions, osmotic or disjoining pressures, and/or the development of capillary stresses occurring within the paste [12]. The connection of shrinkage to paste volume has been observed experimentally for many years, with numerous models having been proposed to estimate contributions of paste shrinkage to the overall shrinkage observed in concretes. Picket proposed a simple relationship in 1956 which relates the total shrinkage in concrete to the shrinkage of the matrix and the volume of paste, as shown in Equation 1 (with the volume of paste being represented by  $(1 - V_{\text{aggregate}})$ , where  $V_{\text{aggregate}}$  is the volumetric fraction of the concrete which is aggregate) [13]. Figure 1 shows this relationship, normalized by the total estimated shrinkage of a concrete with a paste volume of 25%, with values of  $(n)$  which reasonably estimate the range of typical concretes. From this, the relative increase in shrinkage of concretes with higher paste contents can be seen to be approximately linear, with a 5.5 to 7.7% (for  $(n)$  equal to 1.3 and 1.5, respectively) increase in shrinkage for a 1% increase in paste. With this in mind, a few points of emphasis should now be made. The first is that excessively low paste volumes for industrially produced concretes may result in technical challenges with placement and achieving proper consolidation. Secondly, as the volume of paste is reduced, the potential for the interfacial transition zone to percolate, resulting in increased permeabilities [14]. Finally, it should be highlighted that internal curing is intended to mitigate significant early age shrinkage, making this limitation less necessary for the intent of shrinkage reduction (revisions to the specification in 2014 have relaxed the limit on total paste volume to 26% and may be able to be further relaxed without significant changes in the shrinkage behaviour of the IC HPC mixtures).

$$\varepsilon_{\text{concrete}} = \varepsilon_{\text{matrix}}(1 - V_{\text{aggregate}})^n \quad (1)$$

**Figure 1. Estimated relative increase in shrinkage strain of a concrete, normalized to a paste content of 25%. Relationship is based on Pickett's Law [13].**

A secondary effect of the limitation on paste volume is the inherent maximum cementitious materials content of the concrete mixture. In current specifications for Class C bridge deck concretes, this limitation does not exist. During the production of this concrete, producers target minimum strength values which can be easily achieved through the addition of cement to the mixture. A recent study concluded that Class C bridge deck concretes frequently have cement contents in excess of 386 kg/m<sup>3</sup> which may lead to increased susceptibility to the formation of transverse cracking in bridge decks [15].

The final specification measure which promotes higher performance is the limitation on water-to-cementitious materials ratio (w/cm) of 0.36 to 0.43, with a stated allowable tolerance of  $\pm 0.025$ . This limitation on w/cm leads to the production of concrete that, when a high degree of hydration is reached, will have minimized the capillary porosity [16]. The minimization of capillary porosity will result in concrete that has a lower permeability and diffusivity [5]. A secondary consequence of specifying the low paste volume and w/cm is the inherent necessity for producers to perform accurate aggregate moisture tests and account for excess water in the mixture at all times during the production of IC HPC.

## 2.2 Internal Curing Specifications

The internal curing in the IC HPC is specified to be achieved using a pre-wetted fine lightweight aggregate. The amount of LWA used for internal curing is intended to supply 7 kg of water per 100 kg of cementitious materials [17]. This quantity was multiplied by 1.025 by INDOT to account for an additional margin of safety in the specification (i.e., supply a total of 7.17 kg of water per 100 kg of cement). The approved mixture design was used to ensure a fixed volume of LWA is supplied (not less than 20% of the total volume of fine aggregate volume) based upon laboratory measured values for the LWA absorption and specific gravity at 24 hours. According to the specification, at the time of production the LWA absorption and specific gravity is to be measured. The target batch weight of LWA is then specified to be determined by multiplying the weight of dry LWA necessary to supply 7.17 kg of water per 100 kg of cement (as determined by the 24 hour laboratory moisture properties of the LWA) multiplied by the total moisture of the LWA measured on the day of production.

In preparation for the production of IC HPC, the producer is required to wet the lightweight aggregate with a suitable sprinkler system for a minimum of 48 hours or until the absorption of the LWA is consistently maintained above the design absorption value. The stockpile of LWA is to be drained for 12 to 15 hours immediately prior to its use in IC HPC construction. Manipulation of the stockpile should be done as necessary to achieve a uniform moisture state while wetting and draining. To determine the LWA moisture state on the day of production, the specification cited the provisions in Appendix B of ACI 211.2 which utilizes a centrifuge spinning at 500 rpm for 20 minutes in order to achieve a pre-wetted surface dry condition for absorption testing [18]. Since the inception of this research, this technique has been improved upon by Miller et al. to utilize a centrifuge spinning at 2000 rpm for 3 minutes to achieve a pre-wetted surface dry condition of the LWA [19] and has been subsequently standardized by the state of Indiana in Indiana Testing Method 222 [20]. A variability study has also been conducted [21] showing that the centrifuge method reduces the coefficient of variation in measured moisture contents of LWA

by an order of magnitude compared to the so-called “paper towel” test, recommended in ASTM C 1761 [22].

In order to ensure that the IC HPC mixtures achieve the stated goals of improved durability and reduced permeability, certain performance measures based on standardized tests were specified. At the point of placement, the concrete mixture is to have a measured slump between 63 to 140 mm, a target air content of 6.5%, and the measured relative yield shall not be excessively high or low. The specified compressive strength at 28 days shall be a minimum of 34 MPa. Finally, the IC HPC shall achieve a target resistance to chloride ion permeability of no greater than 1500 coulombs as measured by the rapid chloride penetration test (ASTM C 1202/ AASHTO T277) at 56 days of age [23]. It should be noted that the specification for Class C concrete does not include any limitations on measures of resistance to chloride penetration, only specifying a maximum w/cm of 0.443 and a minimum 28 day compressive strength of 30 MPa. The performance criteria have been summarized in Table 1.

**Table 1. Internally cured, high performance structural concrete specification parameters [4].**

<b>IC HPC Specification Criteria</b>	
Batching Tolerance	± 1%
Slump Range	63 - 140 mm
Target Air Content	6.5%
w/cm	0.36 - 0.43
f <sub>c</sub> , 28 d	> 34 Mpa
RCP Test, 56 d	< 1500 C
Internal Curing Water	7.17 kg/kg cem

### 3. Project Information and Mixture Designs

The IC HPC bridge decks that were cast were made by four separate producers, located in four different regions of Indiana and being supervised by four different INDOT district engineering units. The bridges had varying span lengths (maximum span lengths ranged from 8.5 m to 26 m) and varying structural configurations (single span composite with steel girders, three span continuous composite with steel girders, and two span continuous composite with prestressed concrete beams with an integrally cast pier).

The specimens obtained in this study were produced on the same day that each bridge deck was cast using the same mixture proportions, batching and mixing system, and aggregate moisture adjustments as was used for the bridge deck. Upon completion of the deck pour, two separate concrete trucks were ordered at each producer’s facility, containing 2.3 m<sup>3</sup> (three cubic yards) of concrete each. The first truck contained the IC HPC as batched that morning while the second truck contained the equivalent HPC, where the LWA in the mixture was replaced with normal weight fine aggregate.

The cementitious materials used in the study include Type I ordinary portland cement, Class C fly ash or ground granulated blast furnace slag (GGBFS), and densified silica fume. The aggregate consisted of a normal weight natural fine aggregate and a normal weight limestone conforming to INDOT gradation 9 [24]. To achieve internal curing, an expanded shale lightweight fine aggregate was used to replace a portion of the normal fine aggregate. The moisture state of the LWA was determined using the centrifuge method [25] where, at the time of batching, the measured absorption ranged from 18.7 to 20.2% for all mixtures. The measured surface moisture contents of the LWA for all mixtures ranged between 6.6 to 9.9%.

The as-batched mixture proportions of the concretes used in this study can be seen in Table 2. The naming convention of each mixture is denoted by the concrete mixture type (IC HPC or HPC) and a numeral indicating the base mixture for each bridge deck in no particular order. Concrete mixtures IC HPC 1 and HPC 1 were made using the same mixture proportions with the only difference being the replacement of fine aggregate with LWA for the purposes of internal curing. Air entraining admixture, high range water reducing admixture (HRWRA), mid-range water reducing admixture (MRWRA), and retardant admixtures were added at the discretion of each producer in order to meet specifications for air content and slump. Inspection of Table 2 shows that variation in the w/cm exists throughout these mixtures. Based on field observation it is advised that special attention be paid to all sources of excess water during production (e.g., surface moisture of aggregates, wash water in the truck, and batching

error). In general, the target fresh properties were obtained with the exception of those marked. Table 3 shows the price of the IC HPC and HPC mixtures in this study, indicating that the additional cost for internal curing may be minimal. As a part of one of the contracts involved in this study, two identical bridge decks were replaced with one bridge deck consisting of the mixture referred to herein as IC HPC 1 while the other bridge deck was constructed with a traditional Class C concrete. The constructed cost difference of these bridge decks is \$35/yd<sup>3</sup> (~\$27/m<sup>3</sup>), representing a premium of 0.13% of the cost of one bridge deck replacement to implement the internally cured, high performance concrete.

**Table 2. As-batched mixture proportions [26].**

	IC HPC 1	HPC 1	IC HPC 2	HPC 2	IC HPC 3	HPC 3	IC HPC 4	HPC 4
W/CM	0.405	0.428	0.396	0.403	0.447	0.422	0.465	0.398

#### 4. Laboratory Measured Properties

A series of tests were performed to characterize the overall behavior and performance of the IC HPC and HPC materials. Table 4 lists the results of mechanical behavior as measured through ASTM C 39 [27], ASTM C469 [28], and ASTM C496 [29], and the result of the rapid chloride permeability (RCP) test (ASTM C1202 [23]), allowing for the assessment of the performance in relation to the limits set forth in the specification. In addition to this information, the linear unrestrained autogenous shrinkage strain at 7 days is provided (as measured by ASTM C1698 [30], with a modified geometry of 72 mm diameter and 305 mm length for concrete) as well as the total shrinkage due to drying for 91 days in a 50% relative humidity (RH) environment, a modified version of ASTM C157 [31] performed on 72 mm by 72 mm by 286 mm prisms with the drying beginning after 24 hours of curing in molds (i.e., no additional water

curing was provided). The results of these tests are reported as strain in the concrete, where negative strain values indicate shrinkage. Finally, the diffusion based service life of these mixtures (where cracking was not considered) was estimated using an extended Nernst-Planck equation coupled with non-linear moisture diffusion [32]. The full results of the testing performed on these mixtures are available in a report by Barrett et al. [26]. In an effort to put the performance of the IC HPC class of concrete into perspective, data from previous research by Di Bella et al. performed on an industrially produced Class C concrete has also been provided [2]. Inspection of the results from laboratory testing of each of these mixtures indicates four main conclusions:

1. All of the IC HPC mixtures met (even well exceeded) the limitations set in the specification.
2. Internal curing in the IC HPC mixtures significantly reduced the autogenous shrinkage after 7 days of curing.
3. Improvements in the performance of IC HPC mixtures compared to the traditional Class C concrete are substantial, even when compared to the lowest performing IC HPC mixture.
4. The IC HPC mixtures tested in this study provide a bridge deck material that achieves an estimated service life of nearly 60 years or more, and when accounting for propagation time for corrosion, a service life of 75 years is achievable (AASHTO design life for bridges is 75 years [33]).

**Table 4. Selected material properties and performance of IC HPC, HPC, and Class C concretes.**

	$f'_c$ (28 d) [MPa]	$E_c$ (28 d) <sup>1</sup> [GPa]	$f'_t$ (28 d) <sup>1</sup> [MPa]	RCP Test [C]	$\epsilon_{Auto}$ (7 d) <sup>2</sup> [ $\mu\text{m}/\text{m}$ ]	$\epsilon_{Tot}$ (91 d) <sup>3</sup> [ $\mu\text{m}/\text{m}$ ]	Est. Service Life <sup>4</sup> [Years]

<sup>1</sup> $E_c$  and  $f'_t$  are inferred for IC HPC Class based on AASHTO C5.4.2.4-1 and 5.8.2.2 (this will be discussed in the next section) [33]. These values were measured directly for all other mixtures in this study.

<sup>2</sup>Autogenous shrinkage strain as measured by a modified version of ASTM C 1698 for concrete [30].

<sup>3</sup>Total shrinkage strain of prisms undergoing drying at 50% RH after 1 day of sealed curing [31].

<sup>4</sup>Estimated service life based on extended Nernst-Planck equation simulated using Stadium® software [34].

<sup>5</sup>Class C concrete strength and RCP values reported by Di Bella et al. [2]; service life estimation reported by Weiss et al. [35].

<sup>6</sup>IC HPC Class concrete performance requirements according to special provisions established by the INDOT [4].

## 5. Discussion of Field Observations

This section will summarize the major observations from the construction process of the four IC HPC bridge decks. While avoidable issues during construction were witnessed, two points should be emphasized. First, four bridge decks utilizing internal curing are now in service and the concrete materials produced for each of bridge decks in this study achieve higher performance in laboratory testing (strength, shrinkage, and chloride resistance) than traditional INDOT Class C bridge deck materials. Second, a mixed specification of prescriptive and performance based parameters was successfully used to produce these bridge decks, resulting in higher performance concretes. In addition to these observations, comments on the impact of IC HPC mixtures on current design specifications and the potential for cracking of these mixtures will be discussed.

## 5.1 Summary of Lessons Learned from the Trial Batch, Production, and Construction

The key areas of emphasis to the successful implementation of internally cured, high performance concretes in field have been listed.

- Prewetted lightweight aggregate can be successfully used in the production of internally cured concrete if the moisture condition of the aggregates are understood, controlled, and accounted for in production. This study implemented a new testing technique that utilizes a centrifuge to rapidly condition the lightweight aggregate to a surface-dry condition and reduces variability in testing over previous testing methods [19]–[21].
- Variability in moisture states within a stockpile of prewetted lightweight aggregate should be controlled through appropriate means (working the stockpile, proper soaking and draining) or measured and accounted for throughout concrete production.
- Batching issues were observed which would be present regardless of the concrete mixture proportions, whether the concrete mixtures are internally cured or not, or regardless of the constituent materials used during production. Special attention, training, and education for batch plant operators to fully understand how to properly make moisture adjustments and change scale jog rates (i.e., the rate at which the gates on the aggregate bins open and close to drop aggregate on the scale) when producing mixtures containing lightweight aggregates may serve to avoid potential issues.
- Pumping issues were observed which would be present regardless of the concrete mixture proportions, whether the concrete mixtures are internally cured or not, or regardless of the constituent materials used in concrete production and are avoidable with additional training and education.
- Segregation issues was potentially observed on one deck that was independent of whether the concrete mixtures are internally cured or not and are avoidable with additional training and education.
- Trial batches should be used to identify and solve potential issues for production prior to date of construction, as exemplified by the third bridge deck in this study.
- Previous research has shown that the pressure based air meter and the volumetric air meter yield the same result for internally cured concrete mixtures, indicating that the use of the pressure based meter is permissible for IC HPC materials [36].

## 5.2 Impact on Design Specifications

The codified equations for predicting the modulus of elasticity ( $E_c$ ) and the splitting tensile strength ( $f_{ct}$ ) using the square root of the measured compressive strength show good agreement with experimental data within the tolerance of the estimation ( $\pm 20\%$ ). The equations have been provided here [33]:

$$E_c = 1,820\sqrt{f'_c(ksi)} \quad \text{AASHTO C5.4.2.4-1}$$

$$f_{ct} = \frac{1}{4.7}\sqrt{f'_c(ksi)} \quad \text{AASHTO 5.8.2.2}$$

## 5.3 Impact on Shrinkage and Cracking

As briefly discussed previously, the unrestrained shrinkage of the IC HPC and HPC mixtures were characterized using modified versions of ASTM C1698-09 and ASTM C157-08. In addition to these tests, the restrained shrinkage behaviour was characterized using the dual ring test [37], [38]. This test utilizes two concentric rings made of invar to provide restraint to expansion and shrinkage under sealed conditions (i.e., autogenous shrinkage only). After 7 days, the temperature of the test is reduced at a standard rate in an attempt to induce thermal cracking and assess how close the concrete sample was to cracking. The results of this testing are summarized here:

- The IC HPC mixtures exhibited a reduction in measured linear autogenous shrinkage strain of 70 to 90%, with the maximum measured strain of any IC HPC sample at 7 days being  $30 \mu\epsilon$ .
- The IC HPC mixtures exhibited a reduction in measured residual tensile stress due to autogenous shrinkage of 80% with the maximum measured stress of any IC HPC sample at 7 days being 0.5 MPa (72 psi), or approximately 10% of the available tensile strength.

- The IC HPC mixtures exhibited a reduction in measured peak induced thermal stress of 25 to 55% and is likely associated with a reduction in the coefficient of thermal expansion of the internally cured mixtures.
- The IC HPC mixtures exhibited a reduction up to 50% in the rate of induced stress due to temperature reduction and is likely associated to the more compliant nature of the internally cured mixtures.

Collectively, these results indicate that the presence of internal curing reduces the residual tensile stress due to autogenous shrinkage to negligible quantities while also providing a more robust response to thermal loading at early ages.

## 6. Summary and Conclusions

Internal curing is a practice-ready, engineered solution that may lead to the production of higher performance concretes which have a reduced potential for cracking. To aid practitioners in the implementation of internal curing in practice, spreadsheets which automate calculations necessary for quality control for lightweight aggregates, mixture proportioning, and moisture adjustments are available [26]. The authors emphasize that the implementation of such technologies alone does not guarantee higher performance however, as the production of such concrete requires a degree of technical competence in design, production, and construction of concrete materials. As is the case with the production of any concrete, internally cured or not, performance will be directly tied to the careful accounting of water, be it on the surface of aggregates, in the mixing drum after washing, or elsewhere. Special attention should be paid to the proper operation of batching systems, while placement techniques should be reviewed to minimize unwanted effects, and proper finishing and curing techniques must always be practiced. The results of laboratory testing carried out on field produced samples indicates that the concretes met the performance limitations set in the standard specification. The IC HPC concretes cast in the state of Indiana in 2013 achieve an estimated service life improvement of 3 to 4.5 times that of the conventional bridge deck concrete specified and the results from restrained shrinkage testing indicate that the IC HPC mixtures reduce the residual tensile stress due to autogenous shrinkage to negligible quantities. Collectively, these results indicate that IC HPC materials may provide longer service life with a lower potential for cracking, but only after performing the basics of concrete production properly will the full benefits of internal curing be actualized.

## 7. Acknowledgement

The research performed in this study was conducted in the Charles Pankow Materials Laboratory at Purdue University. The authors would like to express their deepest gratitude and acknowledge those who have made the laboratory and its operation possible. This work was supported in part by the Joint Transportation Research Program administered by the Indiana Department of Transportation and Purdue University under SPR 3752.

# Physical Properties of Extrusion Panel Using Ground Granulated Blast-Furnace Slag and Electric Arc Furnace Slag

Ha Seog Kim<sup>1</sup> and Sea Hyun Lee<sup>1</sup> and Dae Hyun Back<sup>1</sup>

<sup>1</sup>Korea Institute of Construction Technology/Advanced Building Research Division

**Abstract:** Carbon dioxide generated from construction materials and construction material industry among the fields of construction is approximately 67 million tons. It is about 30% of the carbon dioxide generated in the fields of construction. In order to reduce carbon dioxide in the fields of construction, it is necessary to control the use of fossil fuel consumed and decrease carbon emission by reducing the secondary and tertiary curing generating carbon dioxide in construction material industry. Therefore, this study produced an extrusion panel by using cement as the base materials and substituting binding materials up to 40% to analyze strength characteristics.

According to the results of strength characteristics by the replacement binder (Low energy curing Admixture) showed an apparent active strength improvement. In particular, specimens substituting binder as 45% indicated the greatest strength improvement. When binding materials was used with substitution, it showed strength characteristics similar or higher than specimens made from tertiary autoclave curing as secondary steam curing.

**Keywords:** Carbon dioxide, Steam curing, Ground granulated blast-furnace slag, Electric arc furnace slag

## 1. Introduction

The dramatic industrial development in recent years has led to the improvement of living standards for mankind. However, fossil fuel has been the primary energy source, accounting for 80 to 85% of all energy sources used to support such industrial activities, and this has led to the massive generation of greenhouse gases (GHGs), contributing to global warming.

Korea rose in the global rankings according to the national CO<sub>2</sub> emissions from 9th to 8th place in 2008, with the CO<sub>2</sub> emissions measured to be 528.7 million tons as of 2009. Of the GHGs emitted, 42.3% are generated in the construction fields. Accordingly, the Korean government has set a target to reduce the GHG emissions to 30% of BAU by 2020 including the GHG emissions in the construction fields. Of the construction fields, which are the source of 42.3% of the CO<sub>2</sub> emissions in Korea, the construction material industry generates 670,000 tons of CO<sub>2</sub>, which accounts for 30% of the total CO<sub>2</sub> emissions generated in the construction fields.

In recognition of the fact that the construction materials generating the largest volumes of CO<sub>2</sub> are cement and structural steel, efforts have been made to reduce the CO<sub>2</sub> generated from these materials, but they have been largely unsuccessful due to the limitations of the reduction technology and materials in use. Thus, there needs to be more diverse measures proposed with the aim to reduce the CO<sub>2</sub> emissions in the construction material industry.

Generally, in the construction material industry, curing at room temperature as well as secondary and tertiary curing processes are performed following product formation for the purpose of acquiring target performance, realizing the desired strength in the early stages, improving productivity and promoting workability. It is the combustion of fossil fuel during these curing processes that causes the generation of CO<sub>2</sub> in large volumes, and countermeasures are urgently needed.

On the other hand, cement extrusion panel is one of the main dry walls used in the industry that is a lightweight yet strong material with many other advantages such as excellent dimension stability, constructability and moisture tolerance. However, the areas of its use are relatively limited due to its high production costs compared to gypsum boards and lightweight concrete panels resulting from the use of large amounts of cement compared to silica, the use of high-cost raw materials such as fiber and viscosity agents as well as the secondary steam curing and tertiary autoclave curing processes following its formation.

Accordingly, this study was conducted with the aim to reduce the use of fossil fuels and carbon emissions by lowering the need for the secondary and tertiary curing processes in the construction material industry as part of the efforts to reduce CO<sub>2</sub> emissions in the construction fields according to the domestic GHG reduction policy.

The possibility of eliminating the tertiary autoclave curing process was confirmed by using steam curing high-strength admixture based on the blast furnace and electric arc furnace slags according to the findings of the preceding research. The cement binder used in the extrusion panel was replaced with the admixture according to the level as a means to review the applicability to secondary concrete products.

## 2. Experimental Plan and Method

### 2.1 Experimental plan

In this study, an extrusion panel was fabricated by substituting cement, which is the conventional binder, with low-energy curing admixture (LA) in order to determine its applicability of LA in the production of extrusion panels.

Table 1 shows the experimental plan in which the experimental factor was set as the LA substitution rate, while Table 2 shows the composition of the low-energy curing high-strength admixture used in the experiment and Table 3 shows the mixing ratio used in the experiment.

**Table 1. Experimental plan of extruding mixture**

Factors	Levels	Test items
Replacement ratio(%)	20%	- Compressive strength - Flexural strength - Density - Moisture content ratio - Absorption ratio
	30%	
	40%	

**Table 2. Composition of Admixture(LA)**

Sum	P	K	S	C	G	K <sub>2</sub> SiF <sub>6</sub>
100%	50%	17%	15%	5%	7.9%	0.1%

P = Ground Granulated Blast-Furnace Slag K = Kaolin, S = CSA, C = Electric Arc Furnace Slag  
G = Glauberite, K<sub>2</sub>SiF<sub>6</sub> = Fluosilicate salt

**Table 3. Experimental mix**

Mix ID	W/P (%)	Powder(%)					Fiber(%)			M.C (%)
		C	L.A	S.P	S.S	C.P	P.P	W	Pulp	
Base	27	42.8	0	22.5	21.2	4.54	2.42	5.05	0.76	0.69

L40		25.7	17.1	22.5	21.2	4.54	2.42	5.05	0.76	

L.A = Low energy curing Admixture, S.P = Silica Powder, S.S = Silica Sand, C.P = Crush Sand, W = Wollasonite  
P.P = Polypropylene fiber, M.C = Methyl cellulose

### 2.2 Experimental method

The extrusion specimen was fabricated as a 300×1,000×35 mm panel using the extruder model SY-05S of Japanese manufacturer I. The specimen was then cut at a length of 12 mm to test the flexural and compressive strengths of the extruded specimen according to KS L ISO 679.

### 2.3 Curing method

As for the curing of the specimen formed by extrusion, room-temperature curing and atmospheric steam curing processes were performed. In the case of the base specimen, in which only cement was used, autoclave curing was performed. Room-temperature curing was performed in a constant temperature and humidity chamber at 20±1°C and RH 60±5%. On the other hand, atmospheric steam curing was performed

at 80°C and RH 100%, during which the conditions were raised for 4 hours and maintained for 5 hours prior to the natural cooling process. For the atmospheric steam cured specimens, autoclave curing was performed under the conditions of 180°C, 10 atm, RH 100%, during which the conditions were raised for 4 hours and maintained for 5 hours prior to the natural cooling process.

## 2.4 Used material

The materials used include Type 1 ordinary Portland cement sold by domestic company A, as well as Type 3 BF slag produced as a byproduct of the pig iron process by company U with a Blaine fineness of 7,400 cm<sup>2</sup>/g and CSA produced by domestic company H with 36.5% Al<sub>2</sub>O<sub>3</sub> content and a Blaine fineness of 4,500 cm<sup>2</sup>/g.

Calcined kaolin refers to kaolinite calcined in the metakaolin manufacturing process, and the calcined kaolin produced by domestic company B with a Blaine fineness of 4,200 cm<sup>2</sup>/g was used as it is low in cost even though it has low reactivity compared to metakaolin.

The CAC used was atomized EAF slag that was ground to have a Blaine fineness of 5,000 cm<sup>2</sup>/g. It had similar chemical composition as ultra-rapid hardened CA, and characterized by high heat of hydration and quick-setting property. Also, glauberite and fluosilicate salt was used in order to contribute to the pozzolanic reaction of slag and calcined kaolin. These two materials promote the pozzolanic reaction involving the calcium hydroxide produced from the cement hydration reaction after the transition into soluble silica caused by hydrolysis in the cement matrix, and this is known to improve durability through the inhibition of crack formation and an increase in hydration heat, neutralization, and enhancement of freezing-thawing resistance. The characteristics of each of these materials are summarized in Table 4 to 8.

Also, the viscosity agent used to adjust the viscosity and improve the lubrication characteristics during the extrusion process was a product manufactured by domestic company S with viscosity of 40,000 cps and density of 1.26 g/cm<sup>3</sup>. In addition, inorganic Wollastonite, organic pulp and artificial fiber polypropylene (PP) were used as fiber materials to enhance the tensile strength.

### 3. Results and Discussion

Table 4 shows the results of the experiment, indicating that substitution of more than 30% of the cement with LA resulted in a strength level that was equivalent to or higher than that of autoclave cured products.

**Table 4. Test results**

	L20	L30	L40
Moisture content ratio	1.05	0.32	0.28
Absorption ratio	18.05	17.47	15.26
Density	1.63	1.7	1.59
Compressive strength	36.8	38.96	38.96
Flexural strength	13.31	14.98	17.44

#### 3.1 Moisture content

All three types were equivalent to the reference moisture content as shown in Fig. 1. Of particular note, L30 and L40 had moisture content, ranging from 0.32 to 0.28. High moisture content in extrusion panels is known to cause reduced strength as a result of twisting and cracks caused by drying shrinkage. Thus, low moisture content is considered advantageous in terms of physical performance and durability.

Figure 1. A variation of moisture content ratio according to curing process and LA replacement ratio.

### 3.2 Absorption ratio

The absorption rates of all three types of specimen that varied according to the LA substitution ratio were equivalent to the reference absorption rate as shown in Fig. 2. Of particular note, L40 had the lowest absorption rate at 15.26. In the case of extrusion panels used in the exterior, because they are exposed to open air, high absorption rate can cause issues related to stability and aesthetics due to increased weight, cracks and discoloration resulting from water absorption in the rainy season. Thus, exterior panels are required to have low absorption rate to prevent such problems.

### 3.3 Moisture content

Fig. 3 shows the varying density characteristics according to the LA substitution ratio. L40, in particular, had the lowest density at 1.59. The lowered density is deemed to be due to the fact that the density of the substituting material, LA, is lower than that of cement. Conventional cement-based extrusion panels have high density, which causes difficulties in construction due to the increased unit weight. Accordingly, it is deemed that substituting cement with LA, with lower density, will facilitate construction.

Figure 2. A variation absorption ratio according to curing process and LA substitution ratio.

Figure 3. A variation of density according to curing process and LA substitution ratio.

### 3.4 Strength

Fig. 4 shows the compressive strengths of the specimens according to the LA substitution ratio. All three types were shown to be lower than the reference level. L20 had the lowest compressive strength at 36.8 N/mm<sup>2</sup>, whereas L30 and L40 had compressive strength of 38.96 N/mm<sup>2</sup>, which was near the reference strength of 39.2 N/mm<sup>2</sup>. Generally, BF slags are known to be a potentially hydraulic material, which does not contribute to early hydration and reacts to stimulants such as alkali. Thus, compared to the general room-temperature curing process, steam curing promotes hydration of cement in the matrix, leading to the generation of large amounts of calcium hydroxides, which then activate BF slags and contribute to the promotion of strength. Similar results were observed in this experiment. In addition, CSA is thought to have

contributed to the promotion of matrix strength as a result of the active production of ettringite due to the rapid hydration of  $C_3A$  in the early ages and the increase in the  $SO_3^-$  content.

As shown in Fig. 5, the flexural strength was observed to rise with increased LA substitution ratio, similar to compressive strength, and the specimens, except for L20, satisfied the standard level. The flexural strength of the base was shown to be 15.2 N/  $mm^2$  after the autoclave curing process. Although the flexural strength of L30 was observed to slightly lower than that of the base at 14.98 N/  $mm^2$ , it still satisfied the standard level for extrusion panels, which is 14.0 N/  $mm^2$ . Also, L40 had flexural strength of 17.44 N/  $mm^2$ , which was higher than that of the base containing cement as the binder that had been autoclave cured. This result is thought to be due to the fact that low LA substitution rate leads to poor hydrate production and insufficient heat of hydration for the strengthening of the internal area of the matrix.

Figure 4. A variation of compressive strength according to curing process and LA substitution ratio.

Figure 5. A variation of flexural strength according to curing process and LA substitution ratio.

#### 4. Conclusion

The following conclusions were reached based on the results of the experiment in which cement was substituted with BF slag-based LA as a means to reduce the number of curing processes during the production of extrusion panels, which are secondary concrete products:

- a. Based on the results of measuring the moisture content according to the LA substitution ratio, it is deemed that lower substitution ratio is more advantageous as it results in lower moisture content and improves the physical performance and durability of the extrusion panel.
- b. Based on the results of measuring the absorption rate according to the LA substitution ratio, higher LA substitution ratio resulted in lower absorption rate, which enhances the stability and aesthetics of extrusion panels that are used in the exterior.

- c. Higher LA substitution ratio was shown to lower the density of the extrusion panel and this is deemed to be more advantageous compared to cement-based extrusion panels, which cause difficulty in construction due to high weight.
- d. As for the strength characteristics, specimens containing LA that were steam cured had equivalent or higher strengths compared to the autoclave cured specimen.
- e. Based on the experimental and empirical research results above, it is deemed that substitution with LA will make it possible to eliminate the autoclave curing process and reduce the duration of the steam curing process; however, further research is necessary to determine the long-term durability, resistance in connection with exposure to the external environment, and optimum mixing ratio for the extrusion panel manufacture.

# Finite Element Modeling of Shape Memory Alloy Confined Reinforced Concrete Column

Khaled Abdelrahman<sup>1</sup> and Raafat El-Hacha<sup>2</sup>

<sup>1</sup>PhD Candidate, Department of Civil Engineering, University of Calgary

<sup>2</sup>Associate Professor, Department of Civil Engineering, University of Calgary

**Abstract:** Strengthening and repair of critical structural elements such as concrete columns is an ongoing research state that seeks for innovative and practical ideas. Recently, the use of smart materials such as Shape Memory Alloys (SMA) has been introduced to civil engineering applications for repair and strengthening of concrete columns. The thermo-mechanical properties of the SMA allows for practical and reliable active confinement mechanism, compared to the passive confinement mechanism applied by the conventionally used materials such as Fibre Reinforced Polymers wraps and concrete/steel jackets. In addition, SMA materials provide significant ductility making them potentially attractive for seismic applications. Despite the many structural benefits of using SMA as confinement material, the current literature include very limited numerical attempts to predict the behaviour of SMA confined concrete columns. Thus, the main objective of this study is to develop a numerical finite element (FE) model capable of predicting the stress-strain characteristics of SMA confined concrete subjected to uni-axial compression loading. The validity of the developed FE model was verified by comparing the results with the experimental data conducted on SMA confined concrete. The results clearly show the capability of the FE model to capture accurately the stress-strain characteristics of SMA confined concrete.

**Keywords:** Confinement, Concrete, Finite Element, Shape Memory Alloy (SMA)

## 1. Introduction

Catastrophic failure due to seismic events has been mainly attributed to the collapse of critical structural elements such as columns. Attaining reliable, safe and efficient designs of our current infrastructure can be achieved through numerous strengthening techniques of the deficient concrete columns. Traditional strengthening techniques include confining the concrete columns with concrete or steel jackets. However, these methods were considered inefficient as the strengthening materials suffered from the same deterioration effects as the parent material. The evolvement of non-corrosive and light-weight composite materials such as Fibre Reinforced Polymers (FRP) became attractive to researchers worldwide. FRP wraps/jackets have been experimentally proven to increase the strength and ductility of concrete columns. However, the FRP wraps/jackets confine the concrete column through a passive confinement mechanism, which means that the concrete requires to undergo significant damage prior to the activation of the FRP. Research studies have shown that engaging the confinement material prior to achieving any damage to the concrete through active confinement mechanism is deemed to provide superior performance in terms of the strength and ductility of the concrete. Several attempts have been made using traditional strengthening materials to actively confine concrete columns [1-3]. However, these proposed techniques to provide active confinement were considered costly, impractical, and required extensive labor time. Recently, the use of smart materials such as Shape Memory Alloys (SMA) has been introduced to civil engineering applications for repair and strengthening of concrete columns [4, 5]. The thermo-mechanical properties of the SMA allows for practical and reliable active confinement mechanism that overcomes all the drawbacks associated with the current active confinement techniques.

The SMA's are a class of alloy that exhibit shape memory recovery (up to 8%) inherited through its unique thermo-mechanical properties. The most commonly used type of SMA for confinement applications include Nickel ( $Ni$ ) and Titanium ( $Ti$ ) as its composition elements. The SMA's have two distinctive phases, a high temperature phase called austenite ( $A$ ) and a low temperature phase called martensite ( $M$ ). The austenite phase is considered as the parent phase and the martensite phase is considered as the product phase. The transformation from one phase to the other can occur by either applying an external stress or by changing the temperature. The SMA's are characterized by four distinctive temperatures; austenite start temperature ( $A_s$ ), austenite finish temperature ( $A_f$ ), martensite start temperature ( $M_s$ ) and martensite finish temperature ( $M_f$ ). The confinement technique using SMA rely on the recovery stress generated as the SMA material transforms to its original (un-deformed) state. The confinement methodology simply involves wrapping a pre-strained SMA wire along the perimeter of the concrete column. Then, heating the alloy above a predefined transformation temperature would trigger the shape memory characteristics of

the SMA wire. Constraining the ends of the SMA wire to the concrete column and since the concrete column is basically incompressible, a reactive force is created by the pre-strained SMA wire as they attempt to regain their original (un-deformed) state producing an active confinement pressure. This confinement technique has been tested experimentally and the results showed that the actively SMA confined concrete specimens exhibited superior performance in terms of the strength and ductility when compared to unconfined concrete specimens [6-14]. The SMA's currently emerging as a new strengthening material for civil engineering applications have a relatively high material cost constricting the diversity of experimental research to be conducted. Thus, adopting a computerized numerical method using finite element approach would allow to further investigate the confinement characteristics of the SMA confined concrete efficiently. Thus, the main objective of the study presented in this paper is to develop a numerical finite element model using a non-linear finite element program capable of predicting the stress-strain characteristics of SMA confined concrete subjected to uni-axial compression loading.

## 2. Finite Element Modeling

### 2.1 General

Several parameters are subject to investigation in order to achieve a successful numerical model capable of simulating the complete behaviour of SMA confined concrete under axial compressive loading. Therefore, a realistic definition of the constitutive relationship of the materials involved is necessary, in this case, namely the concrete and the SMA wire, and the interfacial bond between them. In addition, this section also includes the geometric modeling and the list of elements used to model the SMA confined concrete.

### 2.2 Constitutive behaviour and material model

The non-linearity of the concrete can be modeled using the Concrete Damage Plasticity (CDP) predefined in the *ABAQUS* software. The CDP requires the definition of the concrete stress-strain relationship in compression and tension, as well as certain parameters to define the plastic flow and the yield surface criteria. In order to input the most appropriate concrete model for this numerical problem, the stress-strain characteristics of the SMA confined concrete was first investigated. Figure 1 displays the experimental results of SMA confined concrete cylinder subject to uni-axial compression loading tested by the authors as a part of a preliminary investigation to assess the stress-strain characteristics of SMA confined concrete. The results show that SMA confined concrete possess distinctive features from solely active or solely passive confinement behaviour. Prior to loading, the SMA actively confines the concrete through a confinement pressure equivalent to the residual recovery stress generated by the SMA wire. During loading, as the concrete gains significant dilations, the SMA wire passively engages to confine the concrete until failure of the SMA wire is achieved.

Figure 1. Stress-strain behaviour for SMA confined and actively confined concrete

In order to compute the active confinement pressure generated by the SMA wire onto the concrete column, the equation proposed by Mander et al. [8] was adopted. The equation quantifies the amount of lateral confinement pressure ( $f_l$ ) produced by the transverse reinforcement on a circular concrete section and is defined by:

$$f_l = \frac{2f_h A_{sp}}{s d_s} \quad (1)$$

where,  $f_h$  is the tensile stress of the transverse reinforcement,  $A_{sp}$  is the area of the transverse reinforcement,  $s$  is the center-to-center spacing for circular hoop or the pitch spacing for spiral hoop, and  $d_s$  is the cross-sectional diameter of the concrete specimen.

Figure 2. Stress-strain behaviour for confined and unconfined concrete (Mander et al.,[8]).

Mander et al. [8] also proposed a unified stress-strain approach for confined concrete transversely reinforced by circular ties or spirals (Figure 2). Although the model was developed based on transverse steel reinforcement, once the steel yields and reaches a state of constant stress, this represents an active confinement state. This concept can be further extended to represent the active confinement state induced by the constant recovery stress generated by the SMA wire. The proposed equation to determine the longitudinal compressive concrete stress ( $f_c$ ) is defined by:

$$f_c = \frac{f'_{cc} x r}{r - 1 + x^r} \quad (2)$$

where,  $f'_{cc}$  is the confined concrete compressive strength defined by:

$$f'_{cc} = f'_{co} \left( -1.254 + 2.254 \sqrt{1 + \frac{7.94 f'_l}{f'_{co}}} - 2 \frac{f'_l}{f'_{co}} \right) \quad (3)$$

where,  $f'_{co}$  is the unconfined concrete strength, and

$$x = \frac{\epsilon_c}{\epsilon_{cc}} \quad (4)$$

where,  $\epsilon_c$  is the longitudinal compressive concrete strain.

$$\varepsilon_{cc} = \varepsilon_{co} \left[ 1 + 5 \left( \frac{f'_{cc}}{f'_{co}} - 1 \right) \right] \quad (5)$$

where,  $\varepsilon_{co}$  is the unconfined concrete strain, and

$$r = \frac{E_c}{E_c - E_{sec}} \quad (6)$$

where,  $E_c$  is the modulus of elasticity of the concrete in MPa

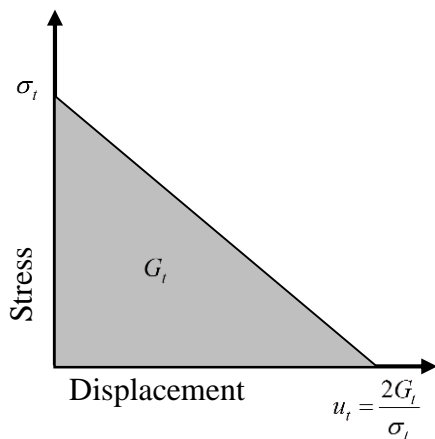

$$E_c = 5000 \sqrt{f'_{co}} \quad (7)$$

and  $E_{sec}$  is secant modulus of elasticity of the concrete in MPa

$$E_{sec} = \frac{f'_{cc}}{\varepsilon_{cc}} \quad (8)$$

The above set of equations was used to develop a stress-strain relation of concrete specimen actively confined by a constant confinement pressure equivalent to the initial active confining pressure from the SMA spirals. As shown in Figure 1, the initial stress-strain response of the SMA confined concrete follows the paths of the purely active confined concrete with an initial active confining pressure from the SMA spirals. As the concrete dilates and reaches its peak strength, the SMA spirals engages passively and deviates away from the path of the purely active confinement case. Thus, it reasonable to assume that the behaviour of the SMA confined concrete follows the behaviour of an equivalent purely active confinement case until the peak load. The post peak behaviour critically relies on the passive confinement mechanism that cannot be captured using Mander et al. [8] model. Thus, the initial active confinement pressure is accounted for in the input compression model and the finite element model captures the post peak behaviour considering the passive confinement mechanism of the SMA spirals.

The parameters defined for the CDP include the dilation angle ( $\psi$ ), which controls the amount of plastic volumetric strain. Based on experimental research, a dilation angle of  $30^\circ$  was selected [9]. Secondly, the ratio of the initial equilibrium yield stress to the initial uniaxial compressive yield stress is defined with a default value of 1.16 [15]. Thirdly, the flow potential eccentricity ( $\epsilon$ ) is defined with a default value of 0.1 [15]. This ensures that the dilation angle remains almost constant over a wide range of confinement pressures. Lastly, the ratio of the second stress invariant on the tensile meridian, to that on the compressive meridian ( $K_c$ ) is defined with a default value of 0.667 [15].

**Figure 3. Tensile stress-displacement relationship of concrete**

**Figure 4. Axial tensile stress-strain behaviour of SMA wire**

The tensile constitutive model of the concrete defined for the CDP was expressed as the relationship between the tensile stress and the cracking displacement (Figure 3). The cracking displacement ( $u_t$ ) at which complete loss of strength occurs is defined through Equation 9. The fracture energy ( $G_f$ ) varies with the compressive strength of the concrete. In order to accurately capture the behaviour of the SMA spirals, the property was based on the SMA wire tensile coupon test results after the stress recovery to account only for the passive confinement generated by the SMA wire during loading. The result of the SMA tensile coupon test is plotted in Figure 4.

$$u_t = \frac{2G_f}{\sigma_t} \quad (9)$$

where,  $\sigma_t$  is the cracking stress of the concrete.

### 2.3 Geometric modeling

The concrete cylinder was modeled with full geometry in three dimensions (3D) as there was no computational expense involved. The boundary conditions of the specimens were simulated by restraining the rotational and displacement degrees of freedom for the nodes located at the bottom end of the cylinder (Figure 5). A displacement control mode was applied to the opposite end of the cylinder until failure was achieved by rupture of the SMA wire to simulate the failure mode achieved experimentally. Based on experimental evidence found by visually investigating the contact behaviour between the concrete and the SMA wire at various intervals during the experimental testing, no form of slippage behaviour was recognizable. Thus, it can be concluded that, a good bond was usually maintained between the concrete surface and the SMA wire. Accordingly, the interaction between the concrete and the SMA wire was modeled using a surface tie. This constraint ties the two surfaces together for the duration of the simulation. The concrete was modeled using an eight node linear brick element C3D8 and the SMA wire was modeled using as two node linear 3-D truss element T3D2 (Figure 6). These elements were selected from the standard element library in *ABAQUS*.

Figure 5. Boundary conditions of the FE model

Figure 6. Mesh detailing of the FE model

### 3. Verification of the Finite Element Model

To validate the finite element model, the experimental data conducted by the authors on SMA confined concrete was utilized. The concrete cylinder used in this study measured 100 mm in diameter and 200 mm in height. The type of SMA wire used was NiTi with a smooth cross-sectional diameter of 1.9 mm. According to the manufacturer [16], the mechanical characteristics of the SMA wire, which include the ultimate tensile strength, elastic modulus and strain at failure of the SMA wires were 818 MPa ( $\pm 50$  MPa), 462 MPa ( $\pm 5$  MPa), and 41 % ( $\pm 5\%$ ), respectively. Based on the recovery stress test performed on the SMA wire, the maximum recovery stress and the residual stress attained by the SMA wire was 581 MPa and 485 MPa, respectively. The SMA wires were wrapped circumferentially around the perimeter of the column at a pitch spacing of 10 mm. At the ends of the cylinder, the SMA wires were coiled with two additional turns that were fixed and tightened to the concrete cylinder using U-clamp connectors. As the SMA wires were shipped in predefined lengths, the intermediate splices of the SMA wires were connected with U-clamps to ensure continuity of the wires across the height of the cylinder. The SMA confined specimen was subjected to uni-axial compression loading at a loading rate of 10 kN/sec to failure.

The comparison between the experimental data and the FE prediction model is shown in Figure 7. The results clearly show the FE model can capture accurately the axial stress-axial strain and the axial stress-hoop strain relationships of the SMA confined concrete, taking into account the softening branch of the concrete behaviour. The model also captured accurately the peak strength achieved by the SMA confined concrete specimen with a percentage difference of less than 1 % between the experimental and the predicted peak strength. To further investigate the behaviour of the SMA confined concrete specimen, the stress and strain nephograms of the SMA wire and the stress nephogram of the concrete cylinder are shown in Figure 8. It can be clearly seen that the maximum lateral stress and strain experienced by the SMA wire and the concrete cylinder were found at the mid-height of the cylinder. Due to the relatively low aspect ratio of the test cylinder, the platen effects that were accounted for by imposing representative boundary condition, significantly affects the deformation shape of the cylinder forming a bell shaped curve (Figure 8). This effect amplifies the lateral strain measurements of the SMA wire and the concrete cylinder at the mid-height of the specimen eventually leading to rupture of the SMA wire and concrete spalling at this mid-height zone.

Figure 7. Comparison between FE predicted results and the experimental data

**Figure 8. Lateral stress and strain nephograms of the SMA wire and the strain nephogram of the concrete cylinder.**

#### 4. Conclusions

This paper presented a 3-D FE model to predict the stress-strain characteristics of actively SMA confined concrete. The model is capable of simulating the overall stress-strain response, as well as accurately predicts the peak strength and the post peak softening behaviours of the confined concrete. In addition, the numerical results from the FE model showed good agreement with the experimental data. The FE model is currently being extended to simulate the behaviour of large-scale reinforced concrete columns confined with SMA wires. Once developed, the FE model can be used as a valuable tool to investigate several parameters such as varying the concrete strength, the pitch spacing of the SMA wire, slenderness effects, size effects, and the eccentricity loading. These results produced by the FE model can be used in the development of simple design models to be implemented in the design codes.

# Modelling the Reactivity of Nano-silica in Cement Paste

Madhuwanthi Rupasinghe, Rackel San Nicolas and Priyan Mendis

Department of Infrastructure Engineering, The University of Melbourne.

**Abstract:** Integration of nano materials into concrete with the aim of improving its performance is a key research area at present. While various attempts has been made to find out the significance of nano-silica on concrete, there is a lack of in-depth understanding over the effects of its substitution on hydration of cement and its role in the microstructural evolution of the binder. In this study the effects of commercial colloidal nano-silica in substitution of cementitious pastes, in fractions from 0 to 12w% are analysed using Calorimetry, Thermal Gravimetric Analysis (TGA) and Backscattered electron (BSE) imaging. A model to predict the hydration characteristics of the nano modified cement paste is developed. Through both modelling and experimentation, results reveal that nano-silica in substitution of cement improves the hydration and increases the compressive strength. The optimum composition of replacement level was found at 8w% by of cement.

**Keywords:** Cement paste, nano-silica, CH content, hydration, pozzolanic activity

## 1. Introduction

With the increasing research focus on nano-materials and nano-technology within the past couple of decades, the effects of nano-particles on construction materials has been of great research interest. Concrete is the most widely used man made material in the world. Most of the current research on nano-engineering concrete has been focused on including nano-materials into concrete with the aim of increasing its performance. These include increasing strength characteristics, reduction of porosity and increasing durability. Nano-materials that have been included in concrete include Carbon Nano-Tubes[1], nano-silica [2-6], nano-TiO<sub>2</sub> [7] nano-Fe<sub>2</sub>O<sub>3</sub>, nano-Al<sub>2</sub>O<sub>3</sub> [8, 9] and nano-clay [10]. Nano-materials facilitates cement hydration through providing more nucleation sites for the cement particles to hydrate and acts as a filler material within the paste [6]. This paper focuses the effects of nano-SiO<sub>2</sub> on cement paste and it mainly concentrates on the pozzolanic reactivity of the nano-material.

Nano-silica is available in both powder form and colloidal dispersion. Research has been carried out on including both these forms in concrete [6, 11-13] . The colloidal form, when compared with the powder form, has the advantage of better dispersion within the cement paste, thus reducing the probability of forming agglomerates [12]. In contrast to many of the nano-materials previously studied, nano-silica not only provides nucleation sites for cement hydration, but also participates in the hydration process by reacting with the Calcium Hydroxide (CH) produced during cement hydration, which is known as the pozzolanic reaction [3, 6]. Ordinary cement hydration produces Calcium Silica Hydrate (CSH) and CH [14, 15]. CSH is the main strength carrying material in the cement paste, and CH is considered to have a detrimental effect on strength characteristics of concrete [14]. Nano-silica reacts with the CH and produces more CSH into the paste, thereby increasing the overall strength characteristics of the cement paste [6].

However, despite these previous studies, there is still a lack of in-depth understanding of the mechanism of incorporation of nano-silica on the hydration of a cement binder, and its role in microstructural evolution and gel chemistry. This is crucial in understanding the long-term mechanical and durability performance of concrete. Therefore, this study reports the microstructural changes taking place in nano-silica/cement binders up to the age of 28 days, as a function of the time of curing and the nano-silica content in the range 0-12%, using thermogravimetry and Backscattered Electron Imaging(BSE).

## 2. Materials and methods

### 2.1 Materials

The cement used in this study was a General purpose cement as per AS 3972-2010 (Australian Standard for General purpose and blended cements). An amorphous colloidal nano-silica suspension, Cembinder 8, was used which was produced by Akzo Nobel, Germany[16]. Table 1 and Table 2 below provide the chemical composition of cement specifications of nano- silica, respectively.

**Table 1: Chemical composition of cement**

Compound	Chemical composition (%)
Silica (SiO <sub>2</sub> )	20.38
Alumina (Al <sub>2</sub> O <sub>3</sub> )	7.89
Iron oxide (Fe <sub>2</sub> O <sub>3</sub> )	0.75
Calcium oxide (CaO)	65.02
Magnesium oxide (MgO)	0.98
Sulphur trioxide (SO <sub>3</sub> )	2.21

**Table 2: Specifications of nano-silica**

Property	
Density (g/cm <sup>3</sup> , 20°C)	1.4
pH	9.5
Viscosity (mPas)	<15
Solid content (% w/w)	50

### 2.2 Introduction to Thermal Gravimetric Analysis (TGA)

Thermal Gravimetric Analysis (TGA) is a widely used method for the quantification of the pozzolanic reaction extent. In this method, the sample is gradually heated from room temperature to a defined maximum temperature, and the weight of the sample and the temperature is monitored and recorded. As the temperature is increased, the mass of the sample reduces at particular temperature ranges due to decomposition of its chemical components. Through obtaining the reduction of the mass at the corresponding temperature range and following the necessary calculation steps, the amount of the chemical component that was decomposed at that temperature range can be quantified. This method was used to quantify the amount of CH in the samples, and is described further in the section below.

### 2.3 Sample preparation and testing

For the preparation of the cement paste samples, constant water to binder ratio of 0.3 was used for all cement pastes. The water content of the nano-silica suspension was taken into consideration, and the externally added water content was altered to maintain a constant w/b ratio. Table 3 provides the description of the samples. Isothermal calorimetry was carried out just after mixing the samples, and rest of the paste was poured into moulds to harden.

Isothermal calorimetric was carried out using a TAM Air isothermal calorimeter. The base temperature was  $25 \pm 0.02^\circ\text{C}$ . Fresh paste was mixed externally, weighed into an ampoule, and immediately placed in the calorimeter, and the heat flow was recorded for the first 40 hours.

For TG analysis, the cement paste samples were de-moulded after 1 day, and were cured at a constant temperature of  $20^\circ\text{C}$ . Crushed samples were obtained from the hardened cement pastes at different ages 1, 3, 7 and 28 days. The proceeding of the hydration reaction was stopped using acetone, and the samples were tested for TGA in a Perkin Elmer Diamond instrument. In the TGA procedure, the following steps were adhered [17].

- I. Hold the sample at  $30^\circ\text{C}$  for 20 minutes
- II. Heat from  $30^\circ\text{C}$  to  $1000^\circ\text{C}$  at  $10.00^\circ\text{C}/\text{min}$
- III. Hold at  $1000^\circ\text{C}$  for 5 minutes
- IV. Cool back to  $30^\circ\text{C}$  at a rate of  $40^\circ\text{C}/\text{min}$

The microstructural analyses of the cement pastes at 28 days were carried out under FEI Quanta Scanning Electron Microscope (ESEM). The backscattered electron (BSE) imaging mode of the SEM was used to obtain the micrographs.

**Table 3: Sample descriptions**

Sample ID	% Nano-silica (by weight)	Cement (g)	Cembinder (g)	Water(g)	w/b
CO	0	100	0	40	0.3
NS4	4	96	8	36	0.3
NS8	8	92	16	32	0.3
NS12	12	88	24	28	0.3

## 2.4 Calculation of the CH content

The pozzolanic reactivity of nano-silica is calculated based on the CH content of the cement paste samples at different ages. Details of the evaluation of CH content based on TG data can be found in [18]. The CH content of the hydrated paste samples is calculated as at time  $t$ ,  $CH(t)$

$$CH(t) = \frac{74.09}{18.01} \cdot \frac{m_{420}(t) - m_{540}(t)}{m_s} \quad (1)$$

where  $m_{420}(t)$  and  $m_{540}(t)$  are the mass of the sample recorded at 420°C and 540°C during the TGA test, and  $m_s$  is the anhydrous mass of the sample. (74.09/18.01) is the molar mass ratio between CH and H<sub>2</sub>O.

To get an idea on the pozzolanic reaction compared to the performance of the plain cement paste at time  $t$ , the CH contents are normalized as follows.

$$CH_{norm}(t) = \frac{CH(t)}{CH_{ref}(t) \cdot f_c} \quad (2)$$

$CH_{norm}(t)$  and  $CH_{ref}(t)$  are the normalized CH content of the paste and the CH content of the reference paste at time  $t$ , respectively.  $f_c$  is the fraction of cement present in the sample.

## 3. Results and Discussion

Figure 1 shows the results of isothermal calorimetric analysis. It can be seen that nano-silica accelerates the initial hydration process by 3-4 hours. As the percentage of nano-silica increases in the paste, the quicker the peak occurs. It can also be noted that peak heat flow is also increased as nano-silica content increases within the paste. The curves for NS8 and NS12 are almost the same, indicating that after 8% replacement, significant changes on heat of hydration are not achieved. This gives an indication 8% replacement level is a threshold limit for the acceleration of the initial reactivity of the cement paste. Beyond 8% replacement, there is limited possibility of nano-silica accelerating the hydration reaction.

Figure 1. The heat release curves of the samples

Figure 2 illustrates a curve obtained from TGA, along with a plot of the first derivative of the TG curve (DTG). Three main peaks can be seen on the DTG curve, and among them, the peaks occurring around 420°C-540°C and 600°C-800°C are the peaks corresponding to the decomposition of CH and CaCO<sub>3</sub>, respectively [18].

Figure 2. The TG curve and the DTG curve for one sample

The normalised CH contents obtained through analysing the TG curves of different samples at 1 day, 3 day, 7 day and 28 day are shown in Figure 3. The normalised CH content reflects the CH content of the

paste with respect to a plain cement paste having the same amount of cement content. Therefore, a lower normalised CH content implies less CH content and more hydrated phase present in the mix. The normalised CH content of the mix decreases as the nano-silica content is increased, up to 7 days. But at 28 days, the performance of NS12 seems to be less than that of NS8, as NS8 exhibits the lowest normalised CH content among the pastes tested. Less CH contents implies that more CSH is produced in the mix, and a denser paste structure is achieved. Pozzolanic activity can result in higher amounts of strength carrying CSH into the paste, which ultimately makes the nano-modified paste to have higher compressive strength [4, 6]. These results suggest that 8% replacement level is the optimum cement replacement level with nano-silica with regards to the pozzolanic reactivity.

Figure 3. The normalized CH content of the paste samples over time

Figure 4 below shows a BSE images for the samples obtained at 28 days. Depending on the mean atomic number of a particular phase, the brightness of the phase on the BSE image differs. For a typical cement paste, unhydrated cement particles appears as the brightest. It is then followed by CH, C-S-H, and the epoxy filled pores [19]. Through comparing the microstructures in figure 4, it can be seen the amount of capillary pores (i.e. the darkest area) is less for NS8 than for the other samples. NS12 seems to have the least amount of unhydrated cement.

Figure 4. BSE images for the (a) Control sample (b) NS4 (c) NS8 (d) NS12 at 28 days

The microstructural images obtained in this study were quantified based on the grey scale using an image processing software ( MeVisLab). Figure 5 shows the results of the image quantification analysis. It can be observed that the quantity of unhydrated cement decreases with the increase of nano-silica content. This is because increasing nano-silica content also implies a decrease in the cement content of the mix, as nano-silica is included as a cement replacement material. The more important phenomenon is the variation of the quantity of capillary pores. It can be seen that NS 8 has the lowest capillary pore content out of the mixes tested. Lower capillary pore content implies a higher amount of hydrated phase in the paste, and a dense paste structure. Thus, through hydration quantifications of TGA and image quantification of BSE microstructural images, it is clearly observed that 8% cement replacement with nano-silica is the optimum replacement with regards to a dense microstructure with minimum amounts of CH content.

Figure 5. The unhydrated cement content and the capillary pore content of the cement pastes through BSE image quantification

#### 4. Conclusions

Following the hydration reactions and investigating the microstructure of the nano-silica substituted matrices brings a new understanding of the microstructural evolution and sustainability of this system. From the results, it can be concluded that nano-silica actively reacts with the CH from the hydration of the cement paste through the pozzolanic reaction. It can also be concluded that 8% cement replacement with nano-silica is the optimum replacement level. The above characterisation of samples over the time of curing has enhanced our understanding of the behaviour of binders with nano-silica when replacing cement. Such a micro-scale understanding is essential for predicting the macro-scale mechanical and durability performance of nano-silica/cement based construction materials.

**Abstract:** Concrete prism tests (CPT) were performed on samples having various alkali content and at various temperature. Assuming the shape of the expansion curve, three parameters describing expansion were obtained by data fitting. Then the dependence of these parameters on alkali amount and temperature were calculated. By using the basic information, expansion behavior measured in field exposure test was reproduced. There are some necessities to modify some parameters, so that appropriate ASR estimation in arbitrary condition becomes possible. The effect of SCMs can be taken into account with the decrease in alkali amount due to their substitution to cement.

**Keywords:** CPT, ASR, expansion estimation, fitting, field exposure.

## 1. Introduction

Durability design of concrete is the center of recent concrete technology. Modeling concrete degradation is based on material characters, environmental conditions, and so on. However, regarding to alkali-silica-reaction (ASR) expansion, although various mitigation procedures have been proposed, quantitative estimation of expansion and damage is still hardly established and there are difficulties in preparing countermeasures and maintenance only based on environmental conditions and grade of structures. In this study, based on expansion curves from concrete prism test (CPT) performed under different temperature conditions and with different alkali amounts, expansion in real condition is estimated and the results are compared with exposed concrete blocks. Then, some factors affecting the estimation of ASR expansion are discussed.

## 2. Importance of modeling

The final goal of this study is not the only expansion estimation by ASR but integrated evaluation system of the soundness of some existing concrete structures. Especially, for nuclear power plants (NPP), advanced aging management technical evaluation is required for prolonging its service life. In Japan, the evaluation procedure of alkali reactivity of aggregate has some limitations because the tests being used are classical chemical method and mortar bar test in general and CPT wrapped by a set paper. Of course, chemical method and mortar bar test cannot detect compositional and size pessimum effects and late expansive aggregate. In Figure 5, the relationship between various factors affecting ASR and aging effects on the performance of concrete members is shown. Reactivity of aggregate is the only one part of even for concrete members not the integrated system. Based on the nature of aggregate, various factors such as alkali amounts, mix proportion including pessimum effects, environments including temperature and humidity, and details of member including thickness and confinements affect ASR of members in concrete structure.

ASR does not affect equally the performance of various members in NPP because each member has each requirement in the integrated system. The goal of ASR management is the safety evaluation of facilities in future based on present state. The fundamental concept is summarized in Figure 4. From usual visual inspection and monitoring, when features of damages are detected, petrographic analysis and accelerated expansion test for cores will be carried out. Then, future performance and safety will be evaluated. In this paper, a method of modeling of ASR expansion estimation is proposed.

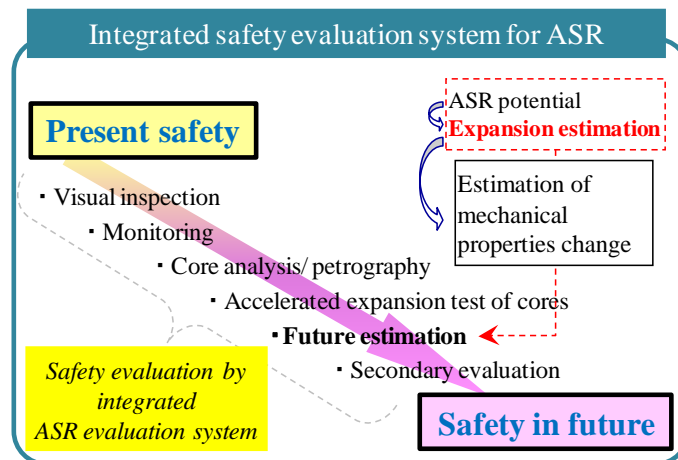

Figure 2. Meaning of modeling of ASR expansion in integrated safety evaluation system for ASR.

### 3. Experiments

#### 3.1 Materials

Two kinds of coarse aggregate, Agg-A and Agg-D were used. Agg-A is a rapid expansive type of andesite containing a large amount of cristobalite and opal and showing compositional pessimum effect. Agg-D is a late expansive type of sandstone origin hornfels containing cryptocrystalline quartz. According to the chemical methods JIS A1145, Agg-A is not innocuous and Agg-D is innocuous. According to the mortar bar test JIS A 1146, Agg-A is not innocuous and Agg-D is innocuous. According to accelerated mortar bar test ASTM C1260, Agg-A is potentially harmful and Agg-D is obscure. As non-reactive aggregate, pure limestone was used because its reactivity was judged as innocuous by a reference.

Cement used was normal Portland cement of 52.5 class having density of 3.16 g/cm<sup>3</sup> and Blaine specific surface area of 3110 cm<sup>2</sup>/g. Fly ash used was classified type II according to JIS A6201 having density of 2.30 g/cm<sup>3</sup> and Blaine specific surface area of 4190 cm<sup>2</sup>/g. Blast furnace slag used was composed of 95.6 % of glass having density of 2.89 g/cm<sup>3</sup> and Blaine specific surface area of 4400 cm<sup>2</sup>/g.

#### 3.2 Concrete Prism Test

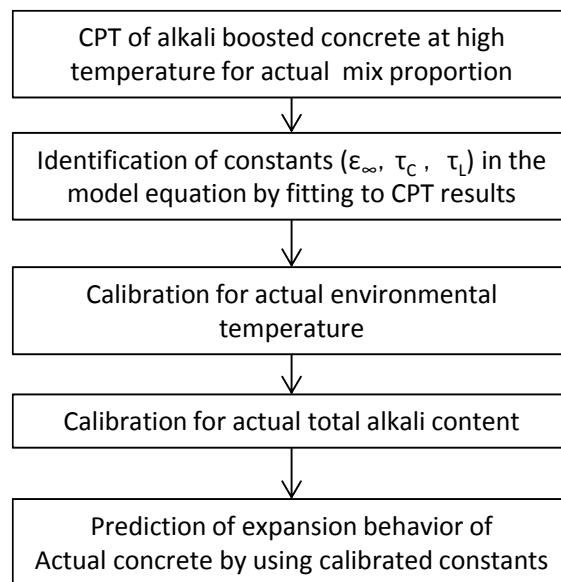

According to RILEM AAR-4, CPT was carried out by keeping demolded concrete prisms of 7.5x7.5x25 cm in stainless steel containers and in humid condition at 60°C. However, for Agg-D, only prism size was modified to 10x10x40 cm and wrapped with wet paper.

In order to examine the effect of alkali amounts (Na<sub>2</sub>O<sub>eq</sub>), from Na<sub>2</sub>O<sub>eq</sub> = 5.5 kg/m<sup>3</sup>, which is the standard of RILEM AAR-4, alkali amounts were reduced to several levels. Fly ash was also added in some mixtures.

Regarding mixture proportion, for the sake of being representative of Japanese usual concrete, following conditions were selected: water to binder ratio  $W/B = 0.55$ , unit water content  $W = 160 \text{ kg/m}^3$ . Reactive aggregates were used as coarse aggregate. In order to check the behavior of pessimum effect of Agg-A, the ratio of coarse aggregate was set as Agg-A : limestone = 3 : 7. Agg-D is used as 100% of coarse aggregate. Fine aggregate was non reactive limestone. As legend, abbreviations such as "A30FA25" stand for Agg-A of 30% and fly ash of 25% replacement, which means aggregate type/ reactive aggregate ratio (%) / fly ash (when used only) / fly ash replacement, are used.

**Figure 3. Modeling of ASR expansion [2].**

**Figure 4. Estimation flow of ASR expansion.**

### 3.3 Estimation Method of ASR Expansion

Estimation of ASR expansion of concrete based on CPT was carried out according to previous study [1]. In this estimation, ASR expansion is assumed to be described by expansion curve shown in Figure 3 [2] and by Eq. (1). By the chart flow shown in Figure 4, each parameter included by Eq. (1) was obtained, and those are calibrated by temperature and alkali amounts, then, the expansion at target temperature and alkali amount was estimated.

$$\varepsilon_t = \varepsilon_\infty \frac{1 - \exp(-t/\tau_C)}{1 + \exp\{-(t - \tau_L)/\tau_C\}} \quad (1)$$

Here,  $\varepsilon_t$ : expansion (%) at the age of  $t$ ,  $\varepsilon_\infty$ : maximum expansion (%),  $\tau_C$ ,  $\tau_L$ : time constants related to required time to the initiation of expansion (years) and expansion rate (years), respectively [2].

Figure 5. Correlation between alkali amounts and maximum expansion rate  $\epsilon_{\infty}$  by CPT

## 4. Results and Discussions

### 4.1 Correlation between Alkali Amounts and Maximum Expansion Ratio $\epsilon_{\infty}$

By plotting  $\epsilon_{\infty}$  obtained from CPT as a function of the different initial alkali amounts, the correlation is shown in Figure 5. Alkalis from fly ash were counted. Regarding to Agg-D, because CPT was carried out only at 5.5 kg/m<sup>3</sup> of alkali amount, assuming fly ash addition reduces alkali amount apparently, some points were plotted as follows. Alkali content in fly ash was considered. According to previous study [3], even when fly ash or blast furnace slag are used in some quantity, regardless of the kind and amounts of supplemental cementitious materials, there is a proportional correlation between ASR expansion and OH<sup>-</sup> concentration and the OH<sup>-</sup> concentration is determined by alkali concentration in solution phase. Based on this study, from the alkali amount of A30FA25 (5.5 kg/m<sup>3</sup>), by using regression line (solid line in Figure 3) between alkali amounts and for Agg-A, alkali amount can be assumed to decrease to 3.23 kg/m<sup>3</sup> by the replacement of 25% fly ash. Similarly for D100FA25, assuming for Agg-D a parallel regression line to Agg-A (chain line in Figure 3), the apparent alkali amount was assumed to decrease to 3.23 kg/m<sup>3</sup> from the original 5.5 kg/m<sup>3</sup>. For D100FA15, the decrease of alkali in case of substitution of fly ash is assumed to be proportional to the replacement ratio by fly ash, the apparent total alkali of D100FA15 was calculated as 4.04 kg/m<sup>3</sup>. From Figure 5, the alkali threshold of A30 not to expand ( $R_{lim}$ ) can be determined as 1.79 kg/m<sup>3</sup>.  $R_{lim}$  of D100 is 3.07 kg/m<sup>3</sup>. Based on these results, Agg-A of rapid expansive type is thought to be possibly reactive even under the condition of alkali limit of 3.0 kg/m<sup>3</sup>. Although Agg-D of late expansive type is judged as innocuous by the chemical method and the mortar bar test, there is a possibility of expansion, when alkali amounts exceed 3.0 kg/m<sup>3</sup>. Besides, the reactivity of Agg-D can be detected by RILEM AAR-4 since the expansion at 20 weeks exceeded the threshold 0.04% and the acceleration at 60 °C can detect the reactivity of late expansion aggregate.

### 4.2 Comparison between Expansion Estimation in Real Environment and Field Exposure.

Considering the concrete block (40x40x60cm) exposure tests results, carried out using the same origin but a different lot of Agg-A [4], the expansion behaviours are estimated based on the results of CPT with an adaptation to the temperature and alkali amount conditions of field exposure tests. The results are shown in Figure 6. Although there have been studied about the effect of temperature [2] and alkali amount on ASR expansion, behaviours will be different for different aggregate and the dependencies are required to be evaluated. In previous study [1], because of the lack of data,  $R_{lim}$  is assumed as 1.2 kg/m<sup>3</sup> for highly reactive aggregate. However, in this study,  $R_{lim}$  was evaluated and the value was used. As for temperature condition, annual average temperature 17 °C was used for all age of estimation. The estimation was too much during first one year and then the calculation became under estimate more and more for longer ages. However, alkali dependence of expansion, i.e. less expansion in less alkali amounts, was reproduced as a trend. Especially, in the small alkali amount condition, the expansion behaviour was successfully reproduced by the method proposed in this study.

Figure 6. Expansion behaviors of field exposure concrete blocks having different alkali amounts and expansion estimation results based on CPT

Figure 7. Expansion behaviors of CPT for Agg-A with various alkali amounts and fitting results.

### 4.3 Discussion on the Differences between Field Exposure and Estimation.

#### 4.3.1 Problems in fitting

Temperature effect on ASR expansion for existing structure is described in LCPC guideline [6]. Because this study is aimed to estimate the field expansion of newly built concrete structure based on CPT, both effects by temperature and alkali amounts have to be considered and special attention has to be paid for alkali leaching. In this study, unfortunately, there are limitations to consider the effects of alkali leaching and the effects are ignored.

The results of CPT for Agg-A having various alkali amounts and fitting results are shown in Figure 7. For the expansion estimation of field exposure condition, fitting parameters obtained from the data of 5.5 kg/m<sup>3</sup> of alkali amounts has been chosen in order to shorten test period. In Figure 7, there are some scattering of data but there are clear tendency of discrepancy between data obtained and regression curves in the alkali amounts of 3.6 or 5.5kg/m<sup>3</sup>. In the earlier ages 0.2 or 0.3, the regression overestimated but in longer ages 0.4 or 0.5 years, the regression underestimated. For the prism containing 5.5 kg/m<sup>3</sup> of alkali, the expansion continues to increase for all period of experiments although

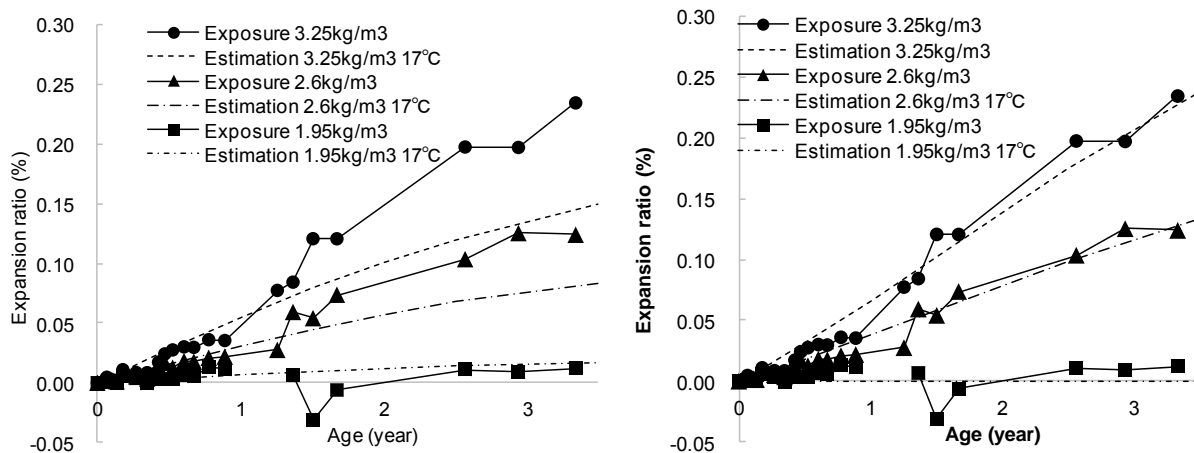

the estimated fitting result reached saturation  $\varepsilon_t$  in the age of 0.2 years (10 weeks). Therefore, the  $\varepsilon_t$  used in estimation was underestimated compared to field exposure and then the estimation underestimated. This result suggests the inappropriateness of fitting CPT data to a model indicated in Figure 3.

#### 4.3.2 Effects of temperature on each parameter

In Figure 6, because an appropriate fitting result was obtained in the smallest alkali amount condition, the results of A30 with 3.1 kg/m<sup>3</sup> of alkali were compared to the alkali amount 3.25 kg/m<sup>3</sup> of field exposure. Each parameter was obtained and estimation results are shown in Figure 8 left. However, only slight improvements were observed. Even in limited alkali amounts, in high temperature condition, it is indicated that the expansion of CPT became limited.

There may be some possible reasons for this behaviour such as 1) at high temperature such as 60 °C, the expansion mechanism became different such as generated ASR gel became fluid and dispersed in paste without significant expansion, 2) as pointed out by previous studies [5], at high temperature, alkalis tend to leached out from concrete prisms, and 3) activation parameter  $U_\infty$  [1] calibrating temperature dependence was too small. The calibration of each parameter against temperature and alkali amounts are based on some limited number of experiments and expected to contain significant error. And also, temperature and humidity change surely affect the ASR expansion in field that are not considered in this study.

Therefore, selecting two parameter  $\varepsilon_\infty$  and  $\tau_L$  having significant effects, these two parameters were adjusted to the expansion curve of field exposure and the results are shown in Figure 8 right. The expansion behaviors of field exposure test were successfully reproduced by this equation. In this estimation, the calibration of  $\tau_C$  was carried out according to reference [1], and so, if appropriate  $\varepsilon_\infty$  and  $\tau_L$  can be obtained from CPT, the accuracy of the estimation of ASR expansion will be improved. For this purpose, there is necessity to accumulate CPT results for various temperature and alkali amounts.

**Figure 8. Expansion behaviors of field exposure concrete blocks having different alkali amounts and the expansion estimation results based on CPT A30 with 3.1 kg/m<sup>3</sup> of alkali amounts (right) and parameters used were calibrated for best fitting (left).**

## 5. Conclusions

By the discussion of the effect of parameters on the estimation of ASR expansion, although the data for various temperature and alkali amounts are not enough and there remain problems in accuracy, it is possible to estimate ASR expansion quantitatively based on appropriate expansion parameters. Another unique point of this study is the consideration of the adding effect of SCMs by exchanging its addition to the reduction of alkali amounts. Expansion estimation in field based on CPT with various mixtures is expected useful for the durability design of structure. In future, appropriate procedure of CPT will be also applied for concrete core accelerated expansion test required for reasonable maintenance.

# Enhancing Mechanical and Durability Properties of Recycled Aggregate Concrete

George Dimitriou<sup>1</sup> and Michael F. Petrou<sup>2</sup>

<sup>1</sup>Research fellow, University of Cyprus

<sup>2</sup>Professor, Department of Civil and Environmental Engineering, University of Cyprus

**Abstract:** The main difference between Recycled Concrete Aggregate (RCA) and Natural Aggregate (NA) is the amount of cement paste attached on the former. This investigation examines the effect of RCA to concrete and a method to improve the properties of recycled aggregates and the properties of the Recycled Aggregate Concrete (RAC). Three types of coarse RCA and two types of mineral admixtures were used. Mineral admixtures (industrial by-products), namely Fly Ash (FA) and Silica Fume (SF) were used as partial replacements of cement to improve the durability properties of concrete. The coarse aggregates were evaluated according to their resistance to fragmentation, soundness, absorption and density. The RAC mixtures were evaluated according to their compressive strength, flexural and splitting tensile strength, modulus of elasticity, chloride permeability, sorptivity and porosity. The results revealed that an adequate quality concrete can be produced from RCA and it can be used for construction activity. The RAC quality can be even further improved using a simple treatment method and the durability properties can be improved by the incorporation of mineral admixtures. Finally, cost analysis showed that RAC mixtures can be less expensive than NA mixtures even with the additional cost of the treatment.

**KEYWORDS:** Recycled concrete aggregates, attached cement paste, treatment method, mineral admixtures, recycled aggregate concrete, mechanical and durability properties

## 1. Introduction

According to the World Commission on Environment and Development (WCED), "sustainable development is a development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (1). When considering the total amount of natural resources in a large scale, in Europe for example, the exploitation of resources might not be as significant as in a smaller scale, in Cyprus for instance, where the increased exploitation may reduce the resources to a crucial level, due to country's small size, compromising the needs of the following generations.

There is a significant research activity regarding the mechanical performance of RAC which in most cases shows that the strength of RAC is adequate for use as structural concrete. On the contrary, the replacement level of natural with recycled aggregates and the durability properties of RAC are still researched, since a wide variability in the results is reported. In fact, the durability properties are still under examination and so the RCA are used only for secondary level construction activities, as road base and landfilling materials.

The difference between recycled and natural aggregates stems from the fact that during the recycling process of the old concrete, a certain amount of mortar from the original cement remains attached on the aggregate particles. Hence RCA consists of two materials: natural aggregate and attached cement paste. The drawbacks come from the cracks and fissures, which are formed during processing and mainly from the existence of an old interfacial transition zone (ITZ) and a layer of adhesive mortar on the aggregates. In order to enhance the properties of RCA, it is fundamental to elaborate a treatment method that is capable to remove the adhering mortar at such level that diminishes the negative effects.

The microstructure of RAC is much more complicated than that of conventional concrete since it includes two kinds of ITZ, one between the RCA and the new cement paste and a second one between the RCA and the old cement attached. The old cement paste possesses many micro-cracks and fissures and has high porosity (2), thus it becomes the weakest link in RAC, since its strength is the upper limit of the strength of concrete. As the paste-aggregate bond strength increases, the concrete strength also increases (3,4). RAC are weaker than NA and the failure happens through the aggregates themselves (including the old ITZ) instead of the new ITZ (5,6). Like the high strength concrete, the recycled aggregate concrete fails through the aggregate in addition to failure of the old ITZ (2,7). The presence of the attached cement paste is significant since recycled aggregates consist of 65-70% by volume of natural coarse aggregate and 30-35% by volume of old cement paste (4).

In general, RCA are of lower quality than NA. RCA have higher absorption value and lower density. The water absorption of RCA ranges from 3 to 15% (4,7). The presence of the mortar hinders the density value of the recycled aggregates (2200 to 2400 kg/m<sup>3</sup>) (4). Furthermore, the resistance to fragmentation is lower and their texture is more porous, rough and irregular due to crushing of the old concrete.

The lower quality aggregates have an immediate effect on the quality of the hardened concrete. The increase in the replacement ratio of RCA decreases the compressive strength of RAC. Generally, the compressive strength can be 10-25% lower than conventional for 100% replacement. Etxeberria et al. reported losses of 20-25% for 100% replacement, maintaining the same effective w/c ratio (0.50) and the same cement content (5). However, the use of 20%-30% RCA produces no significant changes with respect to the control mixture with 0% RCA (2,5,8).

There is a drop of 10-35% of the splitting tensile strength using 100% RCA (2). Tabsh and Abdelfatah found a 10-35% drop in tensile strength (9). During the determination of splitting tensile strength many researchers concluded that the failure initiated not only from the interfaces between the recycled aggregates but also from the recycled aggregates themselves (2).

Regarding the modulus of elasticity, Rao et al. found a reduction of 34.8% using 100% RCA compared to the control concrete (10). Xiao et al. noticed a reduction up to 45% for modulus of elasticity with 100% replacement of RCA (2).

The durability properties of RAC deteriorate at a further extend than mechanical properties, with the increase in RCA content. Thomas et al. noted that the open porosity of RAC increases with w/c ratio and the degree of replacement and concluded that a 20% replacement of NA with RCA decreases the density value around 5% than in the case of control concrete (8). Kou and Poon found 9.5% lower resistance to chloride permeability for the 100% RCA mixture (11). Rao et al. reported 7.37% water absorption for concrete with 100% RA and 6.54% for concrete with 50% RCA (10).

The use of fly ash and silica fume (or microsilica), creates some minor negative effects on the mechanical properties of the concrete but it improves substantially the durability properties of RAC. The use of fly ash presents reduced permeability and better workability. Silica fume due to its small size and its large surface area is changing the microstructure of concrete and improves it, creating a denser matrix. Although fly ash and silica fume have some drawbacks, such as reduced early strength and increased water demand respectively, the synergistic effect using both mineral admixtures as cement replacements is important and more beneficial than using each other alone.

The objective of this research is to determine whether a mix design incorporating RCA as replacement of NA and mineral admixtures as partial replacement of cement is able to achieve an adequate performance for structural applications. Furthermore, RCA are subjected to a treatment method to reduce the amount of the attached cement paste and improve their properties.

Apart from the mechanical and durability properties, the environmental and economic aspects of the RAC are of equal importance and a comparison of NA with RCA is presented. The potential environmental and economic benefits could ameliorate RAC image to the public and boost its usage.

## **2. Experimental program**

### **2.1 *Materials and testing methods***

In order to be able to quantify the cement paste attached, the aggregates were subjected to a thermal treatment method as described, in detail, in Sanchez de Juan and Gutierrez (12). It contains several cycles of high temperatures (500 °C) and soaking in water. The thermal method was selected as it can be used for all types of aggregates (including limestone), is more consistent and it is easier to perform. It was also proved to be the most effective and it had lower variability compared to other methods (13).

Both mechanical and durability properties were determined according to international standards. The coarse aggregates were evaluated according to their resistance to fragmentation (EN 1097-2:2010), weathering properties (EN 1367-2:2009), absorption and density (EN 1097-6:2000). The RAC mixtures were evaluated according to their compressive strength (EN12390-3:2009), flexural (EN 12390-5:2009) and splitting tensile strength (EN 12390-6:2009), modulus of elasticity (ASTM C 469 –

02), chloride permeability (ASTM C 1202-97), sorptivity (capillary absorption) and porosity (open porosity).

## 2.2 Concrete Constituents

Four types of coarse aggregates were used in this research, namely three RCAs and one NA. The RCAs tested are:

- RCA-L (laboratory), aggregates from crushed good quality laboratory concrete which represent the best case scenario of RCA.
- RCA-F (field), aggregates from crushed field concrete, provided by a local supplier.
- RCA-T (treated), aggregates from crushed field concrete (same as RCA-F) that were subjected to a treatment method to remove the attached cement paste.

A simple low-cost treatment method was used on field recycled aggregates in order to improve their mechanical properties. RCA-F aggregates were placed into an 8 m<sup>3</sup> modified concrete mixer. The mixer was rotated at a speed of 10 rpm for 5 hours. A total of around 3000 rotations were performed. During this process water was added removing smaller particles, dust and the weaker adhering mortar. At the end of the rotation period, the aggregates were sieved through a modified sieve in order to discard aggregates with sizes lower than 4 mm. The final product was named RCA-T and presented substantially better properties, as it is described in the following sections.

Coarse natural aggregates were used, with nominal sizes 4/10 mm and 8/20 mm. Only natural fine aggregates were used in all mixtures. The water used was drinkable tap water from the laboratory. All mixtures contained Superplasticizer (Sika Viscocrete 4000). Three binders were used: Ordinary Portland Cement (OPC), CEM I 42.5 R, as the main binder, Microsilica and fly ash as partial replacements of cement. Binders' properties are presented in Table 1.

**Table 1: Constituents of Binders**

Property	Fly Ash	Silica Fume	Portland Cement
SiO <sub>2</sub> content, %	40	85 to 97	21
Al <sub>2</sub> O <sub>3</sub> content, %	17	-	5
Fe <sub>2</sub> O <sub>3</sub> content, %	6	-	3
CaO content, %	24	<1	62
Surface area, m <sup>2</sup> /kg	420	15000 to 30000	370
Specific gravity	2.38	2.22	3.15

## 2.3 Concrete mixtures

A total of 12 mixtures were cast. The mix design is presented in Table 2. The same mix design was adopted for all mixtures. The effective w/c ratio was kept constant at 0.48. All aggregates and cement replacements were made by weight and the design method used in this study was the Direct Weight Replacement (DWR) method, which has been used extensively throughout the literature, mainly because its simplicity. Two series of mixtures were cast. In the first series, of 8 mixtures, there is a replacement of NA with different types of RCA while in the second series, of 4 mixtures, there is additionally a replacement of cement with mineral admixtures. The second series' specimens were also tested at 56 days due to the presence of mineral admixtures. For the mixtures without mineral admixtures the 28-day period of curing was considered adequate. The replacement ratios of the mixtures are presented in Table 3. The code names of each one consist of "R" for RCA, "L" (laboratory), "F" (Field), "T" (Treated), depending to the type of RCAs. "100" or "50" represent the replacement ratio of aggregates. "F25" represent the utilization of fly ash and the replacement ratio of cement with fly ash. Finally, "S5" represent the use of silica fume and its replacement ratio. Cubes of 100mm were used to determine the compressive strength, the sorptivity and the porosity. Cylinders  $\Phi$ 100 x 200 mm were used to determine the rapid chloride permeability, while the  $\Phi$ 150 x 300 mm cylinders were used to determine the tensile splitting strength and the modulus of elasticity. Prisms 100 x 100 x 500 mm were used to determine the flexural tensile strength.

**Table 2: Mix proportions**

Constituents	Quantity (kg/m <sup>3</sup> )
Cement	400.0
Water	192.5
Coarse Aggregates 8/20 mm	655.4
Coarse Aggregates 4/10 mm	263.8
Sand 1 (natural sand) 0/4 mm	559.5
Sand 2 (extra fine limestone)	108.4
Superplasticizer	6.4

**Table 3: Replacement Ratios**

Mixtures	Replacement ratio of coarse aggregates	Type of aggregate	Fly Ash	Silica fume
Control	0%	Natural	-	-
RL100	100%	RCA-L	-	-
RF100sa	100%	RCA-F	-	-
RF100ps	100%	RCA-F	-	-
RF100	100%	RCA-F	-	-
RT100	100%	RCA-T	-	-
RF50	50%	RCA-F	-	-
RT50	50%	RCA-T	-	-
RF100F25	100%	RCA-F	25%	0%
RF100F25S5	100%	RCA-F	25%	5%
RT100F25	100%	RCA-T	25%	0%
RT100F25S5	100%	RCA-T	25%	5%

## 2.4 Casting and curing

Concrete mixtures were prepared using a mixer available in the Laboratory of Civil and Environmental Engineering, University of Cyprus. Aggregates were in air-dried condition (except for "RF100ps" mixture) and the proper water corrections were made, according to aggregates' moisture and absorption values. Slump tests were performed with a slump target of  $200 \pm 30$ mm, aiming to create a relatively fluid and workable concrete. The desired slump was achieved by adjusting the amount of superplasticizer added in the concrete mix. The vibration was applied quite carefully to avoid segregation. The samples were removed from the moulds after 24 hours and were placed in water tanks at a constant temperature of 21 C°.

## 3. Results and discussion

The results of the tests are discussed in the following section with an emphasis on the mechanical and durability properties of hardened concrete but also on the effect of the treatment method on aggregates.

### 3.1 Properties of aggregates

The mechanical and physical properties of the four types of aggregates used for this research are presented in Table 4.

**Table 4: Mechanical and Physical Properties of Aggregates**

Properties	NA	RCA-T	RCA-F	RCA-L
LA (%)	29	15	32	29
Apparent Particle Density (Mg/m <sup>3</sup> )	2.69	2.74	2.72	2.60
Particle Density (Mg/m <sup>3</sup> )	2.52	2.49	2.28	2.21
Particle Density in SSD (Mg/m <sup>3</sup> )	2.58	2.58	2.44	2.37
Moisture Content (%)	0.5-0.6	2.6-2.8	2.7-2.9	2.1-2.2
W.A. 24 (%)	2.5	3.7	7.2	7.0
Soundness (%)	30	14	41	-
Mortar content (%)	0	9	24	23

NA in Cyprus present higher absorption values, reaching up to 4.5% (14) and thus the 2.5% is considered lower. The RCA-T aggregates had much lower absorption values, compared to RCA-F and RCA-L (around 50%). From the tests performed on aggregates it is clear that:

- The density and absorption values are related to the amount of the cement paste attached.
- The treatment method, which resembled a prolonged Los Angeles test, removed not only a major amount of cement paste but also some weaker or fractured aggregates keeping only the stronger and sounder ones producing the RCA-T aggregates that had very good resistance to fragmentation.
- The treatment method decreased the total amount of the attached cement paste by 62% and produced sounder and rounder aggregates.
- RCA-T aggregates proved to be of a better quality than the other types of RCA and in some tests they performed even better than NA.

### 3.2 Workability

The shape and texture of the aggregates and the attached cement paste has an impact on the workability. The mixture "RF100sa" was cast in order to examine the effect of the shape and texture of aggregates on the workability, thus the amount of superplasticizer used was kept the same as "Control". This resulted in a low slump value of 50mm. Table 5 presents the slump and superplasticizer values of each mixture.

**Table 5: Slump and Amount of Superplasticizer**

Mixtures	Slump (mm)	Superplasticizer (Kg/m <sup>3</sup> )	Superplasticizer/cement ratio (%)
Control	198	3.50	0.87
RL100	220	3.00	0.75
RF100sa	50	3.50	0.87
RF100ps	190	2.50	0.62
RF100	170	4.60	1.15
RT100	185	2.50	0.62
RF50	194	3.25	0.81
RT50	195	2.00	0.50
RF100F25	170	5.90	1.48
RF100F25S5	190	6.25	1.56
RT100F25	196	2.58	0.65
RT100F25S5	195	2.90	0.73

The slump test results showed that:

- The mixtures containing RCA-T aggregates needed less superplasticizer in order to reach the target slump value. Due to the rounder shape, RCA-T aggregates had better workability compared to RCA-F aggregates but even to the natural aggregates.
- The replacement of cement with mineral admixtures increased greatly the amount of the superplasticizer that was needed. Especially the microsilica-mixtures demanded the biggest amount. This occurred due to the higher surface area of microsilica particles that increased the water requirement.
- Presoaking the aggregates affected the workability since having the same w/c ratio, "RF100ps" mixture needed 0.62% (of the amount of cement) superplasticizer while "RF100" needed 1.15%.

### **3.3 Mechanical properties**

Table 6, presents the results of the mechanical properties of all concrete mixtures tested.

#### **3.3.1 Compressive Strength**

The compressive strength test results indicate that the use of RCA affected negatively the strength of the concrete. The results for the 100% substitution of NA coarse aggregates with RCA showed losses of 16.8%, 34.1% and 13.8% for "RL100", "RF100" and "RT100" respectively. For a replacement ratio of 50% the losses were 25.7% and 11% for "RF50" and "RT50", respectively. The use of SSD aggregates had only a minor impact on the 28-day strength. It should be noted that despite the decrease, the RAC mixtures manage to reach high compressive strength values. The difference between the RCA-T and RCA-F aggregate mixes is substantial; there is a 23.6% and 16.5% difference in compressive strength for incorporation ratios of 100% and 50% respectively.

In the second series, the difference between mixtures, consisted of the two different field aggregates (RCA-T, RCA-F), is also clearly noticed. Regarding the use of mineral admixtures, although the 28-day compressive strength was low, the 56-day strength presented only a slight decrease compared to the mixtures without mineral admixtures. The lower early strength can be attributed to the slow pozzolanic reaction of fly ash. For the optimal scenario of 100% NA replacement and 25% and 5% replacement of cement with fly ash and microsilica, respectively, "RT100F25S5", the 56-day strength reached a compressive strength of 60.3 MPa. The use of fly ash and microsilica produced only minor losses compared to the mixtures without mineral admixtures. Comparing the use of fly ash with the use of both fly ash and microsilica, it can be noticed that the use of microsilica did not provide higher early strength, as it was expected due to its rapid pozzolanic reaction. Regarding the 56-day compressive strength, microsilica did not have neither positive nor negative effects.

Taking into account all the compressive strength test results:

- All RAC mixtures provided good compressive strength values that decreased as the replacement ratio of NA with RCA increased.
- Differences between RAC containing RCA-T and RAC containing RCA-F aggregates were particularly significant for both series of mixtures and underlined the effect of a simple treatment method.
- The 28-day compressive strength of concrete mixtures decreased with the increase in recycled aggregate content. This was due to the presence of the old ITZ that worsens the mechanical and physical properties of the recycled aggregates.
- Comparing the "RN100ps" with "RN100", it can be concluded that the effect of presoaking the aggregates was insignificant.
- The use of fly ash and microsilica as partial replacement of cement produced a low early strength but their 56-day strength was almost the same as the 28-day strength of mixtures without mineral admixtures.
- Despite the use of recycled aggregates, that according to literature should present high variability, the standard deviation was relatively low for all the tests (ranging between 1-6% of the mean values). Though, standard deviation of compressive strength increased with the increase of recycled aggregates in concrete. The Control mixture presented the lowest deviation.

**Table 6: Summary of Results**

Mixtures	Compressive strength (MPa)			Flexural strength (MPa)	Indirect tensile (MPa)	Modulus of elasticity (GPa)	Porosity (%)		Sorptivity (mm <sup>2</sup> /min)		Rapid Chloride Permeability (Coulombs)	
	7 days	28 days	56 days				28 days	56 days	28 days	56 days	28 days	56 days
Control	58.5	72.1	-	8.6	4.22	27.28	17.44	-	0.092	-	3473	-
RL100	45.8	60.0	-	6.9	4.06	24.03	22.28	-	0.122	-	4870	-
RF100sa	38.6	47.5	-	5.4	2.81	18.25	22.17	-	0.120	-	4861	-
RF100ps	39.5	50.6	-	6.0	3.04	21.33	20.98	-	0.109	-	5822	-
RF100	39.1	47.1	-	6.6	3.14	20.09	21.28	-	0.116	-	5248	-

### 3.3.2 Flexural strength

It can be seen that flexural strength decreased with the increase of recycled aggregate content. The results for the 100% substitution of NA with RCA showed losses of 19.6%, 23.7% and 16.7% for “RL100”, “RF100” and “RT100” respectively. Like the compressive strength test, the “RT100” presented the lowest loss in strength compared to the control mixture. This is an indication of the difference in the mechanical and physical properties of the aggregates. Regarding the SSD aggregates, there was a slight decrease in flexural strength. Etxeberria et al. noted that the recycled aggregates should not be saturated, as that would probably result in the failure of an effective transition zone between the saturated recycled aggregates and the cement paste (5). Regarding the use of mineral admixtures, there was only a slight effect in flexural strength with the incorporation of FA and SF.

### 3.3.3 Splitting tensile strength

There is a drop of 5%-25% of the splitting tensile strength using 100% RCA. The “RF100” presented higher tensile splitting strength than “RT100”. This shows, as expected, that the shape and texture of aggregates affect the strength of the concrete. Matias et al. concluded that the rough and angular contact area allows a better adherence to the new cement paste than NA (15). As a result, “RF100” had higher splitting tensile than “RT100” with the rounder aggregates. The same pattern exists also for the 50% replacement level (“RF50”, “RT50”). The splitting tensile strength test provided a good opportunity to examine the failure mechanism that exists in concrete as the cylinder sample was broken in half at the end of the test. The failure of conventional concrete derives from the interfacial transition zone that is the weakest link. Regarding the RAC, the failure occurs through the aggregates themselves. The control mixture had a matrix failure. The failure surface did not pass through the aggregates but around them, since failure occurred along the ITZ. On the other hand, in most of the cases of the recycled concrete the failure occurred through the aggregates themselves. The RCA-T aggregates though presented a different pattern. There was a combination of the two cases described. The partial replacement of cement with mineral admixtures decreased the splitting tensile strength.

### 3.3.4 Modulus of elasticity

The modulus of elasticity of the recycled aggregate concretes was reduced when the recycled aggregates percentage increased. There was a difference between the RCA-T and RCA-F aggregates. It can be noted that the partial replacement of cement with mineral admixtures had a minor negative effect for RCA-F aggregate concrete but decreased at greater level the RCA-T aggregate concrete.

### 3.4 Durability Properties

The durability tests results are presented in Table 6. The density of the “Control” was typical for normal concrete. The mixtures with RCA had lower density due to the lower density of the attached cement paste. “RT100” however had almost the same density as “Control” indicating the good quality aggregates. The use of mineral admixtures did not have any serious impact on density. Porosity followed the same pattern as density, “RT100” achieved close enough values to “Control” while the use of mineral admixtures had only a minor effect.

Using RCA, the reduction in permeability and the increase of sorptivity, were expected since the recycled aggregates contained a certain amount of mortar and had undergone a crushing process, which was likely to leave cracks in the weaker mortar or weaker aggregates. These cracks would in turn create paths for the fluids to pass through. The increase of the sorptivity coefficient of RAC can also be attributed to the higher absorption capacity of the recycled aggregates compared with natural. The difference though between RCA-T aggregates and RCA-F or RCA-L was evident. Especially the “RT100” mix presented around the same properties as the control mixture while “RL100” and “RF100” presented lower quality.

For the second series of mixtures the RCP and sorptivity values were greatly improved since the use silica fume restructure the matrix leaving fewer paths for the liquid to pass through. Silica fume with high value of fineness filled both the interfaces and the bulk paste and the capillary pores were reduced, hence, the sorptivity and permeability of concrete decreased. The use of fly ash and microsilica refined the distribution of pore size and pore shape of concrete. In concrete mixtures with FA, the average particle size of the mineral admixture was higher compared to microsilica and the pores in bulk paste and the interfaces were not filled adequately. Due to the higher fineness, the use of microsilica seems to react better and produces better values for both RCA-T and RCA-F aggregates. Finally, there was good correlation among durability properties, especially the sorptivity-porosity correlation ( $R^2=0.92$ ) and sorptivity-Rapid Chloride Permeability ( $R^2=0.72$ ).

## 4. Economic aspect

Regarding the cost analysis conducted for this research, some valuable conclusions emerged. The cost of mineral admixtures found to be extremely high, in Cyprus, to be used in a large scale. The cost is much lower in countries with production sources of industrial by-products. The import of these materials raises the cost and makes it much higher than the cost of cement. Table 7 presents the costs of the materials used and the final cost of the mixtures. RCA-F aggregates were the cheapest. The treatment method (for RCA-T) raised the cost of the aggregates but was still lower than the cost of NA. The 50% substitution level of NA with RCA-T (RT50 mixture) was the most cost-effective of all mixtures, in terms of €/MPa. RT50 mixture produced a cheaper concrete that had around the same quality as “Control”. Finally, a useful conclusion is that although RCA-F aggregates were cheaper than RCA-T, the mixtures produced from RCA-F were more expensive since they required greater amount of superplasticizer in order to reach the same level of workability.

**Table 7: Cost of mixtures (€)**

	Unit cost (€/tn)	Control	RT100	RF100	RF50	RT50	RF100 F25	RF100 F25S5	RT100 F25	RT100 F25S5
Cement	84.0	33.6	33.6	33.6	33.6	33.6	25.2	23.5	25.2	23.5
Fly Ash	200.0	-	-	-	-	-	20.0	20.0	20.0	20.0
Microsilica	250.0	-	-	-	-	-	-	5.0	-	5.0
NA	9.3	6.2	-	-	3.0	3.0	-	-	-	-

## 5. Conclusions

Useful conclusions were derived from this research aiming to dispel fears regarding the utilization of RCA into concrete. The key conclusion of this research is that the RAC can provide adequate quality in order to be used in major construction activities. A simple treatment method, in the recycling process of RCA, is capable to reduce the attached cement paste at such level that diminishes the negative effects and to create a better quality RAC which is competitive to normal concrete. The main findings of the research are:

- Properties of aggregates
  - RCA-F aggregates consisted of 24% attached cement paste. A simple treatment method though can reduce the cement paste to 9%, producing aggregates with fewer amount of cement paste, rounder and more sound (RCA-T aggregates).
  - RCA had higher water absorption values, lower density and higher LA and soundness values. Treated recycled aggregates (RCA-T) showed great improvement in all of the tests that were performed, reaching or even surpassing the properties of natural aggregates.
- Replacement ratio of NA with RCA
  - Increasing the replacement ratio resulted in lower quality of concrete compared to normal concrete. Both mechanical and durability properties are negatively affected by the increase of the replacement ratio.
- Type of aggregates
  - RCA-F aggregates provided good quality concrete, taking into account the low quality of aggregates. RCA-T aggregates provided good quality concrete, competitive to control concrete.
  - Presoaking aggregates did not have any clear positive effect on mechanical properties of concrete and instead, a slight decrease in some of the durability properties was noticed.
- The combined effect of mineral admixtures (fly ash and silica fume) proved to be quite significant and improved substantially the durability properties. Especially the use of silica fume had a crucial impact on sorptivity and chloride permeability values. The mechanical properties were relatively the same, though a low early compressive strength was presented due to the delayed pozzolanic activity of fly ash.
- RAC were cheaper than NA resulting to a slightly cheaper concrete. A 50% replacement of NA with RCA-T produces a less expensive mixture with almost the same quality as "Control". In Cyprus, mineral admixtures are much more expensive than cement and their utilization resulted to a higher total cost.

## 6. Acknowledgement

The authors are grateful to Skyrra Vassas Ltd for providing the recycled concrete aggregates and to Vasiliko Cements Public Company Ltd for providing the OPC.

# Effects of Silane Impregnation on Drying Shrinkage of Cement-based Compounds

Pedram H. Mojarad<sup>1</sup> and Gary Boon<sup>2</sup>

<sup>1</sup> Product Manager, Sika Australia

<sup>2</sup> Technology Manager, Sika Australia

**Abstract:** Drying shrinkage can result in shrinkage cracking and durability issues. There are different types of shrinkage reducing/compensating admixtures or methods in concrete industry, which affect the drying shrinkage mechanism in different ways.

On the other hand, there are types of hydrophobic impregnation products in the market, e.g. silanes, siloxanes or their combinations which when applied on concrete surfaces, provide water repellency and bring about reduction of moisture ingress or any deleterious agents dissolved in water, and of course, enhance the durability of cement-based elements. The other aspect of silane impregnation on cement-based compounds is the reduction in capillary water absorption.

Current research project is studying the effect of silane impregnation, applied at early age, on the drying shrinkage of cement-based mortar specimens. Experimental tests have been carried out on sets of OPC mortars, of which some are treated with different silane combinations. Two types of silane products have been used, i.e. liquid and cream, and the specimens were stored in controlled drying environment.

Results illustrate that the application of silane impregnation reduced the amount of drying shrinkage of mortars. Further investigations has shown the shrinkage reduction mechanism was through the reduction of moisture loss through reduction of surface tension of pore water.

**Keywords:** Silanes, hydrophobic, capillary water, drying shrinkage, mortar.

## 1. Introduction

Drying shrinkage is the major contributor to total shrinkage of normal strength concrete [1]. Once mortar and concrete are exposed to dry environment, they begin to lose water and consequently shrink [2]. The loss of free water from large cavities present in paste microstructure may not result in tangible shrinkage; however, the loss of adsorbed water and water held in small capillary pores result in a reduction in disjoining pressure, which is considered to be the principal cause of drying shrinkage [3, 4].

Formation of cracks in cement-based materials can be due to tensile stresses originating from applied loads or different forms of shrinkage when the specimen is restrained. Once the cement-based material cracks, chemicals can enter and diffuse through the cementing matrix. Therefore, controlling shrinkage can bring about cracking control.

Shrinkage Reducing Admixtures (SRA) are one of the methods that are widely used in the concrete industry. The mechanism through which SRAs reduce the drying shrinkage is reduction of surface tension of capillary pores [5]. SRAs are used as admixtures into the concrete during mix.

Silane based products are now being increasingly used in construction jobs. The main reason of using hydrophobic impregnations on concrete and masonry surfaces is that they may bring about water repellency on the surface, which can result in immense reduction of water adsorption. This characteristic is claimed to be achieved by reducing the surface tension of concrete or masonry surface. There are reported literatures showing the influence of silanes (hydrophobic impregnation) on corrosion rate control of reinforced concrete [6, 7].

As defined by EN 1504-2 [8], hydrophobic impregnation is a treatment of concrete to produce a water-repellent surface. The pores and capillaries are internally coated and there is no film on the surface of the concrete. Hydrophobic impregnation products are mainly categorized based on their ability to penetrate into concrete, i.e. <10 mm or >10mm [8].

Different research studies have investigated the influence of silanes on concrete samples. Tittarelli and Moriconi [7] showed that silane can block the corrosion process in uncracked concrete specimens, whereas in cracked concrete specimens, corrosion of steel reinforcements was unexpectedly more severe in hydrophobic specimens rather than in non-treated ones. Using silane as water repellent agent was

found to improve the durability of recycled aggregate concrete [9]. In addition, positive effects of incorporating organosilanes in cementitious system, in regards to workability and strength were reported in research publications [10, 11]. However, limited information on how silanes influence concrete properties have been reported.

This article endeavors to examine the idea that whether reduction of surface tension of concrete surface using silane treatment on surface, can affect the drying shrinkage of concrete samples. This is done through drying shrinkage measurement of samples treated with surface applied commercially available silane products, and comparing them with control specimens.

## 2. Experiments

Two classes of silane molecules based products have been used in this research. Liquid silane contains 99% of active content and also cream-based technology with greater than 80% active content are the silanes used in this project.

Australian Standards were used in the experiments. Standard prismatic test specimens for drying shrinkage were utilized, based on test specifications in AS 2350-13 [12]. For the first 22–24 hours after mixing and casting, all specimens were stored in a moist environment where the relative humidity was more than 95% [13]. After demoulding, all shrinkage specimens were maintained inside a humidity-controlled (23 C and 50% relative humidity) cabinet, for the entire testing period [12].

### 2.1. Raw materials, hydrophobic impregnation treatment

A ready mixed cementitious grout/mortar, readily available in the market was used as cementitious samples in this research project. The cementitious mortar was a general purpose mortar with a drying shrinkage reported greater than of high performance ones. The reason for choosing this mortar was to use the most similar mix to the standard one defined in AS2350.11, in order to compare shrinkage more easily. Mortar was mixed based on manufacturer’s instruction.

Mixing, casting and all tests were carried out at  $22 \pm 1$  C and  $60 \pm 5$  %RH. In order to obtain comparable results for the evaluation of silane treatments, 12 sets (including control sets) were prepared under the same environmental ambient. **Table 1** tabulates the silane treatment regime on concrete samples. Preparation of mortar mixes was carried out in accordance with AS 2350.12 [14].

**Table 1. Specimen labelling, based on treatment regime**

Treatment regime	Silane treatment 2 h after demoulding and after initial measurements	Silane treatment 24 h after demoulding and after initial measurements	Silane treatment 72 h after demoulding and after initial measurements	No silane treatment
Liquid silane @ 150 g/m <sup>2</sup>	LSA-2h	LSA-24 h	LSA-72 h	Control 1
Liquid silane @ 300 g/m <sup>2</sup>	LSB-2h	LSB-24 h	LSB-72 h	Control 2
Cream silane @ 200 g/m <sup>2</sup>	CS-2h	CS-24 h	CS-72 h	Control 3

As shown in **Table 1**, two types of silanes have been used, i.e. liquid silane and cream silane, with active content of 99% and >80 %, respectively.

Liquid silane has been applied in two different consumption rate (based on manufacturer's recommendation), i.e. 150 and 300 g/m<sup>2</sup>. The cream type silane was only applied at a consumption rate, i.e. 200 g/m<sup>2</sup>. Both liquid and cream silanes have been applied by brush onto concrete surfaces, following the treatment regime. As tabulated above, for each set of testing: 1- silane has been applied, only 2h after demoulding, 2- 24 h after demoulding and in the third sets, 3- 72h after demoulding. All Control specimens were left without any silane treatments.

In order to have consistency over all mixes, LSA (set of samples treated with liquid silane at 150 g/m<sup>2</sup>) and LSB (another set with liquid silane at 300 g/m<sup>2</sup>) samples were all mixed in one batch. CS (cream silane treated at 200 g/m<sup>2</sup>) specimens were mixed in a separate batch.

## 2.2. Shrinkage measurement and physical properties

Immediately after demoulding, all specimens were measured for initial length to the nearest 0.001 mm, using a length comparator and stored in a humidity controlled cabinet at a temperature of 23 ±1C and a relative humidity of not less than 50%. Subsequent measurements were after 2, 3, 7, 28 and 56 days of casting. The drying shrinkage was calculated by  $\Delta L/L$ , where  $\Delta L$  is the difference between the initial length measurement taken immediately after demoulding, and the length reading at the particular age, and L is the original length of the sample at initial stage and defined in AS2350.13.

Mass changes of specimens were also monitored in this research, in order to figure out any possible shrinkage reduction mechanism.

## 3. Test results

Results of subsequent shrinkage measurements have been reported in Figures 1-3.

Figure 1. Shrinkage measurement of liquid silane treatment @ 150 g/m<sup>2</sup>

Figure 2. Shrinkage measurement of liquid silane treatment @ 300 g/m<sup>2</sup>

Figure 3. Shrinkage measurement of cream silane treatment @ 200 g/m<sup>2</sup>

Figure 4. Mass change (%) of sample with and without silane treatment

#### 4. Discussion and conclusions

Figures 1-3 display reduction of shrinkage at 28 and 56 days in samples treated with silanes. Silane treatment on existing concrete and cementitious specimens has clearly demonstrated trend of reduction in drying shrinkage of mortar specimens. However, different results were obtained as a function of different consumption rate and type of silanes. In addition, a direct relationship between shrinkage reduction and specimen moisture loss indicating, the lower the moisture loss, the less the drying shrinkage, was observed for each mix.

In terms of drying shrinkage, those samples which were treated with silane 24 h after demoulding show lower shrinkage than those which were treated 2h and 72 h after. The effect of treating 2h after demoulding and 72h after demoulding were very similar.

In these samples and under these conditions, 24hr treatment seems to be the optimum in regards to shrinkage reduction. This might be due to appearance of cracks which may result in deeper penetration of silane into concrete specimens.

The mechanism proposed for shrinkage reduction using silane treatment can possibly be the interruption of moisture transfer from the capillary structures in the mortar due to the presence of hydrophobic molecules near the concrete surface, which results in decrease in water transfer from inner layers and pores of matrix to the surface and consequently decreasing moisture loss of sample. Figure 4 supports this mechanism, since the changes in mass of mixes with silane treatment were less than of that in control samples.

Hydrophobic impregnation is now widely used as concrete protection system on new and existing concrete structures. These findings support extra advantages of using these systems on concrete, specifically at early stages (onset of cracking in concrete). Therefore, when applied properly and with the correct consumption rate, not only do hydrophobic impregnation protect the concrete surface against the ingress of water soluble aggressive ions, but also may bring about shrinkage reduction mechanisms which will mean less cracking of concrete.

A new shrinkage reduction method was introduced and assessed in this project. The highest reduction belonged to 300 g/m<sup>2</sup> of liquid silane, then 200 g/m<sup>2</sup> of cream silane and finally to 150 g/m<sup>2</sup> of liquid silane, all treated after 2 h of demoulding. Thus, this can be concluded that the consumption rate also does have a direct effect on shrinkage reduction of concrete specimens as well as the time of application.

# Fresh Property and Matrix Distribution for Amorphous Steel Fiber Reinforced Concrete

Byoungil Kim<sup>1</sup> and Sea Hyun Lee<sup>1</sup>

<sup>1</sup>Korea Institute of Civil Engineering & Building Technology/Building & Urban Research Institute

**Abstract:** The research was conducted to analyze workability and fiber distributions of amorphous steel fiber reinforced concrete by changing fiber length and fiber addition ratio. The inverted slump cone and vebe tests as well as slump test was performed to understand the fluidity of amorphous steel fibers which have quite different appearance compared to conventional steel fibers. Test results showed that thin plate type of amorphous steel fibers required different test approach to figure out workability since the reduction of workability from slump test was different that from inverted slump cone and vebe tests. In conclusion, fluidity of amorphous steel fibers reinforced concrete was significantly degraded as fiber length and addition ratio increase. Also, fibers spacing in cement matrix was apparently reduced as the increase of fiber length and addition ratios without fiber balling.

**Keywords:** Amorphous steel fiber, Fiber addition ratio, Workability, Fiber distribution, Compressive strength

## 1. Introduction

As the buildings in Korea become taller and larger, the types of admixture added to concrete are also becoming diverse. As the demand for high performance construction material rapidly increased, heavy investment and study on development of high performance cement and concrete composite material by adding the fiber type material are ongoing. Generally, PP, steel, PVA or nylon fibers are added to cement and concrete to distribute the stress generated inside the structure by the pullout mechanism to the homogeneously dispersed fibers in order to reinforce the initial crack control and ductility after bending failure. The crack control mechanism depends on the diameter, thickness, length, tensile strength, mixing ratio, etc. of the fiber. Higher mixing ratio of fibers homogeneously dispersed in the cement matrix particularly is known to not only reinforce the strength but also greatly increase the crack control and energy absorption capability after the flexural behaviors. The leading super-high performance cement-concrete composite materials with fiber content include UHPC (ultra-high performance concrete) and ECC (engineered cementitious composite).

UHPC is the fiber reinforced cement composite with the compression strength of 150 MPa or more and design basis splitting tensile strength of 5 MPa or more. UHPC is the pozzolan type admixture consisting of Portland cement, silica fume or blast-furnace slag fine particles; filling material having aggregates with diameter of 0.5mm or less and SiO<sub>2</sub> content of 90% or more; and other admixture. It has the water-binding material ratio of 0.24 or less and tensile strength of 2,000MPa or more and is mixed with reinforced fibers with diameter of 0.2~0.25mm and length of 10~20mm for 2% or more of total volume<sup>6)</sup>. ECC is the cementitious composite having the pseudo strain hardening and multiple crack properties to show increasing stress as the strain rate increases without degradation of strength even after the cracks are generated under the bending moment or direct stress. Added with organic fiber such as the micron polyethylene (PE) fiber and vinyl (PVA) fiber or the steel fiber, it has 4~8% deformation capacity. The materials included the cement, admixture, fine aggregates, and additives (high performance water reducing agent and viscosity agent).

Unlike the conventional steel fiber requiring the complex and long manufacturing process, the amorphous steel fiber used in this study is rapidly cooled in the plate shape to omit the process after melting and thus the energy consumption is reduced and CO<sub>2</sub> is reduced because there is not carbon removal process. As such, it can be used as the eco-friendly construction material. The amorphous Fe used in the experiment had the tensile strength of 1400~1700 MPa and flexible straight type. Compared to conventional hook type steel fiber, it is easier to process and more durable because of corrosion resistance. The fiber was reinforced to the concrete to experimentally study the fiber dispersion by deducing the workability evaluation method and optimum mixing as well as observing the micro structure according to the change of fiber length and mixing ratio.

## 2. Experimental Plan

### 2.1 Experimental Materials

This study used the class 1 conventional Portland cement and the standard sand with specific gravity of 1.54 and fineness

modulus of 2.8 as the fine aggregates. For the coarse aggregates, the grinded aggregates with maximum size of 19mm and specific gravity of 2.72 were used. The steel fiber used in the experiment is the amorphous steel fiber manufactured by a foreign manufacturer and had the lengths of 10mm, 20mm and 30mm, width of 1.3mm and thickness of 35 $\mu$ m. The amorphous steel fiber is a thin plate type manufactured by rapidly cooling the molten steel so that the nuclei of the generated crystals are not grown to freeze the liquid structure. The specific gravity is 7.2 which is slightly lower than the specific gravity of conventional steel fiber of 7.8, and the apparent volume is much large.

## 2.2 Mixing Design

Fig. 1 shows the research flow to deduce the optimum mixing design to ensure the flowability and dispersibility with the length and mixing ratio as the variables. To ensure the appropriate flowability and homogeneous dispersion of fibers by mixing the amorphous steel fiber, documents related to concrete mixing design here and abroad were surveyed to select the materials (fibers, aggregates and mixing materials) for optimum mixing of amorphous steel fiber. The concrete mixing such as the high performance fiber reinforced concrete (HPFRC), ECC and UHPC, which adds 2% or more fibers to maximize the dynamic property of fibers in the cement matrix and reinforce the tensile strength, flexural strength and flexural toughness in order to reduce the crack and prevent its spread, were considered.

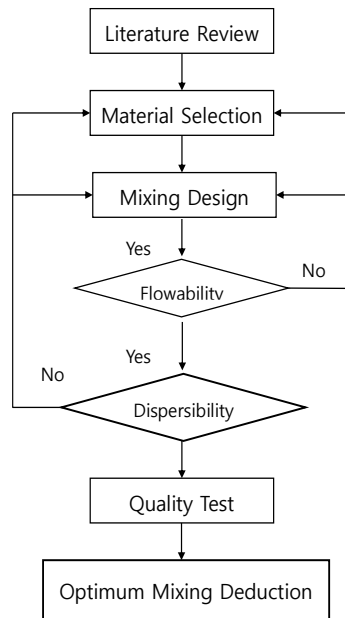

Figure 1. Research flow for optimized mix design

In the reference mixing experiment before the actual mixing, the mixing design factors required for optimum mixing of amorphous steel fiber was studied with the preliminary experiment of W/C ratio, fine aggregate ratio, maximum aggregate size, water reducing agent, viscosity agent and air-entraining agent, and then the flowability and dispersibility experiments were conducted. Lastly, the inverted slump and Vebe tests specific to the high mix amorphous steel fiber were conducted to deduce the optimum mixing for the fiber length and mixing rate to complete the mixing design for quality test of fiber reinforced concrete.

Table 1 shows the mixing design of amorphous steel fiber with length of 10 mm and 20 mm and mixing ratio of 0.2%, 0.4% and 0.6%. The water-cement ratio of 0.45 was selected to maintain the conventional concrete strength. For each fiber length, 0.2%~0.6% fibers to total volume were added. Generally, fiber lumping in the fiber reinforced concrete can be mainly divided into three types. First, lumping of fibers occur due to the difference of the aspect ratio (ratio of length and diameter) of fiber and particles such as the cement and sand when a large volume of fibers is added. Second, it is because of greatly different specific gravities of fiber and concrete materials. The typical fiber gravity of 7.8 is different from that of cement (3.15) or sand (2.5), and thus they are separated from each other during mixing, and the materials of similar specific gravity tend to lump together. Last, lumping of fiber occurs during the compaction work to fill the concrete in the concrete form after mixing. The widely used rod vibrator uses an internal vibrator to fill the concrete in the every corner of the concrete form. After the vibrator is used for a long period, the fibers tend to be compacted in a direction due to the vibration and the effect of adding the fibers decreases. When the compaction is excessive, the steel fibers with high specific gravity settle below and the organic fibers with low specific gravity rise above, and that causes the reinforcing effect of fibers greatly.

In the conventional fiber mixing, if the small amount of fibers is added, it is considered as the additive and the volume change is disregarded in mixing design. If a large amount of fibers is added, it is considered as the mixing material and the volume of aggregate is lowered by the apparent volume of fibers to ensure the fiber dispersibility. To minimize the effect, this study added

the high performance water reducing agent and cellulose viscosity agent to minimize the decrease of flowability due to addition of large amount of fibers. The apparent volume of relatively larger amorphous steel fiber is substituted by the volume of aggregates and deducted. Then the fine aggregates in the same amount as the deducted volume is added to maintain the specific level of granular materials and flowability appropriate to the work.

**Table 1. Mix design**

Symbols	G <sub>max</sub> (mm)	Slump (mm)	Air Content (%)	W/B	S/a (%)	Unit weight (kg/m <sup>3</sup> )						
						W	C	S	G	F (%)	SP (C*%)	VMA (C*%)

The forced twin shaft mixer was used to mix the concrete. The fine aggregates and coarse aggregates were poured first and dry mixed for one minute. Then the cement was added and mixed for one minute. The minimum amount of high performance water reducing agent and viscosity agent diluted in water was added to complete mixing. After the mixing, the slump, air content, inverted slump and Vebe time were measured to study the unhardened concrete property. Moreover, to study the dynamic property of hardened fiber reinforced concrete, the unhardened concrete was poured into the compression strength test piece specimen, and the test sample was initially cured indoor with  $23 \pm 2^\circ\text{C}$  temperature and  $50 \pm 2\%$  relative humidity for 24 hours. The concrete was removed from the specimen and cured in a wet curing room with 100% relative humidity for 28 days. Then the compression strength and flexural strength tests were conducted.

### 3. Experiment Method

#### 3.1 Properties of fresh concrete

When the fibers are added to the concrete, the flowability generally deteriorates because of increased stiffening during the mixing. The workability can be improved when the water reducing agent is added or mixing design is changed. However, to accurately measure the workability of fiber reinforced concrete, an approach different from the slump test used for the conventional concrete is needed. That is because the loss of slump and loss of workability when the fibers are added do not exactly match. This experiment observed the effect of change of flowability of each fiber and its correlation with slump test through the slump test, which is the typical workability measurement method, and inverted slump cone test and Vebe test which are the plasticity characteristics test methods.

The inverted slump time was developed for simple field test to measure the workability of fiber reinforced concrete at low cost. Although the fiber reinforced concrete can show the improved workability, each fiber has the role of increasing thixotropy (a phenomenon of decreasing viscosity when the liquid is subject to shear stress such as agitation and increasing velocity when the shear stress is stopped). The study that showed the slight decreased slump in the mix of PP reinforced fiber and increased workability in the compacting factor test highlights that more accurate workability evaluation is needed<sup>2)</sup>. Moreover, many steel fiber and synthetic fiber manufacturers report that the general slump test is not suitable to evaluate the workability of fiber reinforced concrete and recommend the flowability evaluation by inverted slump test using the vibration to accurately evaluate the workability of fiber reinforced concrete. The test apparatus such as the vibrator, slump cone, bucket and stopwatch can be easily obtained in the field. To maintain the unification of the slump cone and bucket during the vibration, the slump cone is fixed with a wooden frame and the bucket is inserted at the top. In this study, the slump cone was fixed upside down with a wooden frame and placed at the top of the bucket so that there was around 10cm gap between the bucket bottom and inverted slump cone. The inverted slump cone was filled with the concrete in three steps, and the stopwatch was pressed as soon as the bottom plate began vibrating and the time until the inverted slump cone was completely removed of concrete was measured to evaluate the flowability and consistency of the fiber reinforced concrete. As the workability and flowability of the concrete significantly decreased due to the fiber, the bottom hole of the slump cone was instantly plugged, and the fiber reinforced concrete did not naturally flow.

The Vebe consistometer (BS 1881-104) is a tool to measure the remolding ability of the very dry concrete. It measures the energy required for the concrete collapsed by vibration to be remolded. A metal cylindrical vessel is placed on a vibrating table to induce the sinusoidal vibration, and the slump cone is placed at the center of the cylinder. Like the standard slump test, the slump cone is filled with concrete in three steps and then a plastic disk is placed at the top. The time until the concrete is completely collapsed by falling disk is measured. The purpose of Vebe test is to measure the consistency of the very dry concrete. For this

experiment, a slump cone was placed on top of a vibrating table and filled with concrete in three steps. Then the slump cone was removed, and the plastic plate on top was placed in contact with the concrete surface. Then the timer is pressed as soon as the vibration begins, and the time till the slump is completely collapsed is measured.

### 3.1 Compressive Strength Test

To evaluate the impact of fiber reinforcement in the cement matrix according to the amorphous steel fiber amount (0.2%, 0.4% or 0.6% ) and length (10 mm or 20 mm) change, the compression strength of 28-day wet cured cylindrical test piece specimen with 10 mm diameter and 200 mm height was measured using UTM with 2,000 kN capacity.

### 3.2 Secondary electron microscope

For dispersibility of fiber according to the change of length and mixing ratio of amorphous steel fiber, the microstructure of the fiber was observed using a scanning electron microscope (SEM) to compare the dispersion of fibers in the cement matrix, bonding of fiber on the interface, and directional nature of fibers. The magnification of SEM was set to 60~80 times and the spaces between the fibers were measured to evaluate the dispersibility of the fibers at each length (10 or 20 mm) and mixing ratio (0.2, 0.4 or 0.6%).

## 4. Experiment Result

### 4.1 Slump

Table 1 shows the change of workability according to the change of amorphous steel fiber length and mixing ratio. When the fiber length was 10 mm, there was not much change of workability in comparison with OPC when the mixing ratio increased from 0.2% to 0.4%. In the case of 20 mm fiber length, the slump had the relatively smaller value than 10 mm, and the slump value reached 130 mm at 0.6% mixing ratio. In conclusion, the viscosity and flowability decreased as the fiber length and mixing ratio increased. The decrease of workability was the largest at 0.6% mixing ratio.

### 4.2 Inverted slump cone time

Fig. 1 shows the result of inverted slump test at different fiber mixing ratios and lengths. In the case of OPC mixing, the inverted slump time was 5 seconds. The very short inverted slump time is attributed to relatively large flowability. At 10 mm fiber length and 0.2% mixing rate, the inverted slump time increased by around 60% from OPC although the slump value was higher than OPC. In the case of 0.4% mixing ratio, the change of slump value was around 30 mm, or around 13% decrease, but the inverted slump time changed by 320%. As such, the workability decreased much larger than the slump. In the case of 0.6% mixing ratio, the decrease of workability due to the increased inverted slump time greatly increased. For the change of workability at the fiber length of 20 mm at mixing ratio of 0.2%, the inverted slump time increased by 23 seconds for the slump value decrease, indicating much greater decrease than the workability decrease by OPC slump decrease. In the case of 0.4% mixing ratio, the workability decrease was slightly larger than 0.2% mixing ratio, but the concrete flowability greatly decreased by sharp increase of inverted slump time in the case of 0.6% mixing ratio.

Figure 1. Inverted slump cone time vs. slump

### 4.3 Vebe time

Fig. 2 shows the Vebe time at different fiber mixing ratios and lengths. In the case of OPC mixing, the Vebe time was 1.3 seconds. The very short time was attributed to relatively larger flowability. For the workability change at the fiber length of 10 mm, there was little change of Vebe time at 0.2% mixing ratio, then the Vebe time increase twice at 0.4% mixing ratio. At the 0.6% mixing ratio, the Vebe time greatly increased. For the workability change at the fiber length of 20 mm, the rate of flowability decrease by increased Vebe time was around 10 larger than change of workability when the slump decreased by 20 mm compared to OPC slump of 230 mm at the 0.2% fiber mixing ratio. In the case of 0.4% fiber mixing ratio, the result was similar to the 0.2% mixing ratio, and the workability slightly increase. In the case of fiber mixing ratio of 0.6%, the Vebe time by decreased slump greatly increased, and the change of workability was even greater.

Figure 2. Vebe time vs. slump

### 4.4 Compressive strength

Table 2 summarizes the result of compressive strength test with the amorphous steel fiber reinforced cement. Generally, the fiber is mostly used to defer the crack by reinforcing the flexural strength and flexural toughness rather than increasing the compressive strength. The analysis of compressive strength test conducted in this study shows much clear increase of compressive strength than less than 10% change in conventional test. In the case of 10 mm fiber length, the compressive strength increased by around 30% by reinforcing with the fiber regardless of mixing ratio. In the case of 20 mm fiber length, the increase was more than 30%. In conclusion, the increase of compressive strength by fiber reinforcement was clear, and the best result was at the fiber lengths of 20 mm.

Table 2. Test results of compressive strength

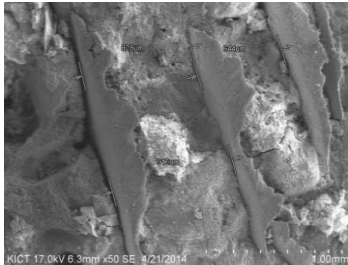

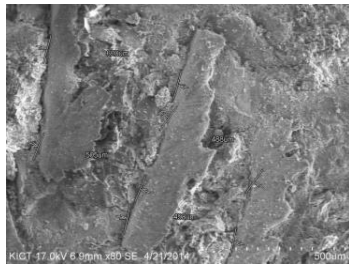

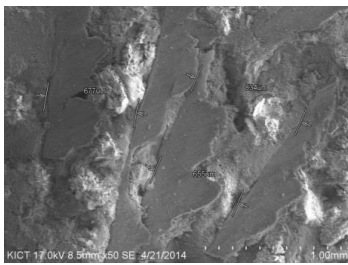

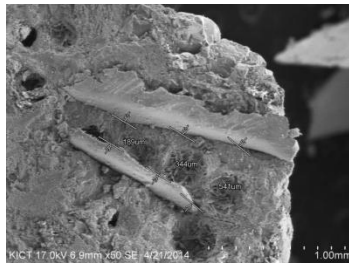

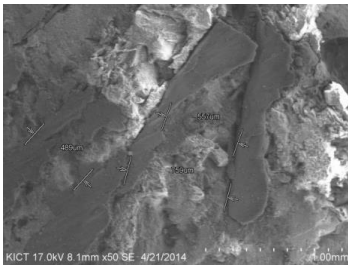

Symbols	Compressive Strength(Mpa)			
	1	2	3	Ave
OPC	34.14	34.05	33.31	33.84
AF-10-0.2	41.05	43.01	42.18	42.08
AF-10-0.4	43.5	41.47	42.26	42.41
AF-10-0.6	42.6	40.78	43.33	42.24
AF-20-0.2	42.12	42.12	42.97	42.4
AF-20-0.4	48.63	45.86	46.89	47.13
AF-20-0.6	43.5	42.95	44.44	43.63

### 4.4 Secondary electron microscope

Table 3 summarizes the SEM observation of micro structure and dispersibility of amorphous steel fibers. In the case of 10 mm fiber length, the spaces between fibers were 816~895  $\mu\text{m}$ (0.2%), 488~628  $\mu\text{m}$ (0.4%), and 189~541  $\mu\text{m}$ (0.6%) indicating that the space between fibers decreased as fiber mixing ratio increased. The fibers were uniformly dispersed with no lumping because of overall stable bonding with cement matrix.

In the case of 20 mm fiber length, the spaces between fibers were 644~912  $\mu\text{m}$ (0.2%), 655~834  $\mu\text{m}$ (0.4%) and 489~759  $\mu\text{m}$ (0.6%) indicating that the space between fibers decreased as fiber mixing ratio increased. Like the case of 10 mm fiber length, the fibers were uniformly dispersed with no lumping because of overall stable bonding with cement matrix. In conclusion, the space between fibers tended to decrease as the fiber length increased and mixing ratio increased. There was not much ununiform dispersion of fibers by fiber lumping regardless of length and mixing ratio.

**Table 3. Microstructure of amorphous steel fibers in concrete matrix**

Fiber content rate	10mm	20mm
0.2%		
0.4%		
0.6%		

## 5. Conclusion

This study compared the result of effective experimental evaluation of flowability and workability of concrete reinforced with amorphous steel fiber, which has benefit of CO<sub>2</sub> reduction and cost saving from simplified manufacturing process, with the fiber length and mixing ratio as the variables. It also conducted the basic research experiment to check if it can be used as the future construction material based on the dynamic characteristics.

- The flowability and workability evaluations through the slump test showed very different result from the Vebe test and inverted slump test.
- Although the Vebe test and inverted slump test showed similar change workability of amorphous steel fiber reinforced concrete to change of fiber length and mixing ratio, the inverted slump test showed clearer change of viscosity to change of mixing ratio.
- Adding the amorphous steel fiber increased the compressive strength by 20~30% in all mixing ratios. The increase of compressive strength was clearer in fiber length of 20 mm.
- Observation of micro structure of fibers using SEM indicated that the space between fibers decreased as the fiber length increased and fiber mixing ratio increased. Generally, the dispersibility of the fibers were excellent, and the bonding structure with cement matrix was stable also.

- e. It is considered that it is more effective to test the flowability and quality with inverted slump test than the conventional slump test to evaluate flowability change from addition of amorphous steel fiber.

**Abstract:** Owing to recent extreme climates, typhoons, floods, and earthquakes have become large natural disaster threats in Taiwan over the years. Such natural disasters have caused damage to some bridges, consequently isolating residential communities located on mountains, and hampering the ability to delivery emergency relief supplies to those communities. In order to provide quick emergency relief, the simple construction of a temporary bridge becomes critical for the transportation of food and medical supplies into the emergency disaster areas. While composite materials for footbridges and vehicular traffic applications have been widely used overseas, they are not suitable for disaster relief applications. The objective of this paper is to present a novel bridge structure for a portable, reusable, and lightweight bridge. This paper focuses on the design concept and experimental verification of a temporary composite bridge for disaster relief. Ultimately, it advocates composite bridges for disaster relief applications.

**Keywords:** composite emergency bridge, cable-stayed composite bridge, lightweight, portable, reusable bridge.

## 1. Introduction

Owing to resented extreme climates, typhoons, floods, and earthquakes have become the large natural disaster threats in Taiwan over the years. For instance, 88 floods were caused by Typhoon Morakot in 2009, causing damage to more than 200 bridges and washing away more than 100 bridges (Fig. 1a). Chi-Chi Earthquake in 1999 also caused damage to more than 150 bridges (Fig. 1b), resulting in isolated mountain communities to which emergency relief supplies could not be easily delivered.

Advanced composite materials have found expanded use in the aerospace, marine, and automobile industries during the past few years due to favorable engineering properties such as high specific strength and stiffness, lower density, high fatigue endurance, and high damping. The advantages of fiber reinforced polymer (FRP) composites make them attractive for use in replacement decks or in new bridge systems, such as (1) bridge decks, including FRP rebar reinforced concrete deck systems, FRP grid and grating reinforced concrete deck systems, deck systems made completely from FRP composites, and hybrid FRP plate reinforced concrete deck systems; (2) FRP composite bridge girders and beams, including glass fiber reinforced polymer (GFRP) composite girders, carbon fiber reinforced polymer (CFRP) composite girders, and hybrid girders; and (3) slab-on-girder bridge systems [1].

(a) Morakot Typhoon

(b) Chi-Chi Earthquake.

**Figure 1. Damage of a bridge and disaster rescue.**

FRP bridge technology has progressed rapidly from laboratory prototypes to actual demonstration projects in this field. It is noteworthy that the world's first pedestrian bridge constructed entirely of FRP composites dates back to 1972, and is a single span (span length of 24 m and a width of 1.8 m) bridge in Tel Aviv, Israel, with a total weight of 2.5 tons of GFRP [2]. The world's first vehicle bridge, Miyun Traffic Bridge, constructed entirely of FRP dates back to 1982, and is a single span (span length of 20.7 m), two-lane (width of 9.2 m) bridge in Beijing, China with GFRP girders made from a hand lay-up process [3]. The bridge was constructed by approximately 20 workers within two weeks assisted only

by a light gin pole and capstan winches. Furthermore, the world's first cable-stayed bridge, the 133 m Aberfeldy Foot-Bridge located in Scotland, is built entirely from composites (GFRP for the super-structure and aramid fiber for the cables) [1].

A movable temporary bridge that is foldable, stretchable, and made with aluminum was designed by using stress base optimization methods [4]. The prototype bridge with a length of 1 m after folding and a maximum length of 5.2 m after extending could bear the weight of three adults. The operating procedure is very simple; only one person is required to complete the assembly of the whole bridge within two minutes. Meanwhile, a new type of scrolling lightweight arched bridge is being researched in the US [5]. The prototype model has a length of 3 m and a width of 0.25 m. The bridge consists of a motor and a cable reel to control the entire retracting, stretching, and recovery. The advantage of a temporary bridge is that only one reel motor is required for the complete assembly of the bridge. A deployable lightweight bridge for transport facility and reduced assembling and erection time used of GFRP pipe and steel adapter for combination of truss bridges, and placed in pre-strength steel cable into GFRP tube to increase the stiffness of the bridge [6]. The current experimental test body is 13 m long, and its advantages over the assembly process without the use of any of the co-bolt assembly steps can be reduced, assembly parts and greatly reduced assembly time.

Nowadays, FRP composites are used mostly in deck systems, footbridges, and vehicle bridges. This paper focuses on the advantages of FRP composites in applications for typhoon, flood, and earthquake disaster rescue in Taiwan. The objective of this paper is to present a novel bridge structure for a portable, reusable, and lightweight bridge. It also focuses on the design concept and experimental verification of a temporary composite bridge for disaster relief and promotes composite bridges for disaster relief applications.

## **2. Concept of a temporary bridge for emergency disaster relief**

### **2.1 Conceptual design of temporary bridge**

In order to design a lightweight bridge that is portable, reusable, and suitable for transportation, the following design requirements are considered: (1) for disaster relief and transportation of goods, the design goals for the temporary bridge are set to a span length of 20 m, a width of 3 m, a live load of 5 tons (for transportation of rescue goods by a truck weighing 3.5 tons), and a deflection-to-span ratio of  $L/400$  (the design goal may be modified by the actual requirement of a disaster region); (2) for satisfying the lightweight requirement, the advantages of composite materials are used for the temporary bridge; and (3) for the short to medium span bridge, a beam-type or truss-type bridge is considered; meanwhile, for the medium to long span bridge, a cable-stayed bridge or suspension bridge is considered.

### **2.2 The major challenges of composite bridges**

The report "FRP bridge – technologies and prospects" [7] showed that the drawbacks of a FRP composite bridge includes (1) the low modulus of materials (compared to steel) and low stiffness of the FRP components which leads to large deflection of the structure, (2) requirement for the joints and connections to be simplified, and (3) the high price of composite materials requiring cost-effective problems to be addressed.

Based on the above literature reviews, the major challenges to be addressed for the design of a FRP temporary composite bridge are as follows: (1) the stiffness of the composite structure system should be improved to meet the deflection-to-span ratio requirement; (2) the effective and simplified joints and connections of the composite structure should be studied; (3) for a lightweight structure that has sufficient strength, acceptable stiffness, and is affordable at a reasonable price, the cost-effectiveness of the composite materials should then determined their use; and (4) a novel bridge structure for the lightweight bridge possessing portable, reusable, and suitable capabilities for manual transportation needs to be innovatively created.

### **2.3 Concept and construction sequences**

The development of a suitable bridge type with the function of quickly to restoring traffic and providing emergency disaster relief is important. This bridge should be constructed within a short time and limited by few manpower and simple tools and should also be portable and reusable.

This study develops a temporary bridge system by using a self-weight balance approach and a cantilever incremental launching method. An asymmetric self-anchored cable-stayed bridge is proposed. The structural segments constructed by heavyweight materials (e.g., steel and concrete) are used as counter-weights at the rescue end and the cross-river segments are constructed by lightweight materials (e.g., composite materials) in order to increase the span to easily reach the isolated island end without any supports or foundations (Fig. 2).

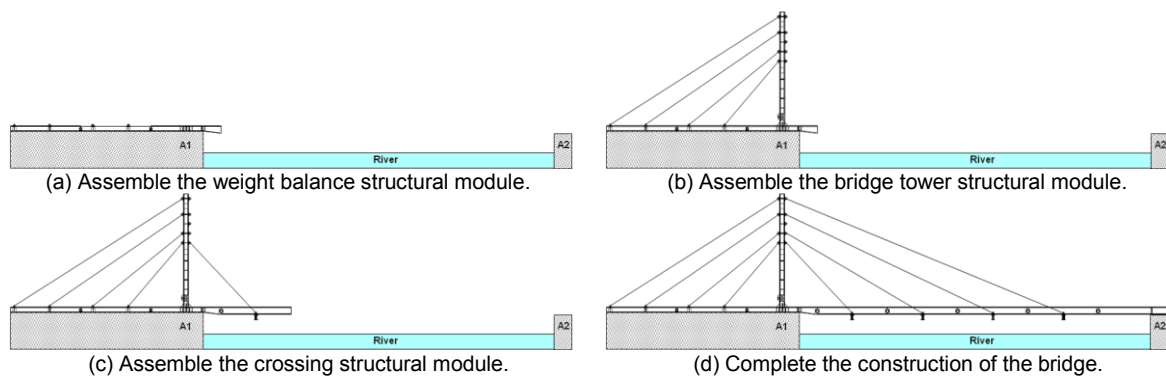

The advantages of this composite bridge include the following: (1) during the construction stage, the asymmetric self-anchored cable-stayed bridge is easily constructed from the rescue end to the isolated island end by using the self-weight balance of heavyweight structural segments and lightweight cross-river segments. The wires of the cable-stayed bridge are helpfully for the construction of cross-river segments by using the cantilever incremental launching method (Fig. 2a); further, (2) during the commissioning completion stage, these wires are effective in reducing the deformation of the bridge caused by live loads from traffic (Fig. 2b).

**Figure 2. Innovation and concept of a composite bridge for emergency disaster relief.**

The lightweight temporary composite bridge system includes a weight balance structural module, a bridge tower structural module, a crossing structural module, and connection cables. The weight balance structural module and the bridge tower structural module are constructed of steel, concrete, and any other heavyweight materials as structural segments. The crossing structural module is constructed of composites and any other lightweight materials. The construction sequences is as follows: (1) assemble the structural segments to complete the weight balance structural module (Fig. 3a); (2) assemble the structural segments to complete the bridge tower structural module, fix the bottom part to the weight balance structural module, and couple the top part to the weight balance structural module via at least one connection cable (Fig. 3b); and (3) assemble the crossing segments between the rescue end and the isolated island end gap (Fig. 3c) to complete the crossing structural module and couple it to the top part of the bridge tower structural module via at least one connection cable (Fig. 3d).

**Figure 3. Construction sequences of composite bridge for emergency disaster relief.**

### 3. Material properties and connection of composite girders

#### 3.1 Material properties of the GFRP girder

The pultruded H-shaped GFRP girders were produced by a local manufacturer in Taiwan. The 410 mm × 20 mm × 200 mm × 18 mm H-shaped composite girders, with a length of 8.0 m, are cut into two parts with lengths of 6.5 m and 1.5 m. The 6.5 m long girder provides moment capacity and bolted connection test for the composite girder as illustrated in the next section. Part of the 1.5 m long girder is cut as specimens for the material property test and as multiple fasteners for the bolted connections test. The experimental results of the material property test for the GFRP girder shows the linear relation of the stress-strain curves for the tensile specimens of the GFRP girder. The elastic moduli

can be obtained from the linear regression of the stress-strain curve, which are 12.73 GPa in the web and 28.30 GPa in the flange of the GFRP girder. Table 1 shows the theoretical and experimental results of the material property test for the GFRP girders. The elastic modulus of the theoretical and experimental results on the web of the composite girder is very similar; however the value shows some difference in the flange of the GFRP girder.

**Table 1. Material properties of the GFRP girder.**

Material type	Position	Elastic modulus E (GPa)	
		Theoretical	Experimental
GFRP	Flange	23.24	28.30
	Web	12.82	12.73

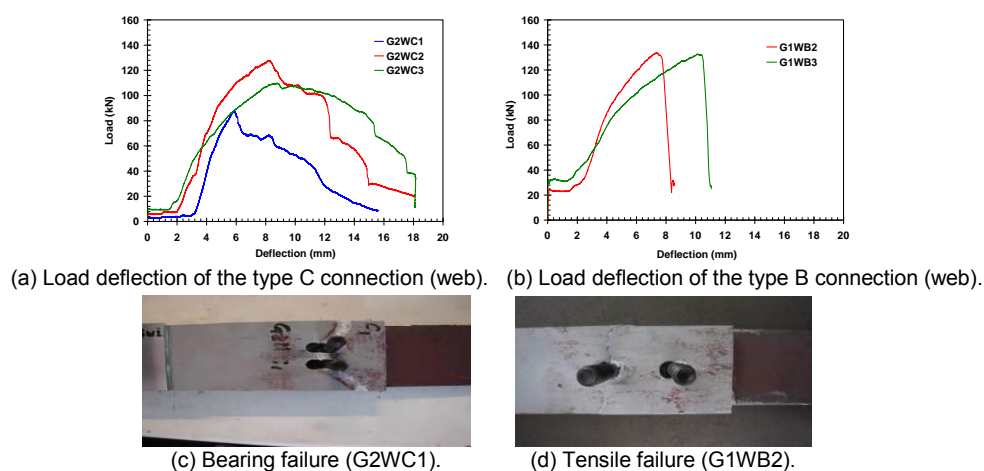

### 3.2 Bolted connection of the GFRP plate

Many researchers have focused on the joints and connections of FRP composite frames [8, 9, 10]. Mechanical connections may be used alone or in combination with other methods of joining composites, either to themselves or to other materials. The literature shows that it is very difficult to achieve a joint resistance in exceed of the FRP materials being jointed with mechanical fastening. This article attempts to employ bolted connections with composite and steel fasteners as the joints of composite frames with H-shaped GFRP girders having cross section of 410 mm × 20 mm × 200 mm × 18 mm and conduct tests for the three types of multiple fastener connections as shown in Fig. 4a. The test setup of bolted connection specimens of composite plates cut from GFRP girders are shown in Fig. 4b.

**Figure 4. Bolted connection test of the GFRP plate.**

The test results are shown in Fig. 5 and Table 2. Fig. 5 shows the typical load deflection curves and failure modes of a bolted connection GFRP plate. There are two types of failure modes that occurred during this test, namely (1) bearing failure mode: the behaviours are ductile and some contact failures are shown in Fig. 5a and 5c; and (2) tensile failure mode: the behaviours are brittle and some cracking failures along the plate are shown in Fig. 5b and 5d. Table 2 shows the test results of multiple fastener bolted connections of composite plates. It is evident that the longitudinal pitch and transverse pitch should be greater than or equal to four times the bolt diameter (4d) for the web and flange of the GFRP girder.

**Figure 5. Load deflection curves and failure modes of the bolted connection GFRP plate.**

**Table 2. Test results of the multiple fastener bolted connection of the composite plate.**

Specimen	Type	Location	Width (mm)	PL (mm)	PT (mm)	Predicted Force (kN)	Test Force (kN)	Force/Per bolt (kN)	Failure Mode*

### 3.3 Bolted connection of the GFRP girder

This article attempts to use bolted connections with composite and steel fasteners as joints of composite frames of a 410 mm × 20 mm × 200 mm × 18 mm H-shaped GFRP girder. Testing for the moment capacity of the composite girder is shown in Fig. 6. The test setups of a four point bending test of a bolted connection of the GFRP girders are shown in Fig. 6a. The test results are shown in Fig. 7 and they indicate that the typical load deflection curves of composite girders and effective modulus can be derived from the slope of the curves; the effective modulus is 20.03 GPa for the girder (Fig. 7a). The failure mode of the GFRP girder is local buckling on its top flange (Fig. 7b). The theoretical and experimental results of effective modulus are compared in Table 3.

**Figure 6. Four point bending test of the benchmark and bolted connection GFRP girder.**

## 4. Design and laboratory testing of a composite bridge

### 4.1 Detail design of a composite bridge

The composite bridge is composed of structural steel and GFRP composite materials. In this paper, steel structural design follows the Taiwan local code of steel building construction [11] and composite structure using the design code proposed by the U.S. Department of Agriculture (USDA) Forest Service [12] and the American Association of State Highway and Transportation Officials (AASHTO) [13]. The following equations are used for the design of the steel components in the temporary composite bridge system:

$$\frac{f_a}{0.6F_a} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0 \quad (1)$$

$$\frac{f_a}{F_a} + \frac{C_{mx}f_{bx}}{\left(1 - \frac{f_a}{F'_e}\right)F_{bx}} + \frac{C_{my}f_{by}}{\left(1 - \frac{f_a}{F'_e}\right)F_{by}} \leq 1.0 \quad (2)$$

$$\frac{f_v}{F_v} \leq 1.0 \quad (3)$$

In these equations, the expressions  $f_a$  and  $f_b$  represent the actual axial and bending stress, respectively;  $F_a$  and  $F_b$  denote the allowable axial and bending stress, respectively;  $C_m$  corresponds to a modification factor;  $F'_e$  represents Euler's critical buckling stress;  $f_v$  denotes the actual shear stress; and  $F_v$  represents the allowable shear stress.

Parallel FRP girder bridge systems are studied to meet the design requirements of a span of 10 m, a width of 3 m, a live load of 5 tons (for transportation of rescue goods via a truck weighing 3.5 tons), and a deflection-to-span ratio of  $L/400$ , which is suggested by AASHTO [13]. The 410 mm × 20 mm × 200 mm × 18 mm H-shaped composite girders are used in the bridge system. The material properties of GFRP are as follows: Young's modulus = 20.03 GPa; density = 1.72 g/cm<sup>3</sup>; and allowable stress = 207 MPa. The detailed design results are shown in Fig. 8. Fig. 8a shows the detailed design drawing and Fig. 8b shows the details of the bolted connection by using bolts and steel connection plates. The numerical results for the number of parallel girders and deflection-to-span ratios are shown in Table 4. The results indicate that a five parallel GFRP girder bridge system could meet the requirement of a deflection-to-span ratio of  $L/400$  under a live of 5 tons.

Figure 8. Design results of the GFRP composite bridge.

Table 4. Numerical results of the GFRP composite bridge.

Material	$E_{eff}$ (GPa)	No. of girders	Deflection (cm)	$L/400$ (cm)	No. of bolts
GFRP	20.03	5	2.508	2.500	240

#### 4.2 Flexural test of the GFRP composite bridge

The experimental setup of the GFRP composite bridge is shown in Fig. 9a and the loading position in order to simulate a small truck weighing 3.5 tons is shown in Fig. 9b. The test program includes a flexural test, a fatigue test, and a strength test. The results of the flexural test are shown in Fig. 10. Fig. 10a shows the linear relation of the load deflection curve. The deformed shapes are shown in Fig. 10b. The maximum displacements are 26.58 mm ( $P = 50$  kN) and 52.94 mm ( $P = 100$  kN), which occurred at the middle span of the B4 girder. The maximum longitudinal strains are  $5.681 \times 10^{-4}$  ( $P = 50$  kN) and  $1.162 \times 10^{-3}$  ( $P = 100$  kN), which occurred at the bottom flange of the B2 girder (Fig. 10c). The flexural test results indicate that the deflection-to-span ratio is approximately  $L/376$ , which is very close to the design requirement of  $L/400$ , under a live load of 5 tons.

Figure 9. The experimental setup of the GFRP composite bridge.

(a) Applied load versus vertical displacement. (b) Deformed shape (100 kN). (c) Longitudinal strain along the depth of B2 girder.

**Figure 10. Flexural test results of the GFRP composite bridge.**

### 4.3 Fatigue test of the GFRP composite bridge

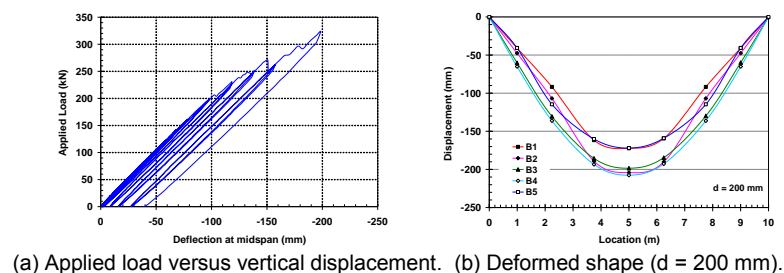

The test setup for the fatigue test of the GFRP composite bridge is identical to that of the previous section and is shown in Fig. 9. The frequency of fatigue loading is 1 Hz and a total of  $2 \times 10^5$  cycles of loading with amplitude for a target design loading of 50 kN are applied to the specimen. Additionally, the specimen is subjected to a static flexural loading after every  $1 \times 10^4$  cycles to examine the stiffness degradation. The test results are shown in Fig. 11. Fig. 11a shows the linear relation of the load deflection curve after every  $1 \times 10^4$  cycles. The stiffness degradation curve is shown in Fig. 11b. The stiffness ratio is defined as the ratio of the stiffness measured after every  $1 \times 10^4$  cycles of loading to the stiffness measured in the first flexural test. The test results show that there is no stiffness degradation over  $2 \times 10^5$  cycles of loading with amplitude for a target design loading of 50 kN.

**Figure 11. Fatigue test results of the GFRP composite bridge.**

### 4.4 Strength test of the GFRP composite bridge

The test setup for the strength test of the GFRP composite bridge is identical to that of previous section and is shown in Fig. 9. The specimen is tested in flexure to failure to examine its residual strength and failure mode. The test protocol includes the displacements, which ranged from 1 cm to 8 cm. Three cycles were applied for each displacement level; two cycles were applied when the displacement amplitude ranged from 10 cm to 16 cm, while only one cycle were applied when the amplitude was 20 cm. The test results are shown in Fig. 12. Fig. 12a shows the load deflection curve at the middle span of the B3 girder; when the displacement is less than 10 cm, the loading and unloading curves are very much linear and elastic, and when the displacement is equal to 20 cm, the maximum load is around 324 kN. The deformed shapes are shown in Fig. 12b. The maximum displacements of 207.56 mm, 204.21 mm, and 198.49 mm occurred at the middle span of the B4, B2, and B3 girder, respectively. The maximum longitudinal strains of  $3.743 \times 10^{-3}$  occurred at the bottom flange of the B2 girder (Fig. 12c). The failure of the specimen was due to the slippage at the connection, but not the GFRP girder itself (Fig. 12d). The strength test results indicate that the design of the proposed composite bridge is deflection-driven, instead of being strength-driven. It also shows that the proposed design has strength higher than is required for a safety factor of more than 4.

(a) Applied load versus vertical displacement. (b) Deformed shape (d = 200 mm).

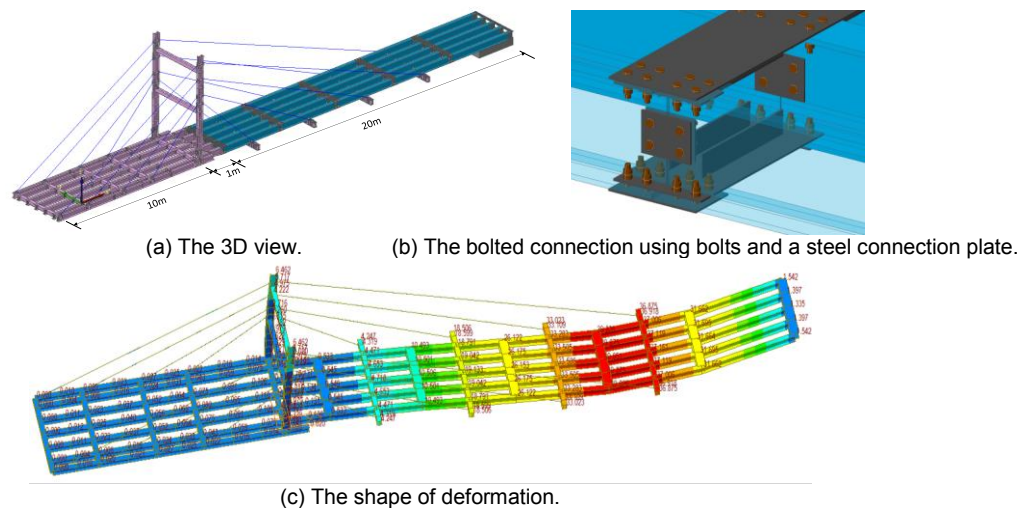

(c) Longitudinal strain along the depth of the B2 girder. (d) Failure mode of the girder.

**Figure 12. Strength test results of the GFRP composite bridge.**

## 5. Experimental verification of the composite bridge for emergency disaster relief

### 5.1 Scenario and design thinking

In order to confirm the construction and usability of the lightweight temporary bridge for disaster relief, a potential scenario for testing is required, and is as follows: a bridge with a span of 20 m was damaged in a disaster area, and thus, a temporary bridge for the transportation and delivery of relief supplies is needed. The concept of weight balance and the incremental launching method proposed in Section 2.3 are considered in the novel emergency bridge design. The design codes and material properties are identical to Section 4.1. We have designed a steel-composite cable-stayed bridge with a span of 20 m, a width of 3 m, and a live load of 5 tons (for transportation of rescue goods via a truck weighing 3.5 tons) and a deflection-to-span ratio of  $L/400$  for the assembled and river-crossing test. Fig. 13 shows the design results of the asymmetric self-anchored cable-stayed bridge. Seven parallel steel girders and H-shape pillars using A572 grade 50 steel with a 294 mm × 200 mm × 8 mm × 12 mm cross section on the A1 side abutment are used as the weight balance structural module, five parallel FRP girders using GFRP with a 410 mm × 200 mm × 18 mm × 20 mm cross section are used as crossing structural module, and double-H-shape steel cross beams are used to aid the crossing of the river (Fig. 13a). We used a steel frame on the A1 side abutment as a counterweight and a cable-stayed type bridge to quickly assemble the lightweight GFRP temporary bridge via the incremental launching method to cross the river and therefore achieve the goal of providing disaster relief. By using the same capacity for connection design (details of the connection are shown in Fig. 13b), the numerical result shows that connection between the steel girder and the GFRP girder is not the critical connection; instead, the critical connection is located at connection G4 between GFRP segment C and GFRP segment D (Fig. 13c).

**Figure 13. Design results of the 20 m span temporary composite bridge.**

### 5.2 Construction sequences and river-crossing tests

The construction sequence is shown in Fig. 14 and is as follows: (1) step 1: assembly of seven parallel steel girders with 294 mm × 200 mm × 8 mm × 12 mm cross sections and a total length of 12 m (3@4m), and a bolted connection at the web of the girder with box cross beams (200 mm × 200 mm × 6 mm) (Fig. 14a and 14b); (2) step 2: assembly of H-shape pillars with 18 connection devices for the steel cable, with 294 mm × 200 mm × 8 mm × 12 mm cross sections and a total height of 6.5 m (Fig.

14c), and a bolted connection with the top flange of the outer girders of the seven parallel steel girders at the third segment (Fig. 14d); (3) step 3: assembly of the first segment of the five parallel GFRP girders (Fig. 14e) and then connection to the third segment of the weight balance structural module (Fig. 14f); (4) step 4: assembly of the second segment of the five parallel GFRP girders by using the same sequence as the previous step (Fig. 14g) and then connection to the first segment of the crossing structural module (Fig. 14h); and (5) step 5: assembly of the third to final segment of the five parallel GFRP girders by using the same procedure as the previous step (Fig. 14i) and completion of the construction sequence to cross the river (Fig. 14j). The test results show that the 20 m span temporary composite bridge for emergency disaster relief was constructed by 30 workers within 6 hours via manpower, simple tools, and a small truck with a crane – ultimately meeting the requirements for emergency disaster relief.

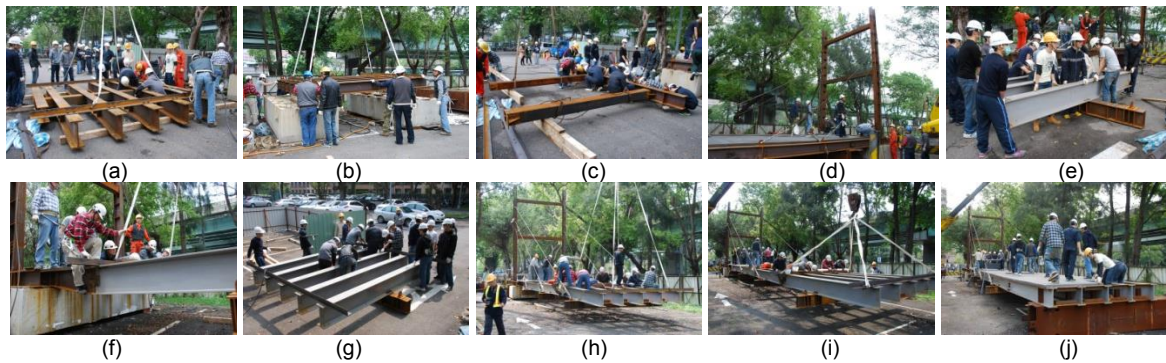

Figure 14. Construction sequence of the 20 m span temporary composite bridge.

### 5.3 In situ full scale flexural and dynamic tests

The experimental setup of a temporary composite bridge with a span of 20 m is shown in Fig. 15a and the different loading positions of a small truck weighing 3.5 tons (total weight 5 tons) is shown in Fig. 15b. The test program includes a flexural test, an off-axis flexural test, and a dynamic test. The results of the flexural and dynamic tests are shown in Fig. 16. The deformed shapes are shown in Fig. 16a. The maximum displacements are 53.41 mm (flexural test) and 56.23 mm (off-axis flexural test) and occurred at connection G4. The maximum longitudinal strains are  $5.05 \times 10^{-4}$  (flexural test) and  $-5.53 \times 10^{-4}$  (off-axis flexural test) and occurred on B3 at the left hand side of connection G4 (Fig. 16b). The deflection versus time at connection G4 is shown in Fig. 16c. The flexural and dynamic test results indicate that the deflection-to-span ratio is around  $L/356$ , which is very close to the design requirement of  $L/400$ , for a live load of 5 tons.

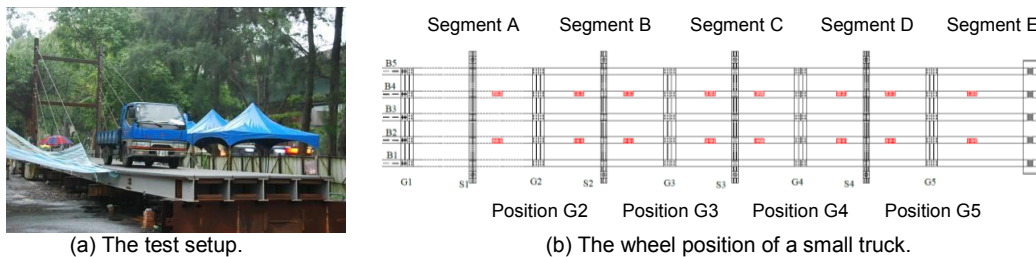

Figure 15. The experimental setup of the 20 m span temporary composite bridge.

Figure 16. Flexural and dynamic test results of the 20 m span temporary composite bridge.

## 6. Concluding remarks

This paper developed a lightweight, portable, and reusable temporary composite bridge for emergency disaster relief. This bridge is an asymmetric self-anchored cable-stayed bridge designed using steel-FRP composite materials to improve the stiffness of the composite frame, reduce the deflection of the bridge, and allow easy travel across a river without any supports or foundations. All of these achievements ultimately reach the goal of disaster relief through the use of the concept of weight balance and the incremental launching method. The current research results are summarized as follows: (1) for bolted connections of the GFRP girder, the longitudinal pitch and transverse pitch should be greater than or equal to four times the bolt diameter ( $4d$ ) for the web and the flange of the girder; (2) for the flexural test of the GFRP bridge with a span of 10 m, the deflection-to-span ratio is around  $L/376$ , which is very close to the design requirement of  $L/400$ , under a live load of 5 tons; (3) for the fatigue test of the GFRP bridge with a span of 10 m, there is no stiffness degradation over  $2 \times 10^5$  cycles of loading with amplitude of target design loading 50 kN; (4) for the strength test the GFRP bridge with a span of 10 m, the design of the proposed composite bridge is deflection-driven, instead of being strength-driven, and the strength is higher than is required for a safety factor more than 4; (5) for the in situ test of a 20 m temporary composite bridge for emergency disaster relief, the novel bridge was constructed by 30 workers within 6 hours through the use of manpower, simple tools, and a small truck with a crane to meet the requirements of emergency disaster relief. The flexural and dynamic test results indicate that the deflection-to-span ratio is around  $L/356$ , which is very close to the design requirement of  $L/400$ , for a live load of 5 tons.

**Abstract:** The concrete slab ballastless track is an advanced track structure with high stability and integrity. However, when the foundation of ballastless track appears large differential sunken deformation, compared with ballast track which can be restored by increasing the ballast under the sleepers simply, the smoothness of concrete slab ballastless track can only be restored by adjusting the thickness of the base plates of fastener system accordingly. But if continuous sunken deformation exceeds specified adjustable range of fastener system, the smoothness of concrete slab ballastless track cannot be restored timely and completely, and then the speed of passing trains has to be limited to ensure the safety. To solve this problem without disturbing the regular operation of the railway lines, we systematically studied a complete set of new quick uplift rehabilitation technology through a series of indoor reduced scale tests and field full scale simulations with real concrete slabs and combined with practical application. Results indicated this technology can restore the smoothness of sunken concrete slab ballastless track quickly and accurately. These will provide valuable references for the rehabilitation of sunken concrete slab ballastless structure.

**Keywords:** grouting, uplift, concrete structure, ballastless track, rehabilitation.

## 1. Introduction

Nowadays, the slab ballastless track with excellent performance, such as low maintenance requirement, a long service life and reduced structure height, etc., is regarded as an advanced track structure [1-2]. In China, it has been widely used in many high-speed railways such as the Shanghai-Hangzhou intercity railway, Beijing-Wuhan high-speed railway and Hangzhou-Changsha high-speed railway and so on. There are currently more than 10,000 kilometres of the slab ballastless track railway, both in operation and in construction. The slab ballastless track commonly includes the rail, fastener, concrete track slab, cement emulsified asphalt mortar layer, and concrete bottom slab [3]. However, when the foundation of ballastless track appears large differential sunken deformation, compared with the ballast track which can be restored by increasing the ballast under the sleepers simply, the track height of the ballastless track can only be restored by adjusting the thickness of the base plates within the range allowed by the fasteners. This has greatly limited the regularity adjustment and restorability of the concrete slab ballastless track. The uncontrollable post-construction foundation settlement of few sections of the high speed railway roadbed is caused by various complex geological conditions. And if continuous sunken deformation exceeds specified adjustable range of fasteners, the smoothness of the slab ballastless track cannot be restored timely and completely, and then the speed of passing trains has to be limited to ensure the safety. This is a big challenge for the high-speed railway operation. These limits seriously affect the operation of high speed railways in some differential sunken concrete structure sections of ballastless track line.

To solve this problem without disturbing the regular operation of the railway lines, we systematically studied a complete set of new quick uplift rehabilitation technology through a series of indoor reduced scale tests and field full scale simulations with real concrete slabs and combined with practical application. We have created a new set of technology and engineering practice to uplift the concrete structure of ballastless track successfully, with no negative effect on existing railway operation. The track smoothness can be restored quickly and accurately. This new technology has been applied successfully to the settlement rehabilitation for the ballastless track line of Daxi Yongji North Station.

This article introduces this new grouting uplifting technology for concrete structure of ballastless track from its uplifting theory, grouting materials, construction process and practical application, in the hope of providing valuable reference for rehabilitation of the differential sunken ballastless track concrete structure of high-speed railway all over the world.

## 2. Uplifting theory

The grouting materials is injected in the ground at discrete locations under the concrete bottom slab to correct differential settlement and to apply compactive forces to the foundation layer. The two components of the foam, which mix as they are injected through a grouting pipe. The expansion pressure it exerts is used to lift the ballastless track structure, remediating a differential settlement problem without excavation. During the overall grouting uplifting of ballastless track concrete structure, the grouting materials is filled into the surface layer of graded broken stone foundation bed through the special grouting equipment, under a certain grouting pressure. The uplifting is realized by the expansibility of the grouting materials and the hydraulic transmission effect resulting from the liquid grouting materials and grouting pressure. The uplifting can be divided into two stages, namely the filling & compacting stage and the uplifting & filling stage.

In the filling & compacting stage, the grouting materials will fill and compact the gaps such as the ones between the supporting layer and graded broken stone layer or those inside the graded broken stone layer. And the track structure will not be uplifted at this stage.

In the uplifting & filling stage, the filled grouting materials and the grouting pressure from grouting equipment will cause hydraulic transmission effect. Meanwhile, the volume expansion from the grouting material solidification will cause expansive upliftiing forces. With the effects of these two factors, the concrete structure can be uplifted continuously and stably, and the gaps between concrete structure and graded broken stone layer due to uplifting can also be filled completely and densely.

## 3. Grouting Material

The grouting material applied is a kind of two component chemical grouting materials [4-5]. After mixing, the material will gel and react to form hardeded concretion within a short time (see Figure 1). This Gel is able to form different volumes and expand as needed. Compared with other grouting materials, the grouting materials have the following features:

Figure 1. Hardened concretion of the grouting materials.

### (1) High adaptability for the construction environment

The grouting material is non-water reactive. The grouting material will cure in both air and water if the ambient temperature is above 5°C.

### (2) High ability of permeation, diffusion and filling

With a certain grouting process, the diffusion diameter can reach up to more than 5 meters and it has a certain volume expansion too (the free expansion ratio can reach up to 20:1 ). The filling ability is outstanding, meanwhile, it can compact the substructure of the filling range to form the sandwich structure (see Figure 2).

**Figure 2. Sandwich structure of grouting material foam layer and graded broken stone layer.**

(3) Filling range controllable

After the mixture of grouting materials, the liquid state will transform into plastic state and then the solid state within a short time. Thus, the filling range is easy to adjust by controlling the reaction speed of two component grouting materials, with no need to set special curtains to prevent the slurry from overflow.

(4) Low density and weight

The structure density formed by this grouting material is around  $100 \text{ kg/m}^3 \sim 300 \text{ kg/m}^3$ , far less than the water density. So compared with cement grouting materials, it does not increase the additional structural load significantly.

(5) Fast in setting and hardening, fast in strength development

The grouting material can reach up to more than 90% of the design strength just within 15 minutes, which can completely meet the strength requirements for railway line operation. As a result, the traffic can be resumed in time after the uplifting of concrete structure.

(6) High volume stability

It almost has no volume shrinkage after the hardened structure formed and will have the feature of a perfect elastomer before 80% of the failure load.

(7) High durability

The hardened grouting materials possess a high durability property with high water proof, frost resistance and chemical erosion resistance.

#### **4. Practical application**

Located at Yuncheng, Shanxi Province, Daxi Yongji North Station, its railway line was designed to be 4 lines of track (see Figure 3). Due to the differential settlement of the roadbed, the concrete structures of slab ballastless track sunken obviously. Therefore, four tracks had serious problems with the smoothness within a range of 80 meters. The maximum settlement of some sections even exceeded 50 millimeters. The railway speed in this sunken section of this line had to be limit to 160 km/h.

In March, 2014, the settlement ballastless track of Yongji North Station was rehabilitated by this overall grouting uplifting technology (see Figure 4). During rehabilitation, when the grouting equipment operated smoothly and the materials reached a stable performance, the grouting uplifting rehabilitation was carried out according to the specified grouting procedure. The electronic level was adopted to monitor the rail elevation change and the total station was adopted to monitor the center line misalignment of concrete structure. When the uplifting height reached the expected height, stop grouting and the high-strength non-shrinking cement material was used to block up the injection holes. It only took 20 days to fulfill this repair work of this sunken section. The concrete structure had no cracking due to uplifting construction.

After rehabilitation, the smoothness of four tracks was improved significantly (see Figure 5 for the track elevation comparison before and after the grouting uplifting rehabilitation). The maximum uplifting height of the concrete structure was up to 52 millimeters (No cracking). The railway speed in this

section had recovered to the design speed of 250 km/h and the dynamic response of the ballastless track in this section showed normally.

Figure 3. North Station of Daxi High-Speed Railway.

Figure 4. Grouting quick uplifting rehabilitation construction of Yongji North Station on site.

Figure 5. Comparison of the elevation of four tracks before and after uplifting rehabilitation.

## 5. Conclusion

The overall grouting uplifting rehabilitation technology for ballastless track has the advantages of rapid restoration, good effect, simple construction, no disturbing railway line operation and little destruction to the existing concrete structure. It is also a rapid, simple and practical method to rehabilitate the ballastless track of the settlement section in a manner that can neither affect the track structure stress adversely nor affect the traffic safety, which is promising in the settlement rehabilitation of the ballastless track in operation. The properties of this two component grouting materials and the resulting solid foam are very versatile and with stringent quality control, this uplift rehabilitation technology can be more effectively and successfully applied to many other construction projects.

# Investigation of Strain and Energy Ductility in SFRP-Wrapped Concrete Cylinders

Nisreen Salameh<sup>1</sup>, Raafat El-Hacha<sup>2</sup>, and Khaled Abdelrahman<sup>3</sup>

<sup>1</sup>MSc student, University of Calgary

<sup>2</sup>Associate Professor, University of Calgary

<sup>3</sup>PhD Candidate, University of Calgary

**Abstract:** Ductility plays a significant role in evaluating the suitability and the degree of reliability of Fiber Reinforced Polymer (FRP) material used in retrofitting applications especially in earthquake prone zones. Ductility enhancement for concrete columns wrapped by Carbon FRP (CFRP), Glass FRP (GFRP) and Aramid FRP (AFRP) sheets has been extensively investigated and many literatures can be found on the subject, however literature on strengthening applications of concrete columns using Steel FRP (SFRP) is rather limited and few has examined the effect of the concrete compressive strength and the number of SFRP layers on ductility. To that end, an experimental program has been conducted on plain concrete cylinders (150 mm x 300 mm), which consists of eighteen SFRP-wrapped cylinders, and six unwrapped control cylinders for comparison purposes. The parameters investigated are the concrete compressive strength and the thickness of the SFRP jacket. The two main ductility indices investigated in the current study are; the energy ductility index, which represents the ratio of the total energy absorption at failure of the SFRP-confined concrete over the total energy absorption of the unconfined concrete, and the strain ductility index, which represents the ratio of the SFRP-confined concrete ultimate strain to the axial strain corresponding to the unconfined peak concrete strength. Results showed significant enhancement in ductility of the SFRP-wrapped cylinders as compared to the unconfined cylinders. It is further observed that strain ductility index and energy ductility index were higher for higher concrete strength and thicker SFRP jacket.

**Keywords:** Fibre Reinforced Polymer, ductility, energy, ductility index, lateral stiffness, lateral confinement ratio.

## 1. Introduction and background

The concept of ductility in structural engineering commonly refers to the ability of a structural element to undergo large inelastic deformation, and hence implies the ability to dissipate inelastic energy, without excessive loss in the structural element load carrying capacity [1]. It is required by code and design guidelines, specifically in seismic prone areas, to design and detail structural concrete members to achieve certain degree of ductility. In concrete compression members, ductile behavior is assured by provision of sufficient transverse reinforcement, which can be internal in the form of stirrups or spiral reinforcement [2] or external in the form of externally bonded fiber reinforced polymer (FRP) jacket [3-16].

Mashrik and El-Hacha [3, 4] performed extensive experimental testing on small-scale plain concrete cylinders wrapped by SFRP jacket, where the effects of various concrete strengths, SFRP jacket thicknesses and section shapes (circular and square) were investigated. Their findings indicate substantial overall performance enhancement in terms of axial strength and ductility. Although their study included the effect of the concrete strength and jacket thickness on ductility, the study was limited to the energy ductility enhancement while the strain ductility enhancement was not investigated. Abdelrahman and El-Hacha [5] investigated the effect of slenderness ratio (defined by the ratio of the height to the diameter to the cylinder) on the ductility of SFRP-wrapped concrete cylinders. The slenderness ratios investigated were 2, 4 and 6. They reported a reduction in the wrapped cylinders ductility as the slenderness ratio increased. Abdelrahman and El-Hacha [6] further compared the ductility performance of large-scale reinforced concrete columns wrapped by SFRP sheets exposed to room temperature and environmental freeze-thaw cycles. The findings from this investigation showed no change in ductility performance of the SFRP confined concrete after freeze-thaw exposure, when compared to the unconditioned columns. It is clear that literature regarding the SFRP-wrapped cylinders ductility is limited and the subject has not been adequately addressed. In this paper, the ductility aspect of SFRP confined concrete is quantified and the effect of several parameters on ductility enhancement is investigated.

Ductility has been traditionally measured in terms of various indices, a common ductility index is known as the strain ductility index,  $\mu_{cc}$ , and is defined as the ratio of the FRP-confined concrete ultimate strain to the

axial strain corresponding to the unconfined concrete strength at peak, as shown in Figure 1 (a). Strain ductility index is calculated as per the following equation:

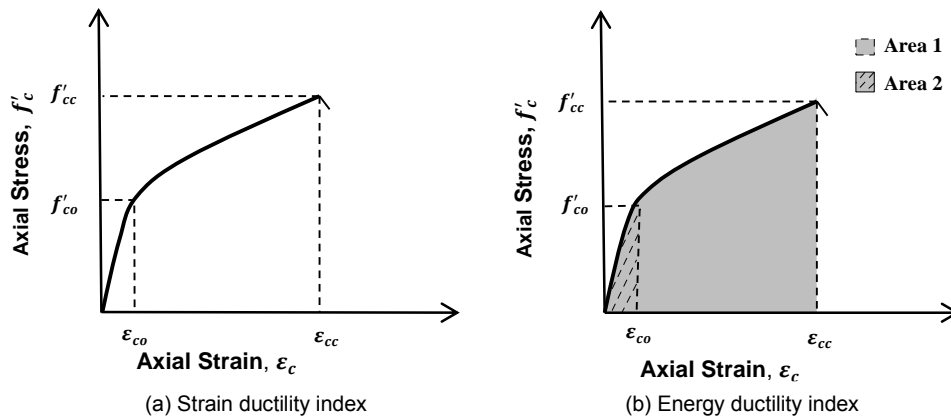

$$\mu_{cc} = \frac{\varepsilon_{cc}}{\varepsilon_{co}}$$

where,  $\varepsilon_{cc}$  is the axial strain corresponding to the rupture of the FRP jacket and  $\varepsilon_{co}$  is the axial strain corresponding to the unconfined concrete strength at peak.

The ductility of FRP confined concrete can be also expressed through an energy ductility index,  $\omega_{cc}$ . The energy ductility index is defined as the ratio of the total area under the stress-strain curve up to the failure of FRP jacket  $f'_{cc}$  (*Area 1*) over the area of the unconfined state up to  $f'_{co}$  (*Area 2*) as shown in Figure 1 (b). Energy ductility index is calculated as per the following equation:

$$\omega_{cc} = \frac{\text{Area 1}}{\text{Area 2}}$$

Figure 1 shows the definition of the different parameters of the ductility indices for a bilinear stress-strain response of the SFRP confined concrete.

**Figure 1. Ductility indices parameters.**

## 2. Experimental Program

### 2.1 Test matrix

A total of twenty-four small-scale unreinforced concrete cylinders measuring 150 mm in diameter and 300 mm in height were fabricated and tested under monotonic uniaxial compression load. The test matrix, as summarized in Table 1 includes eighteen SFRP-wrapped cylinders and six control unwrapped cylinders. The main experimental parameters investigated in this study include the thickness of the SFRP jacket (1, 2 and 3 layers), and the unconfined concrete strength (37.3 MPa and 42.4 MPa). For each combination of testing parameters, three identical specimens were fabricated and tested for repeatability purposes.

The SFRP sheets were applied over the full height of the cylinder in a wet layup process, however, due to the non-flexible nature of SFRP sheets and the tendency of the sheets to open out and detach from the concrete substrate, a day prior to SFRP fabric installation; one edge of the SFRP sheet were attached to the concrete substrate over 20mm of epoxy strip. In addition, the newly SFRP-wrapped cylinders were further wrapped by a flexible plastic sheet and clamped to ensure a complete contact between the concrete surface and the SFRP sheets. The cylinders were left for one day to cure at room temperature before clamps and plastic wrap were removed. In order to avoid premature failure at the overlap zone, sufficient overlap length of 100 mm was provided in all cases.

**Table 1. Test matrix and cylinders details**

Confinement Designation	Number of cylinders tested	Cylinder geometry			Concrete strength $f'_{co}$ (MPa)	FRP Strengthening Scheme			
		X-section	Diameter D (mm)	Height H (mm)		Type	No. of layers	Thickness (mm)	
C37.3-UW	3	Circular	150	300	37.3	-			
C37.3-SFRP1	3					SFRP	1	1.2	
C37.3-SFRP2	3						2	2.4	
C37.3-SFRP3	3						3	3.6	
C42.4-UW	3					42.4	-		
C42.4-SFRP1	3						SFRP	1	1.2
C42.4-SFRP2	3				2			2.4	
C42.4-SFRP3	3				3			3.6	

The designation system adopted in this paper for tested cylinders takes the following general form: C(F)-FBR(N)-SP#(M) where C refers to cylinder; F refers to concrete 28-day compressive strength; FBR refers to fiber type; N refers to number of layers; SP refers to specimen number representation; and M refers to specimen number ( $1 \leq M \leq 3$ ). It should be noted that when N=0, that is, when the cylinder is unwrapped, the notation FBR(N) will be simply replaced by UW notation (unwrapped). It should also be noted that when it is referred to the group of FRP configuration rather than a particular cylinder, the notation SP(M) will be discarded.

## 2.2 Material properties

### 2.2.1. Concrete

Two different concrete mixtures were used in this experimental program; one mixture was prepared at the laboratory of the University of Calgary, the second mixture was provided by a concrete supplier. The average compressive strength of the unconfined concrete was 37.3 MPa ( $\pm 0.7$  MPa) and 42.4 MPa ( $\pm 1.4$  MPa) for the two mixtures, respectively.

### 2.2.2. SFRP jacket

Commercially available steel/epoxy SFRP strengthening system was used to provide the external confinement. The SFRP sheet used in this research was of type 3×2-20-12 made from unidirectional brass coated ultra-high strength twisted steel wires [17]. The 3×2 indicates the number of filament wires per cord. Each individual SFRP cord consists of three straight wires wrapped by two wires at a high twist angle. The third digit indicates density, 20 wires per inch. The final digit indicates the width of the sheet in inch. The mechanical properties of the SFRP sheet reported by the manufacturer are summarized in Table 2. To verify the manufacturer's properties, direct tension tests were also performed according to ASTM [18] on three SFRP coupons and the reported material properties along with their respective standard deviations for the ultimate tensile strength, modulus of elasticity, and strain at failure were 878 MPa ( $\pm 50$  MPa), 68800 MPa ( $\pm 1400$  MPa) and 1.38 % ( $\pm 0.077\%$ ), respectively.

**Table 2. FRP system mechanical properties [17]**

Properties	SFRP 3x2-20-12
Sheet thickness (mm)	1.23
Net cross-sectional area of	0.38mm <sup>2</sup> /mm
Ultimate tensile stress (MPa)	986
Effective modulus (GPa)	66.1
Tensile elongation (%)	1.5

The mechanical properties of the Sikadure® 330 epoxy adhesive reported by the manufacturer for the tensile strength, elastic modulus and elongation at failure are 30MPa, 3.8GPa and 1.5%, respectively [19].

### 3. Test Results

Typical stress-strain curves for tested cylinders from each confinement configuration are shown in Figure 2 (a) and Figure 2 (b) for C37.3 and C42.4 concrete, respectively. Stress-strain curves for corresponding unconfined concrete are also shown for comparison. The substantial increase in the ultimate axial strain due to the SFRP confinement when compared to the unconfined cylinders is apparent in all cases.

Figure 2. Typical stress-strain curves for SFRP-confined cylinders

The strain ductility indices and energy ductility indices for the SFRP-wrapped cylinders are summarized in Table 3. The axial stress data used for calculating the ductility indices were obtained by dividing the load results over the cylinder cross sectional area, the axial strain data used for calculating the ductility indices were obtained from the measurement of conventional 120 Ω foil strain gauge installed at the mid height of the cylinder directly opposite to the SFRP overlap end edge.

Table 3. Ductility indices for SFRP-wrapped cylinders

Cylinder Designation	Strain ductility index		Energy ductility index	
	$\mu_{cc}$	average	$\omega_{cc}$	average
C37.3-SFRP1-SP#1	18	16	35	33
C37.3-SFRP1-SP#2	15		31	
C37.3-SFRP1-SP#3	16		33	
C37.3-SFRP2-SP#1	24	22	69	67
C37.3-SFRP2-SP#2	21		63	
C37.3-SFRP2-SP#3	22		68	
C37.3-SFRP3-SP#1	23	28	89	108
C37.3-SFRP3-SP#2	32		132

C42.4-SFRP3-SP#2	24		121	
C42.4-SFRP3-SP#3	31		167	

## 4. Discussion

### 4.1 Effect of SFRP jacket thickness

The thickness of SFRP jacket, i.e. the number of SFRP layers, plays a significant role in improving the concrete behavior in terms of ductility as indicated by the ductility indices summarized in Table 3 and shown in Figure 3 (a) and Figure 3 (b). This is expected as increasing the thickness of the SFRP jacket directly increases the jacket lateral stiffness and hence increases the effectiveness of SFRP jacket in restraining concrete core lateral expansion. The test results showed that, for cylinders with concrete strength of 37.3 MPa, the strain ductility index was increased by 36% and 70% when the SFRP jacket thickness doubled and tripled, respectively, while, for cylinders with concrete strength of 42.4 MPa, the strain ductility index was increased by 23% and 75% when the SFRP jacket thickness doubled and tripled, respectively.

For cylinders within similar concrete compressive groups, the energy ductility index improved significantly due to the increase of the SFRP jacket thickness. Comparison of the test data shows that SFRP-wrapped cylinders of unconfined concrete strength of 37.3 MPa wrapped with one, two and three layers of SFRP sheets exhibited higher ductility indices by 33, 67 and 108, respectively, when compared to their corresponding unconfined concrete cylinders. This also means that the energy ductility index was increased by 103% and 229% when SFRP jacket thickness has been doubled and tripled, respectively. Similarly, the ductility indices of SFRP wrapped concrete cylinders of unconfined concrete strength of 42.4 MPa and wrapped with one, two and three layers of SFRP sheet was higher by 41, 78 and 139, respectively, when compared to their corresponding control specimens. This also implies that the energy ductility index was increased by 91% and 242% when SFRP jacket thickness has been doubled and tripled, respectively.

Figure 3. Effect of jacket thickness on ductility indices

### 4.2 Effect of concrete compressive strength

The effect of the unconfined compressive strength on ductility indices is graphically presented in Figure 4. It can be clearly seen that for the same SFRP confinement configuration, an increase in the unconfined concrete compressive strength,  $f'_{co}$ , results in a reduction in the strain ductility index. It is well-known that increasing  $f'_{co}$  reduces the FRP lateral confinement ratio. The FRP lateral confinement ratio,  $\frac{f_{lu}}{f'_{co}}$ , is defined in the following equation:

$$\frac{f_{lu}}{f'_{co}} = \frac{2E_{FRP}\epsilon_{FRP}t_{FRP}}{Df'_{co}}$$

where  $E_{FRP}$  is the FRP modulus of elasticity,  $\epsilon_{FRP}$  is the FRP rupture strain,  $t_{FRP}$  is the thickness of FRP jacket,  $D$  is the concrete cylinder diameter and  $f'_{co}$  is the unconfined concrete compressive strength.

To develop a solid understanding on how the FRP lateral confinement ratio affect the strain ductility properties, the strain at ultimate from the constitutive model proposed by Ottosen for concrete under triaxial state of stress should be revisited [12,13].

$$\varepsilon_{cc} = \frac{\varepsilon_{FRP}}{v_{secu}} + \frac{\varepsilon_{co}(1 - v_{secu} - 2v_{secu}^2)}{v_{secu}} \frac{f_{lu}}{f'_{co}} \left[ 1 + 4 \left( \frac{k_l - 1}{\sqrt{3}} \right) \frac{f_{lu}}{f'_{co}} \right]$$

where  $E_{secu}$  is the concrete ultimate secant modulus of elasticity,  $v_{secu}$  is the concrete ultimate secant Poisson's ratio and  $k_l$  is the confinement effectiveness coefficient.

Hence, it would be expected that based on the above equations and given that the same FRP type is used, SFRP, i.e, the rupture strain is the same, cylinders with lower concrete compressive strength feature higher  $\frac{f_{lu}}{f'_{co}}$  and attain higher ultimate axial strains and hence, higher strain ductility indices. This closely match the test results as strain ductility reduces by 6%, 15% and 3% for one, two, and three layers of SFRP jacket, respectively, when concrete compressive strength increases from 37.3 MPa to 42.4 MPa.

On the other hand, the energy ductility index increases as  $f'_{co}$  increases as shown in Figure 4 (b). The increase of the concrete compressive strength from 37.3 MPa to 42.4 MPa results in energy ductility index increase by 24%, 17% and 6%, for concrete cylinders wrapped with one, two and three layers of SFRP sheets, respectively. As oppose to the strain ductility index, which depends only on the ultimate axial strain, which in turn is a function of FRP rupture strain and FRP lateral confinement ratio, energy ductility index is, by definition, a function of the whole stress-strain response. As concrete compressive strength increases, the ultimate axial strain, for the same type of FRP, slightly decreases, as discussed previously, however, the ultimate axial stress increases as concrete compressive strength increases as indicated by the majority of the proposed FRP-confinement models and are generally expressed by the following expression:

$$f'_{cc} = f'_{co} + k_l f_{lu}$$

where  $f'_{cc}$  is the confined concrete compressive strength, and  $f_{lu}$  is the ultimate lateral confinement pressure exerted by the FRP sheets on the concrete core and is represented mathematically by the following equation:

$$f_{lu} = \frac{2E_{FRP}t_{FRP}\varepsilon_{FRP}}{D}$$

Figure 4. Effect of unconfined compressive strength on ductility indices

## 5. Conclusions

This paper presents the experimental results of externally bonded SFRP-wrapped concrete cylinders subjected to monotonic axial loading. Investigation of ductility enhancement due to the effect of the thickness of FRP jacket and concrete compressive strength has been conducted as two ductility indices, namely strain ductility index and energy ductility index have been quantified. The following conclusions can be drawn,

1. Wrapping concrete cylinders with SFRP jacket significantly enhances the ductility performance of confined concrete.
2. Strain ductility index for SFRP-wrapped cylinders increases as the thickness of FRP jacket increases and decreases as the concrete unconfined compressive strength increases.
3. Energy ductility index for SFRP-wrapped cylinders increases as the thickness of FRP jacket increases and concrete unconfined compressive strength increases.

In conclusion, strain ductility index and energy ductility index are both good indicators of ductility, however, strain ductility index measures the deformation capacity of structural member while energy ductility index gives a more realistic indication of the energy absorption capacity of the structural member and hence deemed more suitable to be used in seismic design application.

**Abstract:** Reinforced concrete is the world's most widely used construction material. Exposure of structures to the aggressive mediums from environment in various latent form leads to degradation of concrete and thus significant reduction of lifetime. The corrosion of steel reinforcement is a very serious issue. One of the ways to prevent the corrosion of steel is the use of secondary protection of reinforced concrete structures using advanced technology of migrating corrosion inhibitors. Very often it is a transparent coating emulsion which contains active substances migrating through the concrete matrix to the reinforcement that protects creating a protective film on the surface and passivate the surrounding concrete. There are a number of products from reputable manufacturers that use this technology on the Czech market. This paper is focused on testing a number of selected materials whose effectiveness is evaluated by Ohm's methods of measurement of electrical resistance, which is non-destructive method with high ability to detect state of steel reinforcement.

This research work verifies possibility of application of alternative raw materials in developed renovation coating material. 10% addition of slag was selected as the optimal one. In the consequent step, the corrosion inhibitor was applied with the aim of protecting placed reinforcement against the effect of corrosive environment. As a part of the experimental work, the effectiveness of developed inhibitor with the mark 16 considerably reducing extent of corrosion was verified.

**Keywords:** inhibitors, repair materials, concrete, corrosion.

## 1. Introduction

Corrosion of steel reinforcement is one of the main problems that civil engineering has to face. Concrete is porous material and its matrix can be penetrated by aggressive chlorides, nitrogen oxides and other corrosive substances, which increase the risk of corrosion of steel reinforcement. Aggressive substances also reduce the value of pH of concrete below 10 (pH of rust is 9.6) and the thin layer of stable corrosion products (oxides) on the surface, which was stable before, becomes porous and dissolve. This effect causes penetration of humidity, oxygen and even various ions onto non-corroded steel. This is the cause of increased corrosion of the steel element in concrete. Because it is well known that corrosion products have higher volume (2.5 times larger) than original material, cracks form in concrete and finally the covering concrete layer falls off. (1)

Secondary protection of reinforcement by means of inhibitors of corrosion is a modern and effective way of protection, which can prolong life-time of concrete structures. The basic advantage of the proposed solution is multi-functional utilization of repair material not only for repair of the construction (leveling out) but also its protection by means of integrated corrosion inhibitor, which acts on the original reinforcement built in the structure.

**Figure 1. Corrosion of reinforcement in reinforced concrete structure.**

**Figure 2. Detail of a corroded bar; surrounding concrete is damaged by expansion of corrosion products.**

Corrosion inhibitors are generally all substances preventing corrosion or slowing it down. From the point of their principle, inhibitors are divided into anodic, cathodic and “combined”.

Anodic inhibitors slow down or eliminate reaction on the anode usually by means of reacting with corrosion products and create a protective layer on the surface of the product (steel).

Cathodic inhibitors prevent reaction on the cathode. Reaction products of cathodic inhibitors usually do not stick to the surface of metal as strongly as the anodic ones, and therefore are less effective.

Combined inhibitors influence reaction speed on both cathode and anode, which is advantageous for steel reinforced concrete.

From the point of view of prevailing interaction with metal, the inhibitors are divided into (i) inhibitors creating adsorption layer, (ii) oxidizing inhibitors, (iii) inhibitors creating passivated layer and (iv) “traps”, inhibitors bonding undesired ions from around the corroding steel. (2)

**Figure 3. Principle of action of corrosion inhibitors.**

The aim of this part of the paper is detailed research of the effectiveness of developed corrosion inhibitor interacting with polymer-cement compound and underlying concrete. As the result unique compound was

developed. This product is capable of protecting steel reinforcement in repaired concrete element thanks to the addition of corrosion inhibitor.

## 2. Test methods

Test methods are generally based on proving effectiveness of the new type of the compound as regards protecting steel reinforcement placed in repaired concrete. Test specimens were designed and manufactured from a mortar of lower quality to simulate slightly degraded concrete of initial structure including placing of steel reinforcement. Then, the test specimens were treated with the compound with the corrosion inhibitor and without it. Consequently, the test specimens were subjected to accelerated action of aggressive environment. Development of corrosion was observed on both types of the test specimens (with the corrosion inhibitor and without it) with appropriate test methods in the course of 18 months. The chapters below present individual test methods.

### 2.1 Design and preparation of test specimens

A series of test samples for verification of functionality and corrosion-inhibition properties of the compound were made from mortar, with composition given below, in the forms of dimensions 40 x 40 x 160mm with inserted reinforcement bars. After hardening of mortar and removal of formwork, the corrosion inhibiting compound was applied onto the surface.

Composition of mortar – 1m<sup>3</sup>:

- 400 kg of cement CEM II/B – S 32.5
- 1400 kg of sand, size fraction 2 – 4 mm
- 225 l of water

Figure 4. Diagram of the test specimens

It was necessary to adjust the formwork so that the reinforcement bar could be placed straight in the axis of the beam with overlap ca 20 mm. For this reason, the faces of the forms were designed and made from plywood with dimensions corresponding with the standard steel formwork.

Figure 5. Adjusted form for manufacture of test specimens with holes for placing and fixing steel reinforcement

## **2.2 Apparatus for automatic cycling of test specimen in aggressive environment**

The basis of the apparatus is a set of two tanks, one above another, made from specially treated plastic resistant to aggressive chemicals. Heat resistance of this material is increased to more than 100°C, which ensures its stability during thermal load when the test specimens are dried out. The top tank is divided into three levels by means of stainless perforated racks for easy placing of test specimens in the shape of a beam with dimensions 40 x 40 x 160 mm with 200 mm steel reinforcement built in the test specimen. In the bottom part of the tank there is an outlet valve with time switch for letting out the aggressive liquid, which is 3% solution of sodium chloride (NaCl) or 5.12% solution of sodium sulphate (Na<sub>2</sub>S<sub>4</sub>) in our case.

Cycles go in 12 hour intervals, where influence of a corrosive liquid is regularly changed with drying. The bottom tank is a reservoir of the aggressive liquid, which is stored there for the drying period and then again pumped into the top tank.

**Figure 6. Apparatus for accelerated process of degradation of test specimens**

## **2.3 Ohm method of measuring electric resistance**

Measuring changes of electric resistance of a metal sample is a method, which can be used for non-destructive testing of condition of a steel reinforcement built in a concrete matrix. This method uses changes of the cross-section of the metal which decreases as a consequence of corrosive process and dependence of electric resistance value on this change is known.

This measurement requires a very accurate desk multimeter with the range at least 100 Ω - 100 GΩ, coil ammeter for regulation of the current for measuring circuit, connection leads for connecting the whole circuit and an electric source producing sufficient current.

**Figure 7. Set for measuring with Ohm method**

### **2.5 Detection of corrosion inhibitors by means of dansyl chloride**

As a part of the solution, a new method for determination of presence of corrosion inhibitors was developed and is based on amino-alcohols and amino-groups. This is very important for practice. It is necessary to detect the presence of the inhibitor directly on the structure.

The method is based on the reaction of amino-groups with the chemical agent dansyl chloride in alkaline environment. The results of the chemical reaction are fluorescent products, which can be observed with naked eye when illuminated by ultraviolet light with appropriate wave-length.

Using this method in situ on building structures is not applicable, because dansyl chloride is basically a salt, which has negative influence on construction materials in general. This method is more suitable for laboratory purposes and for cases, when the silicate based test specimens are not tested by means of dansyl chloride for longer time. (3)

**Figure 8. Fracture surface of mortar applied on the underlying concrete body**

**Figure 9. Observation of corrosion inhibitors by means of an indicating agent – a picture under UV lamp – view of the fracture area**

### **3. Design of the material composition of the compound.**

The focus of the research is development of a unique compound in cooperation with manufacturer of renovation materials. The compound is developed for both horizontal and vertical area application with thickness of the layer up to 3 mm while the aesthetic qualities of the surface are accentuated. The main purpose of the compound is planary unification of the surface of concrete structure, where the surface layers were not destructed as a consequence of corrosion of built in steel reinforcement. In this sense, it is a preventive action with the aim of considerable, difficult and time-consuming renovation.

Below mentioned proportion of components was selected for the basic part of the mixture, because it has been verified by the manufacturer as an optimal compound for further development and implementation of secondary raw materials and corrosion inhibitors. The mixture is divided into two basic types of mixes, which will be consequently manufactured separately as a dry (packed) and liquid components.

**Table 1. Basic material composition of the compound**

Material	Proportion (%)
<b>Dry component</b>	
Cement	27.4
Additive	0.14
Fine sand	39.7
Lime filler	22.1
Fibers	0.04
Filler	10.6
<b>Liquid component</b> (mixing proportion 6.25 : 1)	
Defoaming agent	0.7
Plasticizer	3.6
Water dispersion	64.3
Water	31.4

#### 4. Raw materials

##### 4.1 Secondary raw materials

First of all, secondary raw materials with considerable ecological and economic advantage were selected. Based on literature search, blast furnace slag and fly ash were selected as the most appropriate

**Table 2. Chemical composition of slag**

SiO <sub>2</sub> [%]	Al <sub>2</sub> O <sub>3</sub> [%]	MnO [%]	MgO [%]	CaO [%]	S total [%]
37.9	5.8	0.6	11.9	40.0	0.7

**Table 3. Chemical composition of fly ash**

SiO <sub>2</sub> [%]	Al <sub>2</sub> O <sub>3</sub> [%]	Fe <sub>2</sub> O <sub>3</sub> [%]	FeO [%]	MnO [%]	MgO [%]	CaO [%]	K <sub>2</sub> O [%]
50.16	27.5	13.8	3.96	0.06	1.46	2.51	1.35

**Table 4. Sieve analysis of secondary raw materials**

Mesh size [mm]	Rest on the sieve [%]	
	Slag	Fly ash
2.000	0.00	0.00
1.000	0.00	0.00
0.500	0.00	0.24
0.25	0.00	6.17
0.125	1.58	19.62
0.063	7.25	56.77
<0.045	22.00	65.23

## 4.2 *Inhibitor*

### 4.2.1 *Characteristics*

This type of corrosion inhibitor was developed in the project in cooperation with Technical University in Brno and cooperating manufacturer of renovation materials. It is a completely new type of addition inhibitor of corrosion made from inland raw materials, the properties of which should be comparable with existing products of competitors available on home market. This inhibitor of corrosion presents an added value of newly developed renovation materials built in their material composition. Its task is to penetrate into the underlying concrete, passivate it and thus protect the steel reinforcement.

### 4.2.2 *Typical properties*

**Table 5. Parameters of the inhibitor**

Appearance	White powder
Bulk weight	1.06 g/cm <sup>3</sup>
Dosing	3.0 – 4.0 % by weight of cement.

### 4.2.3 *Application*

Powder inhibitor is dosed in the amount of 3-4% by weight of cement. If it is not mixed in the dry mix, it has to be properly mixed in the dry component by mixing for at least 3 minutes (depending on the amount of material). Addition into the material already mixed with water is not recommended because of its powder form, which can influence workability and mixing can be uneven.

### 4.2.4 *Field of application*

- All structures made from steel reinforced concrete, precast concrete, pre-stressed concrete, post-tensioned concrete and concrete used in naval architecture
- Bridges, highways and roads from steel reinforced concrete exposed to corrosive environment (carbonation, de-icing salts and weather influences)
- All structures made from steel reinforced concrete at sea-shore areas
- Addition into the mortar straight at the manufacturer's to increase anti-corrosion effect

### 4.2.5 *Advantages*

- Considerable prolonging of life of steel reinforced concrete structures
- Composition in dry mortar mix
- Non toxic or harmless
- The product has no influence on the basic characteristics of concrete mix
- Soluble in water, inflammable, easy to manipulate
- Protects reinforcement at both anodic and cathode areas
- Migrates through concrete, where it seeks and consequently protects built in reinforcement

## 5. *Results of experimental testing*

### 5.1 *Optimization of addition of secondary raw material*

For the reason of initial experimental verification of optimal addition of secondary raw material in the compound, addition of blast furnace slag and fly ash with dosage 5%, 10%, 20% and 30% by weight of cement were tested. These were in parallel compared with reference test specimen (0% addition of secondary raw materials). Test specimens were placed in water for 7 days and then in climatic chamber at the temperature of 21°C and relative humidity 65% until the age of 28 days.

Evaluation of suitability of secondary raw materials for the renovation compound was focused mainly on the influence of the dosage of addition on bond strength, which was determined with Pull Off test stated in EN 1542:1999.

**Figure 10. Determination of bond strength by means of a pull off test in accordance with EN 1542:1999**

The test results imply that slag is more appropriate raw material. Experimental determination of bond strength by pull off test in accordance with EN 1542:1999 shows gradual decrease of bond strength as the proportion of alternative component is increased. Minimal requirement of the standard EN 1504-3:2005 for bond strength of mortars on base material is 2.0 MPa for class R4. Based on practical experience from renovation works, the level 3.0 MPa is recommended. This determines the optimal addition of 10% of slag.

## 5.2 Verification of selected type of inhibitor

The principle of protection is based in releasing corrosion inhibitors from the renovation compound after its application on the concrete structure. Newly developed compound was considered and developed as a bi-component polymer-cement mortar mix for renovation of concrete structures, onto which any type of a secondary protection can be coated depending on the exposition of the structure. The second aim is to prolong the life of the treated structure using the corrosion inhibiting technology. All these aspects were taken into account when individual components and their proportions were designed.

**Table 6. Material composition of the compound (SH INHB)**

Material	Proportion (%)
<b>Dry component</b>	
Cement	26.4
Slag	2.6
Additive	0.14
Fine sand	39.7
Lime filler	22.1
Fibers	0.04
Filler	10.6
Addition of corrosion inhibitor (4 % by the amount of cement)	1.06
<b>Liquid component</b> (mixing proportion 6.25 : 1)	
Defoaming agent	0.7
Plasticizer	3.6
Water dispersion	64.3
Water	31.4

Individual mix-designs were used to manufacture test specimens; after 28 days of maturing basic physical-mechanical properties stated in the table below were determined. Mixture from Table 1 is used as a reference (SH).

**Table 7. Results of basic tests of the compound**

Compound	Volume weight of fresh mix [kg/m <sup>3</sup> ]	Volume weight of hardened mix [kg/m <sup>3</sup> ]	tensile bending strength: [MPa]	Compressive strength [MPa]	Bond strength to base material [MPa]
SH	1800	1796	10.3	29.6	3.4
SH IHIB	1892	1890	13.0	33.2	3.8

The results show that developed renovation compound (SH INHIB) has higher volume weight, but also higher tensile bending strength, compressive strength and bond strength.

From the point of view of suitability of selected inhibitor, it is necessary to focus on the primary function - protection of reinforcement. Renovation compound was applied on the samples of base concrete (defined in chapter 2), thickness of the layer was 3 mm. Then, the samples were placed in a humid environment for 28 days. Then they were repeatedly exposed to aggressive environment of 3% sodium chloride (NaCl) solution for 18 months. The samples were once a month tested by Ohm method. The table below states percentage of total corrosion of the compound exposed to aggressive environment cycles.

**Figure 11. Percentage of corrosion of the reinforcement**

The values of percentage of corrosion of the reinforcement determined by Ohm method shows that after 18 months exposure the samples treated with inhibiting compound show half rate corrosion than the untreated SH sample. Very low extent of corrosion is apparent on the sample, which was treated with renovation compound with the Inhibitor 16. This was verified also by means of a destructive test and visual assessment, when individual specimens were broken longwise. Figure 5 shows very low corrosion of the specimen with the inhibitor, where corrosion can be observed only at peripheral areas. These are the areas, where aggressive medium penetrates the porous structure at the border line steel-concrete.

**Figure 12. Visual assessment of compounds exposed to chloride environment (SH top, SH INHIB bottom)**

## **6. Conclusion**

There were two options for research verified in this work. First was a possibility of application of alternative raw materials in developed renovative coating material and secondly the possibility of increasing its corrosion protection. As additive of secondary material was 10% of slag selected as an optimum. It ensured bond strength at least by 3 MPa. The consequent step was application of the corrosion inhibitor with the aim of protecting reinforcement against the effect of corrosive environment in the form of 3% solution NaCl. Effectiveness of addition of developed corrosion inhibitor together with the compound was verified; the compound showed unambiguously lower extent of corrosion of reinforcement compared with renovation compound without the inhibitor. The results were verified by measurement of electrical methods and visual assessment after destruction of the test specimens. Further research will verify possibilities of using secondary raw materials and corrosion inhibitors in other types of renovation materials.

# Numerical Investigation of the Flexural Performance of RC Beam Strengthened with Iron-Based Shape Memory Alloys Bar

Hothifa Rojob<sup>1</sup> and Raafat El-Hacha<sup>2</sup>

<sup>1</sup>PhD Candidate, Department of Civil Engineering, University of Calgary

<sup>2</sup>Associate Professor, Department of Civil Engineering, University of Calgary

**Abstract:** The use of shape memory alloys (SMA) in structural engineering applications was limited to small-scale projects and not adapted in practical application due to the high cost of constitutive materials and production schemes. Recently, the iron-based SMA (Fe-SAM) is being developed. The inexpensive constitutive materials of the Fe-SMA and the availability of mass production facilities of steel products makes this material more suitable for large structural engineering applications than the most common shape memory alloys (i.e. NiTi). SMA is mainly characterized by the Shape Memory Effect (SME) phenomenon. The SME represents the ability of the SMA to recover its original shape after being deformed beyond the elastic limits through heating. This paper reports on the finite element modeling of 150×305×2000 mm RC beam strengthened in flexure with NSM Fe-SMA bar. The pre-strained Fe-SMA bar is anchored inside a groove in the tension side of the RC beam and then heated up to 350 °C where the transformation from martensite to austenite phase occurs causing a prestressing force developed in the Fe-SMA bar that counteracts the applied loads. Two beams were modeled; a control unstrengthened beam, and a beam strengthened by NSM Fe-SMA bar. The 3D FE model is validated against experimental test results.

**Keywords:** Near-Surface Mounted, Iron-Based Shape Memory Alloy, Strengthening, Prestressing, Finite Element Modeling.

## 1. Introduction

Structural retrofitting become important as structures worldwide are facing deterioration and increasing load demand. Fiber Reinforced Polymers (FRPs) are widely used to strengthen/retrofit existing structures. In the case of Reinforced Concrete (RC) flexural member, FRPs are applied in the form of sheets, strips, bars, and plates. Several techniques are used to attach the non-prestressed FRPs to the concrete, the Near Surface Mounted technique (NSM), Externally Bonded technique (EB), and Mechanically Fastened technique (MF) [1–3]. One common characteristics of the above listed techniques is the passivity of the strengthening system. In other words, the FRP material will not be activated unless a further deflection occurs to the beam. Therefore, the FRP will only contribute in enhancing the ultimate load capacity. In order to enhance the flexural capacity of the RC beam at service load, few researchers proposed to prestress the FRP. It was proven that the prestressing FRP system has contributed in enhancing the flexural performance of the RC beams in service and ultimate load states [4]. However, the application of the prestressing force to the FRP is challenging. El-Hacha and Gaafar [5] developed anchorage system to prestress the NSM FRP against the RC beam using hydraulic jack. Hadiseraji and El-Hacha [6] proposed the use of Nitinol (NiTi) Shape Memory Alloy (SMA) bar as a prestressing tool to apply prestressing force to the EB FRP sheets and NSM FRP strips. SMAs are known by the ability to recover part of the induced deformation upon heating. This phenomenon is called the Shape Memory Effect (SME) [7, 8]. The current research project proposes a new strengthening technique where SMA bars are utilized as strengthening reinforcements instead of FRPs. The NSM technique is adopted by embedding the pre-deformed SMA bar in a groove cut on the tension side of the beam. Because both ends of the bar are restrained through a steel anchorage plates, the application of heat results in a prestressing force in the bar without the need for jacking tools.

This paper reports on the results of Finite Element Modeling (FEM) of RC beam strengthened in flexure with NSM Iron-Based SMA (Fe-SMA). The results of the FEM is compared to the experimental results. The properties of the SMAs is firstly discussed followed by a brief description of the experimental test results. After that, the FE model is described. Finally, the comparison between the FEM results and the experimental results is presented.

## 2. Shape Memory Alloys

The Shape Memory Alloys (SMA) are metallic alloys and considered as type of smart materials. They are mainly known by the ability to recover part of the deformation upon heating. This unique behavior is attributed to the temperature and stress dependent phase transformation. SMAs exist in two different crystallographic phases, the low symmetry phase called the Martensite phase exist at low temperatures, and the high symmetry phase called Austenite phase at high temperature. The martensite transformation is the key feature of SMAs which occurs by shear lattice distortion rather than atom diffusion. The martensite transformation (austenite to martensite, also called forward transformation) starts at temperature value  $M_s$  (martensite start). The transformation continues until temperature  $M_f$  (martensite finish) where all the material become in martensite form. When the material is heated in absence of stress it will start to transform to austenite at a temperature marked as  $A_s$  (austenite start) in a process called reverse transformation. The material will totally transform to austenite at  $A_f$  (austenite finish) as shown in **Figure 1**. During the cooling process below  $M_f$ , no macroscopic shape change will occur because of the twinning process, where multiple variants coexist, and the phase is called twinned martensite. The martensite variants can be forced to orient (detwin) in a single variant through mechanical loading. The detwinning starts at a stress level  $\sigma_s$  (detwinning start) and finishes at stress level  $\sigma_f$  (detwinning finish) causing macroscopic inelastic strain. Upon heating above  $A_f$  the detwinned martensite phase transforms to the parent austenite phase causing recovery of the inelastic strain. This process is called the Shape Memory Effect (SME) as presented in **Figure 2** [7, 8]. If the ends of the SMA bar are restrained, no recovery strain will occur, alternatively, a recovery stress will develop. The recovery stress results from the SME process can be utilized to introduce stresses to structures.

The most common type of SMA is the Nitinol (NiTi), which is mainly composed of Nickle and Titanium. Nitinol stands for Nickel Titanium Naval Ordnance Laboratory [9]. The application of this material is mainly limited to small-scale applications because of the expensive constitutive materials. On the other hand, the Iron-based shape memory alloys (Fe-SMA) are considered to be the future best candidate for structural engineering applications due to the cheap constitutive materials and production scheme [10–14]. Czaderski et al. [11] used Fe-SMA strips to apply prestressing force to small concrete bars. Soroushian et al. [15] were the first to use Fe-SMA for external tensioning to repair bridge girder in shear.

**Figure 1. Phase diagram of typical SMA, after Lagouda [8]**

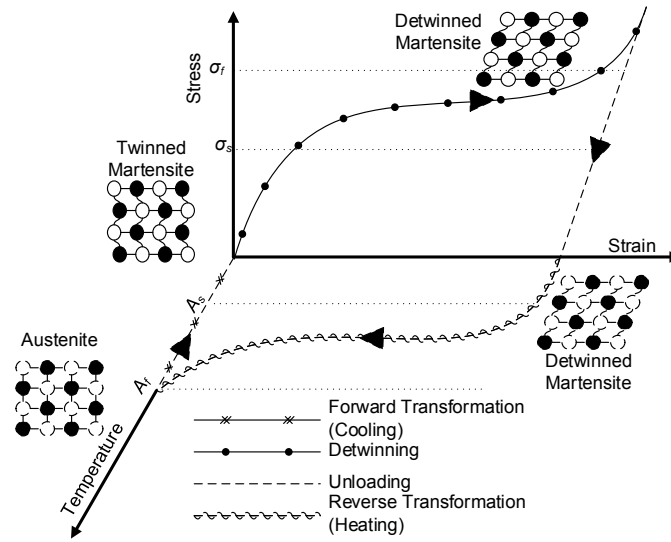

Figure 2. Shape Memory Effect process, after Lagouda [8]

### 3. Description of the experimental program

The experimental program includes the testing of two beams, the control beam (C-B) was tested by Hadiseraji and El-Hacha [6], and the other beam strengthened with NSM Fe-SMA bar (SMA-B) was tested as part of the ongoing research project. **Figure 3** shows the details of the RC beams strengthened with NSM Fe-SMA bar. The bar was initially strained to 6% and then anchored inside a groove cut on the tension side of the beam. The bar was then heated to 350 °C. The heating process caused the activation of the reverse transformation process. Because both ends of the bar were restrained through steel anchors mounted on the beam, a tensile stress developed in the bar causing a prestressing force at the bottom of the RC beam. The groove was then filled with epoxy adhesive. The strengthened beam was tested in four-point bending setup as shown in **Figure 3**.

Figure 3. Details of SMA-B.

The beam was instrumented with four Linear Strain Conversion (LSC) at the mid-span of the beams to monitor the concrete strains (two LCSs were placed on each side of the beam in which one of each is mounted at the level of the longitudinal bottom and top steel; and two LCSs were mounted on the top compression surface of the beam). Two strain gauges (SG) were installed on the tension steel and one was installed on the compression steel, at mid-span of the steel bars. Two laser transducers were used to measure the vertical deflection at the mid-span of the beam.

#### 4. Description of the finite element model

A 3D Finite Element Model (FEM) was developed using the commercial software ABAQUS. Quarter of the beam was modeled by making use of two planes of symmetry, one plane divides the beam in half longitudinally, and one plane divides the beam in half transversely. The symmetry was imposed by boundary conditions as shown in **Figure 4**. The concrete, support, and loading plate were modeled with 8-Node reduced integration continuum element which has three degrees of freedom, translation in x, y, and z directions. Steel reinforcements and Fe-SMA bar were modeled using 2-Node truss elements with three translational degrees of freedom at each node (i.e. x, y, z). The interaction behavior of the reinforcements and the concrete was modeled using the embedded region option, where the response of the host elements (i.e. concrete) used to constrain the translational degrees of freedom of the embedded nodes. The beam was loaded in time-independent displacement controlled mode. The support was imposed by applying boundary conditions. The prestressing force was applied to the Fe-SMA as initial tensile stress value that corresponds to the actual stress value developed in the Fe-SMA bar after heating. The size of mesh was optimized to reduce the computational efforts at the same time making sure that the results are mesh-independent.

**Figure 4. Boundary conditions.**

#### 4.1 Material properties

##### 4.1.1 Concrete

The concrete behaviour was modelled using damaged plasticity model [16]. The compression stress strain behavior was obtained using Carreira and Chu model [17] as presented in Equations 1 to 3.  $f_c$  is the concrete stress,  $\epsilon_c$  is the concrete strain, and  $E_{it}$  is the initial tangent modulus. The concrete compressive strength was about 40 MPa. **Figure 5** shows the stress strain curve of concrete under compression obtained using Equation 1.

$$f_c = f_c' \left( \frac{Bx}{B-1+x^B} \right) \quad (1)$$

$$B = \left( \frac{1}{1 - \frac{f'_c}{\varepsilon_o E_{it}}} \right); \text{ and } x = \frac{\varepsilon_c}{\varepsilon_o}; \varepsilon_o = 0.0029 \quad (2)$$

$$E_{it} = 3320\sqrt{f'_c} + 6900 \quad (3)$$

**Figure 5. Stress-strain of concrete under compression.**

The behaviour of concrete in tension was modelled using tensile stress-crack opening curve as recommended by Coronado and Lopez [18]. This curve is defined based on the tensile strength ( $f_t$ ) and the fracture energy of concrete ( $G_F$ ). Both  $f_t$  and  $G_F$  were obtained using the CEB-FIP model [19] as presented in Equation 4 and Equation 5, respectively. **Figure 6** shows the tensile stress-crack opening relationship.

$$f_t = 1.4 \left( \frac{f'_c - 10}{8} \right)^{2/3} = 3.04 \text{ MPa} \quad (4)$$

$$G_F = (0.0469d_a^2 - 0.5d_a + 26) \left( \frac{f'_c}{10} \right)^{0.7} = 0.0917 \text{ N/mm} \quad (5)$$

where  $d_a$  is the maximum aggregate size, it was taken as 20 mm.

**Figure 6. Tensile stress-crack opening relationship of concrete.**

#### 4.1.2 Steel

A tri-linear stress-strain curve of steel was simplified from the actual test results reported by Oudah [20] as shown in **Figure 7**. All the steel reinforcements have the same mechanical properties. The yield stress is 440 MPa and the modulus of elasticity is 180 GP.

**Figure 7. Simplified stress-strain curve of steel.**

#### 4.1.3 Fe-SMA bar

The diameter of the Fe-SMA bar was 14.3 mm. The bar was 1.1 m long centered in the groove on the tension side of the RC beam. The stress-strain curve of the bar as given by the manufacturer [12] is shown in **Figure 8**.

**Figure 8. Stress-strain curve of Fe-SMA, after Awaji [12].**

### 5. Model Validation

The model is validated against experimental results of a control beam (C-B) tested by Hadiseraji and El-Hacha [6], and a beam strengthened with NSM Fe-SMA bar (SMA-B) tested as part of this ongoing research project. **Figure 9** and **Figure 10** shows the numerical and experimental load deflection curves of C-B and SMA-B, respectively. The load deflection curves obtained numerically shows a good agreement with the experimental results. This indicates the validity of the FE model to simulate the behavior of the modeled beam. The FE model of SMA-B shows slightly higher stiffness and yielding loads, this might be attributed to the loss of prestressing force in the Fe-SMA bar occurred during the experiment due to

anchorage setting. The failure mode of all the numerical models of the beams occurred by crushing of concrete after the yielding of steel bars and Fe-SMA bar respectively, which is in agreement with the experimental results. **Table 1** shows a comparison between the results of the FE models and the experimental results.

Figure 9. FE model results against the experimental results for B-C.

Figure 10. FE model results against the experimental results for SMA-B.

Table 1. Comparison between the numerical and experimental results

Beam →	C-B			SMA-B		
Variable ↓	Exp. Results	FE Results	%Δ	Exp. Results	FE Results	%Δ
Cracking Load: $P_{cr}$ (kN)	19	30	58	40	40	0
Yielding Load: $P_y$ (kN)	104	109	5	127.4	139	9
Ultimate Load: $P_u$ (kN)	124	121.3	2	165.4	160.1	3

## 6. Conclusions

The FE model was validated against the experimental results. The FE model was able to simulate the control beam, and the beam strengthened with Fe-SMA bar. The model can be further used to study the behavior of RC beams strengthened with NSM Fe-SMA bars at different level of prestressing forces, and different Fe-SMA materials. A future work will include the use of comprehensive constitutive model of the Fe-SMA material that will allow the simulation of the behavior of the Fe-SMA bar during heating, including the martensite transformation process and thermal expansion. The model will spot more light on the behavior of the strengthened RC beam during the heating process of Fe-SMA bar.

# Development of Double-Slotted Beam-Column Connection for the Seismic Design of Structures

Fadi Oudah<sup>1</sup> and Raafat El-Hacha<sup>2</sup>

<sup>1</sup>Post-Doctoral Engineering Specialist, Amec Foster Wheeler (formerly PhD Candidate at University of Calgary)

<sup>2</sup>Associate Professor, Department of Civil Engineering, University of Calgary

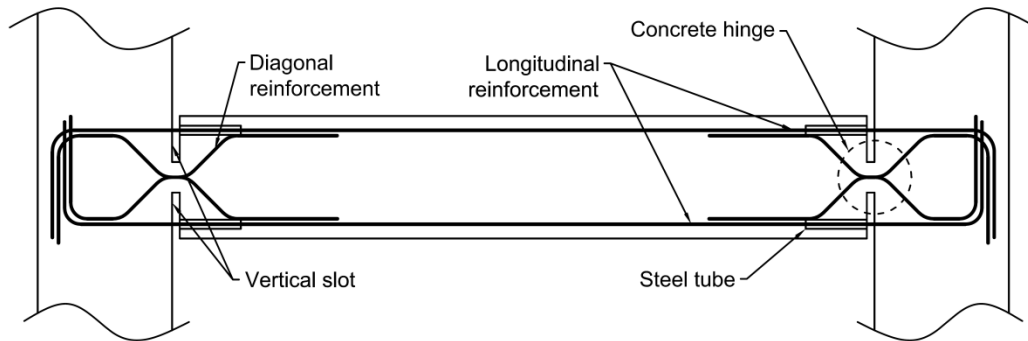

**Abstract:** The Double-Slotted Beam (DSB) system is a new beam-column connection proposed and verified in this research. The DSB system is made of a strong column and a weak beam slotted from both the top and the bottom sides. Both top and bottom reinforcements act as energy dissipation devices in which the energy imposed on the system are dissipated via their hysteretic responses. The DSB system maintains a non-tearing action to the slab attached to the beam member. In this paper, the key design aspects of the newly developed system are discussed followed by experimental evaluation of large-scale beam-column connections. The test results are analyzed with respect to the hysteretic response and energy dissipation. Test results indicate the superior performance of the developed system in terms of achieving a stable and fat hysteretic response with no signs of pinching shear. However, it experienced lower equivalent viscous damping as compared with conventional connections, which open the doors for further enhancements of the system.

**Keywords:** Beam, Concrete, Connection, Slotted.

## 1. Introduction

The continuous development in seismic design of concrete structures is driven by the need to achieve resilient, yet, practical designs of beam-column connections as they represent the most critical components in the lateral loading resisting system. The degradation of the load lateral load carrying capacity and the tearing action of the attached slabs are among the main challenges encountered in the design of conventional concrete beam-column connections (1,2). As such, research in connection design should aim at mitigating the consequences associated with these design difficulties.

An innovative connection design is proposed and validated in this research. The design philosophy of the new system is based on attaining higher drift capacity, achieving a more stable hysteretic response, and attaining a non-tearing action to the attached slab. The system is called 'Double Slotted Beam (DSB)' as it includes two vertical slots made into the beam member at the face of the column (Figure 1).

**Figure 1. Schematic drawing of the DSB connection.**

The DSB system is made of a strong column and a weak beam. A large amount of longitudinal reinforcement is placed in-between the slots in order for it to remain elastic during the plastic rotation of the beam. The top and the bottom reinforcements yield under positive and negative bending, and thus, they act as energy dissipation devices. The energy imposed on the system is dissipated via the hysteresis response of both reinforcements. The advantages of the DSB system are as follows:

1. Non-tearing action. The top slot is anticipated to open and close during the seismic loading. However, if a construction joint is made in the slab at the location of the top slot, a non-tearing action of the slab can be achieved.

2. High drift capacity. The neutral axis at the vertical slot is approximately equal to half of the beam depth. This will lead to higher drift capacity since the strain level in the tension reinforcement decreases with increasing depth of the neutral axis.
3. Plastic hinge relocation. Moving the vertical slot away from the face of the column is anticipated to relocate the plastic hinge effectively.
4. Minimal repair cost. The plastic rotation is concentrated at the slot. Therefore, minimal concrete cracking is anticipated when the connections is subjected to lateral loading.

The design of the connection is discussed briefly following by examining its response via experimental testing. The behavior of the connection is also compared with conventional connection designed to achieve approximately the same ultimate strength.

## 2. Design of Connections

### 2.1 Flexural design

The beam is designed to have similar positive and negative moment capacities. Therefore, the dimensions of the upper and the lower slots along with the amount of the bottom and top reinforcement are set to be equal. A portion of the concrete hinge will be subjected to compression forces, and thus, the stresses induced in the bottom and the top reinforcement will not be the same. The magnitude of the compression forces in the concrete hinge depends on its dimensioning and the width of the cracks developed when the connection is subjected to lateral loading. Each of the top and the bottom reinforcement consisted of 2-15M steel reinforcement (Grade 440).

### 2.2 Shear design

Finite Element (FE) simulation is used to examine the flow of forces within the connection in order to help in designing the amount of stirrups in the beam and the joint. The simplified 2D model intends to provide a general representation of the deformation mechanism and not to provide accurate results in term of load and deflection. Only longitudinal steel (in the beams and columns) and concrete sections were considered in the model. The steel was modeled as a linear elastic material with a modulus of elasticity of 200 GPa. The concrete was also modeled as linear elastic material with a modulus of elasticity equal to 28.5 GPa (3). The concrete section and the steel reinforcement were modeled using 4-node plane strain and beam elements, respectively, in ABAQUS. The tip of the beam was subjected to upward 10 mm deflection upward to induce a positive moment. The column was subjected to 405 kN (determined based on the analysis of the structure included). The column was also hinged at the top and the bottom sides. The size of the mesh was chosen such that to provide adequate level of accuracy. The bottom and top reinforcement in the DSB connections were debonded from the surrounding concrete using the Tube-to-Tube elements for a distance of 200 mm.

The visualization of the minimum principal strains (compressive strains) in the DSB system under positive bending are shown in Figure 2. The behavior under negative bending is similar to that under positive bending due to its symmetric nature, and thus, only positive bending is considered herein. High levels of compressive strains are induced in the concrete hinge. Diagonal compression struts are formed transferring the forces from the edge of the unbonded reinforcement in the beam section to the concrete hinge. Also, two diagonal compression struts are formed in the joint.

**Figure 2. Visualization of the compressive strains in the DSB connection.**

Based on the discussion presented above, the beam is divided into two regions in terms of the detailing of the stirrup reinforcement. In this research, the recommendation on the length of regions are adopted from the Paulay and Priestley (1). Even though the recommendations by Paulay and Priestley (1) are concluded based on the behavior of beams with diagonal reinforcement as a mean for relocating the plastic hinges, their recommendations are applicable to be used in the DSB system based on the observations made about the FE analysis. Region I extends for  $1.5b_d$ , where  $b_d$  is the beam depth. Region I extends from the edge of Region II to the tip of the beam. Region I is a non-critical region in which the conventional design procedure of shear reinforcement is adopted whereas special detailing is required in Regions II. The special detailing of the stirrups adopted in this study was based on the anti-buckling requirements for the design of RC members in CSA-A23.3-04 (3). It is noted that the area of the stirrups right at the face of the vertical slot was doubled in order to accommodate the high shear demand at this region. Diagonal reinforcements are also used to enhance the shear transfer mechanism near the slots as shown in Figure 3. The diagonal reinforcement passes through the concrete hinge extends from the concrete hinge to the top and the bottom concrete fibers. The concrete compression strut that extends between the concrete hinge and the corner of the joint may induce premature failure since the beam in this region acts like a deep beam. Thus, it was determined to include distributed longitudinal reinforcement (4-10M) in this region in order to better resist the shear force and to control the cracking pattern.

### 2.3 Joint design

Based on the observations made with regard to the behavior of the connections in Figure 2, the applied forces onto the joint along with the deformation inside the joint is presented schematically in Figure 3 ( $C$ ,  $T$ , and  $V$  refer to compression, tension, and shear, respectively, subscripts  $c$ ,  $s$ ,  $co$ , and  $b$ , refer to concrete, steel, column, and beam, respectively). Placing the vertical slots at the face of the column in the DSB system leads to the formation of two diagonal compression struts; one transferring a portion of the compression forces from the compression reinforcement to the upper opposite corner of the joint,  $S_1$ , while the other transfers the compression forces in the concrete hinge to the upper opposite corner of the joint,  $S_2$ . The forces in the joint are transferred via two mechanisms; compression strut and truss mechanisms (1). In the former, forces are transferred via the concrete while they are transferred via the transverse steel reinforcement in the latter. For design purposes, only the joint shear value needs to be determined in the joint in order to be able to calculate the amount of the required transverse steel.

Figure 3. Joint shear mechanism in the DSB connection.

### 2.4 Slot width

The width of the slot is designed such that to prevent the closure of the slot under high drift ratios. The width of the slot is calculated using the expression proposed by Oudah (4) (Equation 1) for the design of slotted-beam connections. The width of the slot is found to be 25 mm.

$$S_w = \lambda_{sf} \cdot \theta_d \cdot l_o \quad (1)$$

where  $S_w$  is the width of the slot,  $\lambda_{sf}$  safety factor,  $\theta_d$  design rotation, and  $l_o$  is the distance from the neutral axis to the centroid of the bottom reinforcement.

### 3. Experimental Program

Two specimens were tested under quasi-static loading; one DSB connection and one conventional connection. The specimen details are shown in Figure 4 while the test setup is shown in Figure 5. Four types of instrumentations were used to monitor the behavior of the connections during testing; Linear Strain Conversion (LSC) devices, Laser displacement sensors, Strain Gauges (SG), and the Digital Image Correlation Technique (DICT). The LSC devices were mounted on the beams, columns, and joints in order to measure the concrete deformations while the laser displacement sensors were positioned on the laboratory floor in order to measure the displacement of the beam members under positive and negative bending. The DICT was used to measure the deformation within the joint.

Figure 4. Specimen details.

**Figure 5. Test setup.**

The average 28 days concrete compressive strength is  $40.9 \pm 4.2$  MPa in accordance with ASTM C39/C39M (5). The steel properties of the three rebar diameters; 10 M, 15 M, and 20 M were determined in accordance to ASTM A370 (6). The modulus of elasticity is 187.1 GPa, 180.5 GPa, 194.8 GPa, the yield stress is 484.8 MPa, 484.0 MPa, 435.6 MPa, the yield strain is 0.0026, 0.0027, 0.0022, and the ultimate stress is 730.4 MPa, 729.5 MPa, and 588.2 MPa for the 10 M, 15 M, and 20 M bars, respectively.

## 4. Analysis Results

### 4.1 Hysteretic response

The hysteretic responses are shown in Figure 6. The Control connection failed by crushing of the concrete followed by the fracture of the steel reinforcement in the beam at the face of the column (plastic hinge location) while the DSB connection failed by fracture of the steel reinforcing bar at the slot due to low-cyclic fatigue. The Control connection experienced the typical hysteretic response of conventional beam column connections. The load carrying capacity increased with increasing drift until the maximum capacity is reached. After that, a gradual decrease in the capacity is noticed due to the widening of the cracks and the development of sliding shear plane at beam plastic hinge (located at the face of the column). These actions lead to the so called 'pinching shear'. The increase in the width of the cracks with increasing drift demand makes it difficult for the cracks to close, and hence, to provide a compression force upon the reversal in the bending moment. The delay in the closure of the cracks leads to a reduced stiffness upon the reversal of loading. This behavior is referred to the pinching shear effect and results in the reduction of the amount of energy dissipated during the cyclic loading (7). In the DSB connection, the top and bottom reinforcements provide the main source of resistance for positive and negative bending while a relatively low compression force is transferred in the concrete hinge. Therefore, the effect of the increase in the crack width on lowering the stiffness of the connections is not observed in the DSB connection. Instead, a fat and stable hysteretic response is achieved with no signs of pinching shear.

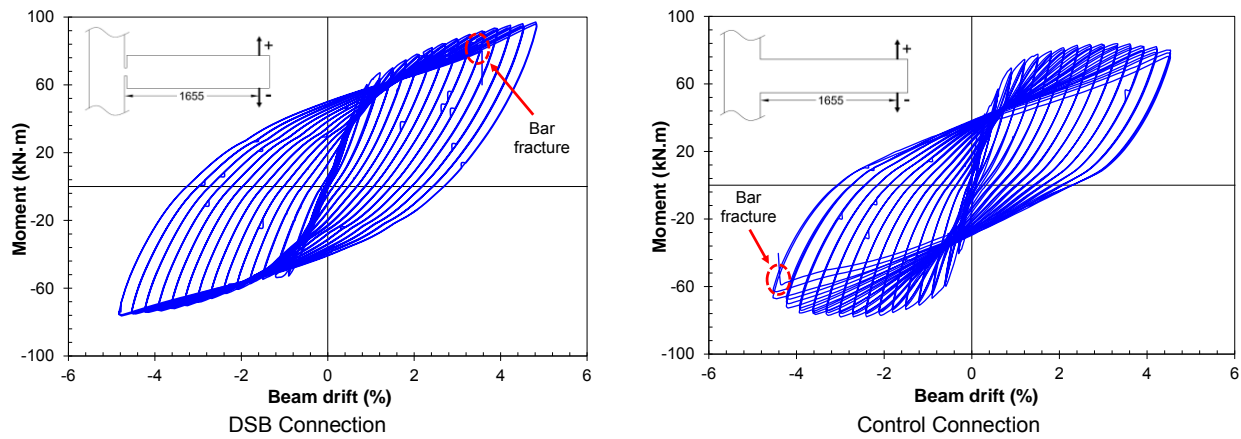

Figure 6. Hysteretic responses.

#### 4.2 Energy and Damping

The energy dissipation is evaluated using two approaches; cumulative energy,  $E_{cum}$ , and equivalent viscous damping,  $\xi_{eq}$ . The  $E_{cum}$  is simply the cumulative hysteretic energy calculated as the summation of the areas enclosed by the hysteretic loops:

$$E_{cum} = \sum_{i=1}^N E_i \quad (2)$$

where  $E_i$  is the energy per cycle  $i$ .

The  $\xi_{eq}$  is also used to evaluate the energy dissipation capacity of the connections and to assess the potential damage. It is a property of the system and depends on the mass and the stiffness (8). The  $\xi_{eq}$  represents the simplest form of damping since the governing differential equation of motion is linear and it can be evaluated using simple experimental test. The  $\xi_{eq}$  ratio is calculated as function of  $E_{cum}$ , and elastic energy,  $E_{el}$ , as follows:

$$\xi_{eq} = \frac{1}{4\pi} \frac{E_{cum}}{E_{el}} \quad (3)$$

The cumulative energy dissipation and the equivalent viscous damping are compared in Figure 7 (a). Even though the post-yielding stiffness of the DSB connection experienced insignificant degradation (Figure 6), the cumulative energy trends of both connections is similar. This is explained by the lower pre-yielding stiffness of the DSB connection as compared with the Control connection. The neutral axis is located approximately at the mid-section in the DSB connection, which contributes in experiencing lower stiffness as compared with conventional connections. The equivalent viscous damping of the DSB connection is lower than that of the Control connection as shown in Figure 7 (a) (0.86 times that of Control connection at drift of 2.5% - drift corresponding to the collapse limit (9)). The lower damping of DSB connection as compared with the Control connection is due to the higher elastic energy in the former as compared with the latter, which is calculated as the product of the load and displacement at each drift amplitude.

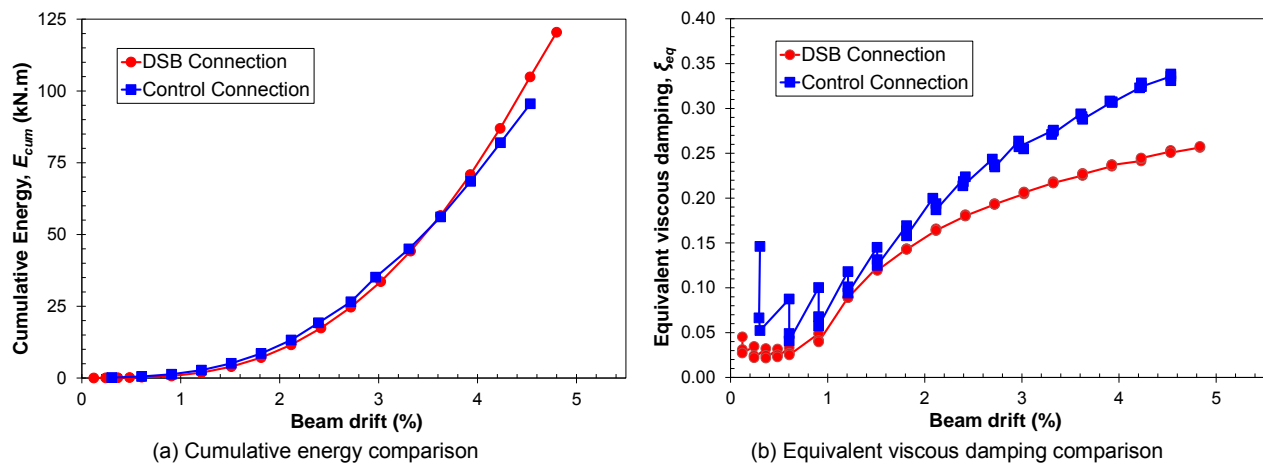

Figure 7. Energy evaluation of the DSB connection.

## 5. Conclusions

A new concrete connection was developed in this study (Double Slotted Beam (DSB)). The flexural, shear, and joint design of the connection were discussed followed by examining its performance experimentally. Large-scale DSB connection was tested and compared with conventional connection. Analysis results indicated the superior performance of the DSB connection in terms of achieving fat, stable, and pinching-shear free response as compared with the conventional one. Cumulative energy comparison indicated that the cumulative energy of the newly developed system follows a similar trend to that of the conventional connection. However, lower equivalent viscous damping was attained by the DSB connection. Thus, further research is needed to enhance the damping property of the DSB system before being introduced into the construction industry.

<sup>2</sup>Associate Professor, Department of Civil Engineering, University of Calgary

**Abstract:** The research summarized in this paper focuses on the development of a validated finite element model as a design tool for future studies and analysis on a novel hybrid steel-free multi-girder bridge deck system. Good correlation between finite element analysis and experimental test results was found in regards to global behaviour, particularly for predictions of peak load condition and failure sequence in the progressive failure mechanism. The developed finite element model was found applicable for use in future design optimization studies as well as investigations for structural response under additional types of wheel load configurations.

**Keywords:** hybrid, bridge, steel-free, finite element, FRP, UHPC.

## 1. Introduction

In the field of structural bridge engineering, significant progress has been made in recent years towards the design of sustainable infrastructure, as a means of addressing the current infrastructure deficit in Canada. The infrastructure deficit, valued at \$12.7 billion dollars for costs directly associated with transportation infrastructure [1], is mainly due to continued deferral of regular maintenance procedures and extended usage of existing structures past their original design life; this is a critical issue with a significant and direct impact on the future of Canadian society. One branch of research focuses on the development of new infrastructure construction methods that limit the vulnerability of the structure to environmental effects, thus reducing maintenance costs throughout the duration of the design lifespan. By ensuring more resilient and cost-effective replacement structures, steps can be taken to resolve the infrastructure deficit.

The use of high performance materials to replace the conventional materials currently used in construction is a feasible approach. Many high performance materials are resistant to the effects of corrosion, which is a primary cause for structural deterioration in current infrastructure due to the presence of structural steel components. In particular, Fibre Reinforced Polymers (FRPs) and Ultra-High Performance Concrete (UHPC) have been successfully adopted in a wide variety of structural applications [2-21]. Nevertheless, the majority of these structural applications include the usage of high performance materials in conjunction with conventional structural materials, such as reinforced concrete, structural steel and prestressed concrete, as composite structures so that the influence of corrosion is minimized but not completely eliminated. Recently, the authors have developed a new design concept for a hybrid bridge deck system that incorporates only high performance materials, without any structural steel components [22]. Extensive large-scale experimental testing of the hybrid bridge deck system specimen under seven different wheel load configurations has confirmed good structural performance that exceed current Canadian code standards for ultimate and serviceability limit states [22].

To evaluate further the feasibility of the proposed hybrid design for practical implementation, however, additional studies are required. The first would be to investigate the performance of the bridge system under a wider set of loading configurations not yet explored during experimental testing, such as multiple lane loadings and the inclusion of more than two truck axles. An additional aspect to consider would be potential design optimizations that can be made to maximize the full structural capacity of the bridge system while minimizing costs. In order to conduct a comprehensive examination, the use of traditional large-scale experimental testing is highly cost-prohibitive and impractical. An alternative to experimental testing, however, is the use of finite element analysis as a tool to implement the crucial studies. Finite element modelling has been used by many researchers as a mean to conduct detailed investigations in the performance of many structural systems, ranging from examinations of small-scale local behaviours [23-26] to global representations of large-scale structural systems [27]. To ascertain the accuracy of developed model and the parameters used to idealize the various components, validation of the finite

element model must first be conducted with direct comparisons with experimental test results. If reasonable accuracy between the experimental data and predicted finite element analysis behaviour is achieved, then the developed finite element model is deemed suitable for use as a design tool for future studies.

The desired outcome of this research program is the development of a finite element model that can reasonably predict the performance of the hybrid steel-free multi-girder bridge deck system without the need for additional experimental testing. As a design tool, the critical parameters that need to be obtained from the finite element model would include the global prediction of peak load and failure modes. To a lesser degree, determination of the local performance in individual structural components using the finite element model, to aid in future design optimizations and modifications in dimensions, would be a valuable asset.

## **2. Description of hybrid steel-free multi-girder bridge deck system design**

The central objective for the design of the hybrid steel-free multi-girder bridge deck system was the successful incorporation of distinct high performance structural elements with linear-elastic material properties into a cohesive bridge system that is capable of exhibiting global pseudo-ductile behaviour. The desired characteristic for successful integration of pseudo-ductile behaviour would be the clear display of a progressive failure mechanism prior to ultimate failure of the hybrid bridge deck system. Thus, with this focus, high performance materials were carefully selected based upon their material properties, particularly in regards to the ultimate strain capacity. Fibre Reinforced Polymers (FRPs) were chosen, with pultruded Glass FRP (GFRP) hollow box beams serving as the core girders of the system as well as the stay-in-place formwork along with Carbon FRP (CFRP) sheets bonded to the bottom face of each GFRP hollow box beam for additional strength and stiffness to the girder system. The pultruded GFRP hollow box beams [28] had an outer depth and width of 228.6 mm and 152.4 mm, respectively, with an all-around wall thickness of 11.11 mm. The bonded CFRP sheets [29, 30] had a thickness of 1.0 mm. Four of the composite FRP girders were spaced side-by-side, with a single 50 mm thick slab of cast-in-place Ultra-High Performance Concrete (UHPC) overtop. The UHPC used is a proprietary concrete product [31] that does not include the use of internal steel reinforcement bars.

To ensure sufficient bond between the UHPC slab and composite FRP girder below, a two-part system was used. The two-part system consisted of an epoxy bonded coarse silica sand aggregate layer bonded directly to the top surface of the composite FRP girder prior to casting of the UHPC slab [24, 32] along with a series of full-depth vertical GFRP threaded rods spaced at regular intervals along the longitudinal span of each composite girders. A combination of horizontal GFRP straps, post-tensioned GFRP rods and diagonal cross-bracing bars were used for composite action and constraint through the transverse cross-section. To reinforce the GFRP hollow box beam at the locations where the composite action GFRP threaded rods traversed the girder system, internal UHPC stiffener blocks were cast within the interior of the hollow box beam. The horizontal and vertical GFRP threaded rods were installed as unbonded structural elements, with PEX tubing serving as ducts to prevent contact between the rods and the UHPC stiffener blocks. All of the GFRP rods (vertical, horizontal and diagonal) were fabricated using a two-step pultrusion process, first of the inner longitudinal load bearing rod, followed by the fabrication of the outer transverse threading [33]. 5/8" 11 UNC threaded rods were chosen for use in the hybrid bridge deck system design, which had a nominal diameter of 15.875 mm. The matching GFRP nuts had an outer diameter of 31.75 mm along with a thickness of 22.225 mm.

During previous stages of the research program, studies were conducted to evaluate the performance of individual hybrid FRP-UHPC girders [4, 5, 9], including optimization studies to ensure the desired pseudo-ductile behaviour was exhibited [11]. Based on the findings obtained from the previous studies, a quarter-scale specimen of the proposed hybrid steel-free multi-girder bridge deck system was constructed for testing. The resulting design dimensions for the quarter-scale hybrid bridge deck system, with associated photographs of the completed specimen, are shown in Figure 1.

**Figure 1. Dimensions and photograph of quarter-scale hybrid steel-free multi-girder bridge deck system.**

**3. Summary of experimental test program and results**

In-depth description and examination of the experimental test results have been presented in another publication [22] and will not be repeated in this publication. A summary of the experimental program and the key experimental findings, necessary for comparison and validation with the finite element analysis (FEA) results, will be presented in this section.

Testing of the hybrid bridge deck system was performed using both service and ultimate condition loading. A simultaneously applied four-wheel load formation was used, based upon the positions of axle 2 and 3 of the CL-625 design truck from the Canadian Highway Bridge Design Code [34]. As mentioned previously in this paper, a quarter-scale specimen of the hybrid bridge deck system was constructed for experimental testing; this was due to constraints in the actuator capacity and space available in the structural lab. Thus, all dimensions and associated parameters were scaled down using scale factors determined through dimensional analysis. Seven different concentric and eccentric load configurations (Load Configurations C1 – C3 and E1 – E4) were examined under service load conditions, with the final ultimate load condition conducted using Load Configurations C1. Diagrams showing the transverse placement of the wheel loads are provided in Table 1. The spacing of the wheel loads in the longitudinal direction was 300 mm about the center of the longitudinal span for all load configurations except for Load Configuration C2, where a longitudinal spacing of 600 mm was used.

**Table 1. Wheel load configurations tested under service and ultimate load condition testing [22]**

Concentric Configurations			Eccentric Configurations		
C1	E1a	E2a			
C2	E1b	E2b			
C3	E3	E4			

Service load condition tests were performed using step-wise quasi-static loading up to a maximum load level of 50 kN. Linear-elastic behaviour was observed within the load range tested for all load configurations with no signs of stress relaxation or creep caused by repeated loading. The final ultimate load condition test was initiated with a similar set of step-wise loading regime up to a maximum total load of 200 kN, after which a loading rate of 0.75 mm/min was applied up until ultimate failure of the specimen. Progressive failure was achieved during experimental testing, with signs of longitudinal tensile cracking in the UHPC slab, buckling in the GFRP cross-bracing bars, tension shear block failure in the GFRP web and tensile fracture in the CFRP sheet and GFRP bottom flange after reaching peak load condition.

## 4. Finite element model

### 4.1 Model development

A three-dimensional (3D) finite element model (FEM) was developed using ABAQUS, a commercial software package. Preliminary validation of FEM results with experimental results was performed and summarized in another publication [35]. A detailed tabulated list of the chosen mesh size and element type used to characterize each structural component is provided in Table 2. The material properties for the structural components used in the FEM, obtained through in-house experimental testing, are provided in Tables 3 to 6.

**Table 2. Basic FE analysis parameters used for the 3D FEM of the hybrid bridge deck system**

Structural component	Element type		Average mesh size (mm)		
	Description	Name	Longitudinal	Transverse	Through depth
GFRP hollow box beam	Continuum shell	SC8R	25	15	5
CFRP sheet	Continuum shell	SC8R	10	10	1
UHPC slab	Solid linear brick	C3D8	25	25	25
UHPC stiffener block	Solid linear brick	C3D8	25	25	25
GFRP rod	Linear beam	C3D8	5	N/A	N/A
GFRP bolt	Linear triangular prism	C3D6	5	9	N/A
Steel plate	Solid linear brick	C3D8	50	50	50
Steel rollers	Linear triangular prism	C3D6	50	6	50

**Table 3. Material property parameters for GFRP hollow box beam [9, 28]**

Material elasticity	$E_1$ (MPa)	21000 (flanges), 16000 (webs)	
	$E_2$ (MPa)	5520

	$G_3$ (kJ/m)	0.9

#### 4.2 Comparison of results: Experimental vs. finite element analysis results

The full spectrum of experimentally tested concentric and eccentric load configurations were implemented and analysed using finite element analysis. Comparison between experimental and FEA behaviour for Load Configuration C1 under ultimate load condition is presented in Figure 2. The labels “A, B, C, and D” refer to transverse positions directly in line with the longitudinal girders whereas labels “A/B, B/C, and C/D” refer to positions directly in line with the middle of the inter-girder space.

**Figure 2. Comparison of experimental and FEA results for Load Configuration C1 tested at ULS.**

The comparison shown in Figure 2 clearly demonstrate a reasonable degree of accuracy between the experimental and finite element analysis results. It is worth noting that FEA conducted under load-controlled conditions provided load-deflection behaviour past the peak load condition that was more consistent with experimental results than FEA results using displacement-controlled load steps. In general, the data obtained through finite element analysis indicated a stiffer global response than observed experimentally. There was good prediction of the peak load, regardless of higher global stiffness of the modelled bridge deck system. Looking at the local responses in the key structural elements (as presented in Figure 2), equally good correlation was observed for load-strain behaviour in the CFRP sheet and UHPC slab. In the case of strain behaviour in the GFRP cross-bracing bars, particularly in the case of bars acting in compression, there were several discrepancies between the experimental and finite element analysis results. This indicates the possible need for further refinements in the modelling of the transverse composite action system.

Whereas the FEA was conducted past peak condition for all of the seven configurations examined, the set of ultimate load condition experimental data was only available for Load Configuration C1. For comparison with the FEA results, linear extrapolations of the experimental data obtained during the service load condition tests for the other six load configurations were used. Since near linear-elastic behaviour was exhibited by the hybrid bridge deck system during experimental testing, the extrapolation of service load condition data was deemed as a safe approximation. To fulfill the length limits of this publication, the full comparison between experimental and finite element analysis results are not presented here for the remaining service load conditions tests. Overall, the predicted behaviour displayed the same key characteristics observed from the ultimate load condition test comparison, with generally higher global stiffness, good correlation of strain behaviour in the CFRP sheet and UHPC slab, as well as moderate correlation in the structural elements making up the transverse composite action system.

## 6. Discussion and analysis

Judging from the extensive comparison of strain behaviour in the various structural elements obtained from experimental testing and FEA, it can be concluded that the developed FEM can be used to adequately predict the global behaviour of the hybrid bridge deck system. Good prediction of local strain behaviours in the CFRP sheet and UHPC slab can also be attained; however, adjustments must be made to the formulation of GFRP cross-bracing bars in order to achieve proper modelled load distribution within the transverse composite action system. Using the modelled global response of the hybrid bridge deck system, detailed assessment of the accuracy of FEA results as compared with experimental behaviour will be discussed in this section.

### 6.1 Live load distribution factor

Firstly, the shear live load distribution factor (LLDF) was examined. As detected previously, there were observed discrepancies in load-strain responses of the GFRP cross-bracing bars obtained from the finite element analysis. This influence on the modelled transverse composite action system may affect the calculated load distribution between adjacent longitudinal girders. A comparison of the shear LLDF is provided in Table 7, showing the fraction of load carried for each girder as well as the percent error in the finite element analysis results as compared with experimental data.

**Table 7. Comparison of shear live load distribution factor between experimental and FEA results**

Load configuration	Experimental				Finite element				Percent error (%)			
	A	B	C	D	A	B	C	D	A	B	C	D
C1	0.20	0.28	0.31	0.21	0.19	0.29	0.29	0.19	-6	3	-4	-13
E1	0.12	0.24	0.31	0.33	0.07	0.25	0.35	0.36	-40	2	14	8
E2	0.05	0.17	0.32	0.46	0.00	0.15	0.30	0.59	-92	-11	-5	27
E3	0.36	0.29	0.22	0.13	0.42	0.25	0.21	0.13	17	-15	-6	-4
E4	0.27	0.29	0.24	0.20	0.29	0.29	0.26	0.15	8	-3	7	-24
C2	0.20	0.32	0.30	0.19	0.17	0.32	0.32	0.17	-16	0	6	-12
C3	0.25	0.27	0.24	0.24	0.25	0.25	0.25	0.25	1	-9	2	7

The shear LLDF obtained through FEA was generally consistent with the experimental results for the seven load configurations tested. For the inner girders, a maximum percent difference of 15% was found. In terms of the outer girders, an initial assessment of the comparative results for the LLDF of the outer girders showed a percent difference of 92%, obtained for Girder A under Load Configuration E2, the most highly eccentric load configuration. Nevertheless, when analyzed in more detail, the low experimental value of LLDF attributed to Girder A (equal to 5% of the total applied load) as compared with a negligible distribution found during FEA (found equal to 0%) resulted in the appearance of an elevated percent difference. If this value was excluded, the maximum percent difference for the LLDF of outer girder would be 40%, found for Girder A when subjected to Load Configuration E1 wheel load placement. Thus, the distribution of forces throughout the hybrid bridge deck system were more accurately predicted by the developed FEM for concentric loading configurations rather than eccentric loading configurations. Overall, there was higher concentration of load within the immediate area of the applied wheel loads from the data obtained from the FEM as compared with experimental results. This is further indication that the modelled system was less effective at distributing load transverse throughout the hybrid bridge deck system than the as-built transverse composite action system.

## 6.2 Peak load condition

Another major objective in the development of the FEM was the ability to predict peak load conditions for additional loading configurations not tested during the experimental program. To assess the accuracy of the FEM, validation was first performed with regards to the peak load of the hybrid bridge deck system under Load Configuration C1, which was tested up to ultimate failure, as well as the linearly extrapolated peak load values from the other experimental tests conducted using service loading conditions. Extrapolation of the service load condition test results to the peak load condition was performed using the percent utilization of ultimate strain capacity in various structural elements during service load conditions tests. Using the experimental set of peak condition strain data under Load Configuration C1 as the defined maximum limit, the strain in the individual structural components under service loading conditions were extrapolated to the maximum limit with a proportionally derived peak load. The governing failure mode at the extrapolated ultimate load condition, and thus the peak load associated with failure of the governing structural element, was determined. A summary of the maximum percent utilization of the governing structural elements during the service loading condition tests is provided in Table 8.

**Table 8. Percent utilization of ultimate strain capacity in key structural elements for all load configurations**

Load Configuration	UHPC		GFRP	CFRP	GFRP rod			
	Compression	Tension			Cross-bracing	PT Rod	Strap	Vertical Rod
C1	3%	10%	5%	4%	4%	18%		
E1	3%	16%	6%	5%	4%	17%		
E2	4%	9%	8%	8%	2%	16%		
E3	3%	5%	7%	6%	2%	16%		
E4	3%	9%	5%	5%	2%	17%		
C2	2%	14%	3%	2%	3%	18%		
C3	6%	12%	5%	4%	1%	16%		
C1 (ULS)	34%	111%	86%	82%	50%	51%	19%	6%

These values represent the maximum percent utilization observed; however, for the transverse tensile strain in the UHPC slab, a large number of strain gages malfunctioned during experimental testing. This prevented a thorough and reliable analysis of peak condition extrapolation to be performed using the tensile strain data set. Instead, the longitudinal compressive strain in the UHPC slab was chosen as a representative parameter for the UHPC failure mode. A final tabulation of the extrapolated experimental peak load associated with each failure mode alongside a direct comparison with peak load calculated through FEA is presented in Table 9.

**Table 9. Summary of extrapolated peak load for service load configurations**

Loading configuration	Extrapolated minimum peak load (kN)						Governing peak load (kN)
	Vertical displacement	UHPC		CFRP tensile strain	Cross-bracing bar		
		Compressive strain	Tensile strain		Compressive strain	Tensile strain	
C1	578	438	552	689	725	539	438
E1	450	348	347	493	279	293	279
E2	341	282	635	380	106	254	106
E3	435	402	1053	486	114	643	114
E4	567	421	621	552	1022	587	421
C2	623	428	384	671	788	610	384
C3	637	270	464	631	182	502	182

The comparison of peak load between experimental results and FEA predictions, shown in Table 9, shows that failure in the UHPC slab was the governing mode of failure for all of the load configurations tested, excluding Load Configuration C2, where the extrapolated data from the mid-span vertical displacement was the limiting parameter. The percent difference between the extrapolated experimental results and the FEA predictions for peak load ranged between 0 – 12% for the governing failure mode in the UHPC whereas a higher variation of 39% was found for Load Configuration C2. It should be kept in mind that the predicted compressive failure in the UHPC slab would be a secondary mechanism following the initial tensile cracking at the top surface of UHPC slab, as a sequence in the progressive failure mechanism observed during experimental testing.

## 8. Conclusions

The outcome from the research presented in this paper is the successful development of a three-dimensional FEM capable of predicting representative global behaviour of the novel hybrid steel-free multi-girder bridge deck system. The FEM provides, with reasonable accuracy, predictions for the peak load condition and failure mode of the hybrid bridge deck system under various load configurations, confirmed through validation with experimental test results. With the globally validated FEM, design optimizations as well as additional examinations into the performance of the hybrid bridge deck system under other load configurations not yet tested in the experimental program can be evaluated. Experimental testing and analytical result both confirm that the initiation of failure commences within the inter-girder region of the UHPC slab, making the transverse tensile strength of the UHPC slab within the two outer inter-girder regions the most critical parameter of the design. Design optimization can be performed to increase the peak load of the hybrid bridge deck system by decreasing the transverse girder spacing, thereby reducing the tensile demand on the UHPC slab. This would also promote higher utilization of material capacity in the other load resisting structural elements.

Overall, the work summarized in this paper combined with the extensive experimental testing conducted previously within this research program confirms the feasible application of the developed hybrid steel-free multi-girder bridge deck system. The analysis performed demonstrates the versatility of the hybrid bridge deck system to carry a wide variety of wheel load configurations. With the aid of the developed finite element model, a reliable means of predicting the expected failure mechanism and load resistance of the hybrid bridge deck system for any load combination is readily available, without the need for extensive experimental testing.

## 9. Acknowledgements

We would like to thank the following companies for their generous donation of materials used in this research project: Lafarge Canada, Pultrall Inc., and Sika Canada Inc. Additionally, we would like to acknowledge the National Sciences and Research Council (NSERC) of Canada and the University of Calgary for their financial support.

# Investigation of Strength and Thermal Intake of Concrete Curing Through Means of Heated Water and Insulation Applied to the Exterior Surface

Jamie Warr<sup>1</sup>

<sup>1</sup>Civil Engineering Student, University of Tasmania

**Abstract:** Producing in-situ and pre-cast components at a fast rate drove research into curing methods to accelerate strength gain which remains a highly researched topic. Options to accelerate curing for in-situ operations are limited, even for pre-cast work some methods are impractical.

This paper investigates the effectiveness of accelerated curing using an insulation plus hot water (55 °C) combination that's suitable both in-situ and for pre-cast work. This reduces costs and optimises sustainability by reusing and reducing consumables.

In this research four identical concrete 'wingwalls' (slabs) are cured simultaneously each using a different part of the combination curing method, the combination itself and a control. Core temperatures were recorded and test cylinders were cured under equivalent conditions to determine compressive strengths.

In a 21 hour interval the combination produced a 120% increase in degree-hours and 83% strength increase relative to the control, the insulation produced 43% less degree-hours and 17% less strength than the combination, slightly more than the hot water method. A finite element model was produced under simplified conditions that imitated the shape of the experimental temperature-time curves.

This straightforward, effective, portable and chemically free method to cure concrete results in a significant strength gain over the short term.

**Keywords:** in-situ curing, insulation, hot water, accelerated curing, sustainability.

## 1. Introduction

Concrete has maintained a vital role in a broad range of infrastructure and civil based projects because of its compressive strength, workability, availability and cost compared to alternatives.

This significance has spurred a great deal of research into many aspects of the concreting process. For instance, attempting to configure the concretes durability, tensile or compressive strength. The quality of curing for concrete is a determining process for many of these aspects - by definition it is the application or moderation of moisture and heat to achieve the desired strength in concrete. This is why it has been the focus of concrete research for a considerable amount of time.

One of the main issues facing concrete usage is curing efficiency. Builders, engineers and many other users constantly strive for the most economical curing solution available. This obviously, but crucially, enables cheap and fast growth with financial ease on the scale of the project.

This research investigates how a reusable and portable curing system affects the heat intake and compressive strength of concrete over a period of days. A system comprising of hot water at 55 degrees Celsius irrigated on the concrete surface using soaker hoses and a 'bubble wrap' insulation overlay, is used.

The effectiveness of heat intake and compressive strength of the system is found using the Nurse-Saul maturity method by contrasting the maturity (in degree-hours) accumulated and compressive strengths of a control, to each component of the curing regime and the combination of hot water and insulation. With the aid of a computer, a model and transient thermal analysis of the systems components was created and compared with the experimental results in an attempt to obtain an approximate analytical solution.

## 2. Slab/'Wingwall' Testing

### 2.1. Procedure

Supplied concrete conformed to bridgework specifications outlined by The Department of State Growth (DSG) of Tasmania [1].

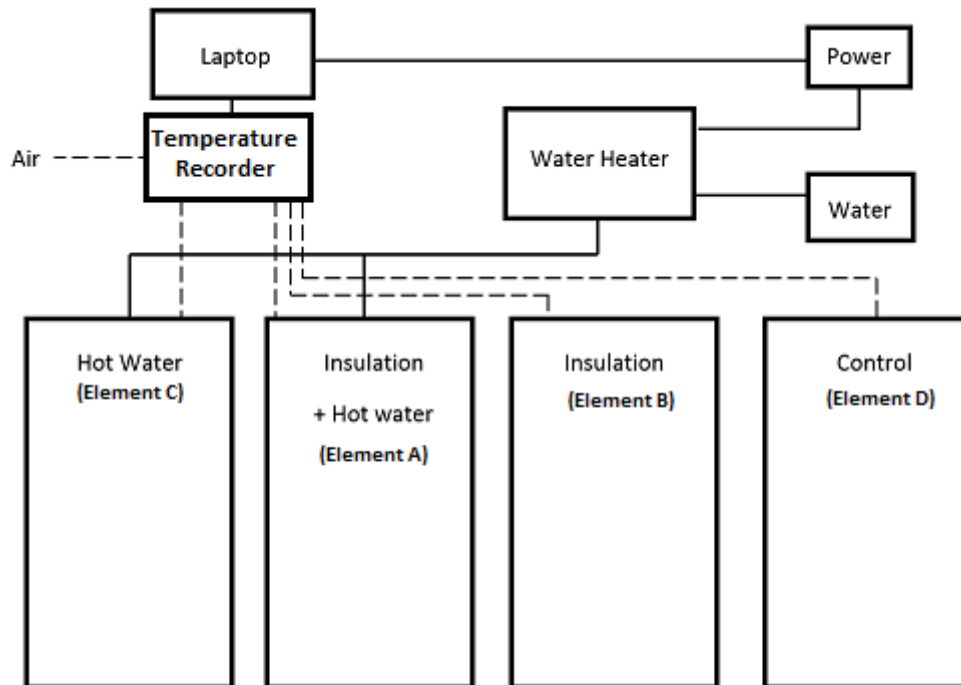

Concrete was poured into four parallel steel moulds. These moulds were rectangular of uniform thickness with dimensions of approximately 2500 x 1300 x 175 mm with a rectangular section removed from one corner (approximately 610 x 750 mm).

Each concrete element was cured under cover and outside in Latrobe (Tasmania), with one of four curing regimes:

- A control which had no curing regime (element D).
- Hot water at 55 °C using sufficient soaker hoses to uniformly saturate the surface (element C). A flow rate of  $5.7 \times 10^{-2}$  L/s was used.
- A single layer of insulation 4.5 mm thick with a thermal resistance (R value) of  $0.11 \text{ m}^2 \text{ CW}$  (element B).
- A layer of insulation with hot water irrigated between it and the concrete slab (element A).

Temperatures were measured with a thermo-resistor sensor and analogue controller system at a 30 second sample rate with an accuracy of  $\pm 1$  °C. The sensor were inserted at the approximate center of mass of the concrete element after two and a half hours from the concrete pour. Partial solidification was necessary to hold the soaker hoses. Data was then recorded for approximately 21 hours starting at 3:00 pm on the 23<sup>rd</sup> of May 2014 to 12:00 am on the 24<sup>th</sup> of May.

The curing system used can be seen in *figure 1*. An in-situ system that was previously used can be found in Appendix A (*figure A.1*).

**Figure 1. Curing system schematic.**

## **2.2. Results**

Below, *figure 2* shows the results of the temperature measurements of each concrete slab. Concrete was poured at approximately 12:40 pm.

The temperature sensor for element C proved faulty around 3.5 to 5.0 hours after commencement. Interpolation with a power law was required with existing valid data to produce the best fit curve.

Figure 2. Temperature-time curves of slab core temperatures.

### 3. Equivalent Cylinder Testing

For this research the commonly used Nurse-Saul maturity function was applied to achieve equivalent curing conditions, it appears as:

$$M(t) = \frac{1}{3600} \sum (T_a - T_o) \Delta t \quad (1)$$

Where:

$T_a$  = average temperature during period of time  $\Delta t$  (degrees Celsius).

$\Delta t$  = time interval (seconds).

$T_o$  = temperature datum at which point no strength gain occurs, typically -10 to 0 (degrees Celsius).

$M(t)$  = maturity or temperature time factor at time  $t$  (°C-hours)

For constant time intervals and the temperature datum at zero, *equation 1* above may be simplified to:

$$M(t) = \frac{\Delta t}{3600} \sum (T_a) \quad (2)$$

This maturity method is measure of the extent of hydration based on the transient energy input in the form of heat. The underlying theory is a large amount of heat in small time will progress the hydration process to the same extent as a small amount of heat in a large amount time.

Research suggests this maturity method provides a reasonable approximation for equivalent work under seven days [2]. As the hydration of the concrete isn't a linear function of temperature and the concretes life, errors tend to progress to unreasonable approximations past this time. It was also found large temperature differentials contribute to higher inaccuracies. Another maturity method that better accommodates the changes, such as the Arrhenius maturity function, should be used instead [3].

It's also suggested that the method be used for relative strength gains and not absolute strength to provide higher accuracy [2], as was used for this research

To find the error in the maturity of the concrete slabs we can modify *equation 2* by substituting the measured temperature ( $T_a$ ) with the error bound of the temperature recording system ( $\pm 1$  °C). This leads to *equation*

3 below. With  $\Delta t$  as the 30 second recording time interval, we sum over each of the 2,392 measurements made.

$$Err(t) = \frac{30}{3600} \sum_{n=1}^{2392} 1 = 19.9 \text{ } ^\circ\text{C} - \text{hours} \quad (3)$$

From the data collected in section 2.1, using equations 2 and 3, table 1 below is created.

**Table 1. Concrete maturity and error bounds.**

Element	Maturity ( $^{\circ}\text{C} - \text{hours}$ )	Difference from control (%)	Percentage of Error (%)
Element A	949.4	120	2.1
Element B	665.4	54.2	3.0
Element C	613.8	42.2	3.2
Element D	431.6	0	4.6

### 3.1. Procedure

A total of 33 Australian Standard 200 x 100 mm cylinders were cast to determine equivalent compressive strengths at 21 hours (duration of slab/element test), 7 days and 28 days for each of the elements. Element B at 28 days provided insufficient test cylinders. Three cylinders were used to determine the compressive strength at each time period, using an Avery 1000 kN universal test machine.

For concrete batch creation, casting and water bathing methods, Australian Standards 1012.1, 1012.8, 1012.8.1, 1012.9.2 were followed where applicable and appropriate. Some aggregates from the original batch were not identical for the cylinder tests, however proportions and sizes were maintained. General Purpose cement was used. Reinforcement was not considered for testing with the equivalent concrete cylinders.

The water bath held six cylinders at a time. It allowed for the moderation of the concretes maturity using a fish-tank water heater to maintain a constant temperature. After the maturity was accumulated as per table 1 above, the cylinders were allowed to sit in a humidifier maintained at a constant 21  $^{\circ}\text{C}$  for the duration of the time period required to test them.

### 3.2. Results

Table 2 below shows the compressive strengths found from the two closest results if in agreement.

**Table 2. Compressive strength results from equivalent tests.**

Element	21 Hour Equivalent Test (MPa)	7 Day Test (MPa)	28 Day Test (MPa)
Element A	17.8	29.2	33.2
Element B	15.6	26.5	-
Element C	12.9	27.4	29.5
Element D	9.7	19.2	26.7

## 4. Transient Thermal Analysis

A finite element analysis package (FEA) was used to model and solve a transient thermal analysis of each curing regime. Finite element analysis programs rely on the discretisation of an object (a model) to perform numerical analysis on a nominal segment or a vertex of the segment that is typically magnitudes smaller than the model itself. These segments are generally quadrilateral or triangular.

The numerical analysis in this case involves solving the heat equation (equation 4 below) at each vertex (coordinates of x, y and z), to determine the temperature distribution with time.

$$\frac{\partial T}{\partial t} = \frac{k}{c_p \rho} \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} + Q_{internal} \right) \quad (4)$$

Where k is the thermal conductivity of the object,  $c_p$  the specific heat,  $\rho$  the density of the medium, instantaneous time t and the instantaneous temperature T. As the concrete generates heat the variable Q provides addition for the heat generated per unit volume.

The model included the steel casting bed, convective affects from the air and hot water, internal heat generation, and effects of the insulation. Each face of the element received a different heat transfer coefficient due to the variation of wind velocity over the element, this was simplified into two cases, the back and underside of the element, and the front (wind facing) and top of the element.

The overall approach to finding a solution centred on 'guess and check'. Given the complexity of the transient thermal analysis being replicated and the limited equipment available, it was impossible to repeat the systems entirety from prior knowledge for a theoretical approach.

For every variable change the internal heat generated by the concrete was calibrated with the control element such that the output core temperature solution was significantly close to the measured values (see figure 3 (a)).

The general process was as follows:

1. Determine the internal heat generated using the control (element D) as a calibration.
2. Determine the thermal conductivity and specific heat of concrete using the insulation experimental data (element B) as the calibration. The insulation had the most accurate parameters and so using the data would allow the use of another system to calibrate without the addition of unknown variables.
3. Repeat step 1 and 2 as necessary.
4. Using the resulting thermal conductivity and specific heat of concrete found in the previous steps, determine the hot water film coefficient using the experimental data (element C).
5. Using values from the above steps produce the output for the combination curing effect (element A).

Table 3 below contains properties and boundaries researched and derived for the model.

**Table 3. Values and ranges used for thermal analysis.**

Parameter	Range	Derived from
Concrete thermal conductivity	1.00-2.36 W/m°C	[5] [6] [7]
Concrete specific heat	900-1250 J/kg°C	[5] [7]
Concrete density	2488 kg/m <sup>3</sup>	Given (batch supplier)
Insulation thermal conductivity	0.041 W/m°C	Calculated from given thermal resistance and thickness
Insulation specific heat	1155 J/kg°C	Calculated [2] [3]
Insulation density	96.2 kg/m <sup>3</sup>	Calculated (given properties)
Steal thermal conductivity	60.5 W/m°C	Given (FEA program)
Steal specific heat	434 J/kg°C	Given (FEA program)
Steal density	7850 kg/m <sup>3</sup>	Given (FEA program)
Hot water film coefficient	10-1600 W/m <sup>2</sup> °C	Empirical formulas [4]
Front/top film coefficient	29 W/m <sup>2</sup> °C	Empirical formula based on local wind speed [8]
Back/underside film coefficient	20 W/m <sup>2</sup> °C	Empirical formula based on local wind speed [8]

The starting values for the thermal conductivity and specific heat of concrete were found through general rules of mixture. Where the total value is the sum of the weighted values of each component. Further research into the properties of each component yielded a total thermal conductivity of 1.2 W/m°C and a specific heat of 1,100 J/kg°C.

#### 4.1. Results

(a) FEA analysis temperature output of control and experimental.

(b) FEA analysis temperature output of insulation and experimental.

**Figure 3. Transient thermal analysis outputs of the control/element D (a) and the insulation regime/element B (b). Plot names are in the form of thermal conductivity/specific heat for concrete of the value that was used in  $W/m^{\circ}C$  and  $J/kg^{\circ}C$  respectively.**

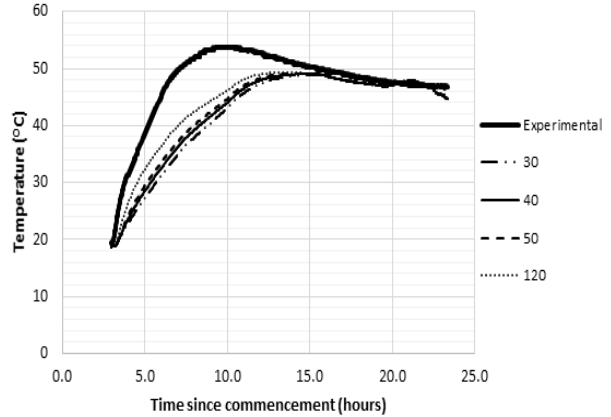

A table of  $R^2$  values to determine closeness of fit (*table 4* below) resulted in a thermal conductivity of 2.36  $W/m^{\circ}C$  and a specific heat of 900  $J/kg^{\circ}C$  for the concrete being the optimal solution. These values were used for the analysis of elements A and C.

**Table 4. Closeness of fit values from the curves generated for figure 3 (b).**

Curve (thermal conductivity/specific heat)	$R^2$ Value
1/900	0.719
2.36/900	0.798
1/1250	0.690
2.36/1250	0.738

(a) FEA analysis temperature output of hot water and experimental

(b) FEA analysis temperature output of combination and experimental.

**Figure 4. Transient thermal analysis outputs of the hot water regime/element C (a) and the combination regime/element A (b). Plot names are the hot water convection film coefficient ( $W/m^2^{\circ}C$ ) that was tested.**

## 5. Discussion

### 5.1. Equivalent Cylinder Testing

*Figure 2* and *Table 1* shows a significant difference in temperature between elements A (insulation and hot water combination) and D (control) leading to an 83% increase in compressive strength within the first 21 hours and 24% after 28 days. Elements B (insulation) and C (hot water) produced a closer maturity yielding a 61% and 33% in increase compressive strength respectively, relative to element D. The seven day tests show elements B and C converge to approximately the same compressive strength. This convergence is expected given only limited amounts of products to hydrate and a decreasing concentration.

Overall we found no immediate correlation between relative strength gain and relative thermal intake of the concrete mass, other than the fact a significant increase in thermal intake will obviously lead to an increase in compressive strength at 21 hours, as expected (see *Table B.1* and *Table 1*).

The strength gain over a period of 28 days for the hot water (55°C) test disagrees with the conclusions drawn from the research conducted by Feyne et al. (2003). They cured and tested concrete compressive strength under a variety of ambient temperatures and type III cement mixtures, with a relative humidity of 50% to 60%. They found almost all mixtures produced inferior strength at 28 days compared to a standard control. For some mixtures this lower strength gain occurred for 24 hour tests.

This research used type I (GP) cement, typically more coarse than type III, however the key difference is humidity. This research essentially used 100% humidity to cure concrete for both experimental components, allowing the hydration to occur continually and at an accelerated rate from the heat input.

We also found element C surpasses element B in compressive strength at seven days (3.4% difference in strength) which highlights the existence of random variance in test cylinders. This can be reduced by testing a greater sample size.

Reinforcement in the elements used for testing was assumed to have negligible effects for both relative strength measurements of the test cylinders and the heat differential between the concrete mass and atmosphere. As the reinforcement has a high thermal conductivity and low specific heat this would have the effect of a faster internal heat transfer. However it would not affect the concrete's hydration process or act as noticeable insulate.

We expect some difference in compressive strength and thermal intake between the cast slabs and test cylinders due to variations in aggregate properties between batches (as mentioned in *section 3.1*). This variation would undermine direct comparison of compressive strength results and thermal intake between slab and cylinder testing. However this study was specifically limited to the relative strength gain of test cylinders, with no comparison between the two tests. The overall thermal properties of the concrete between tests would vary slightly because of this, however similar aggregates were used and proportions were closely maintained to limit the variation.

Error bounds from the equipment tended to be small with *Table 1* above showing a possible maximum error of 4.6% of the total maturity accumulated.

In *Figure 2* near 20-23 hours after commencement, we see that hot water exposed to the atmosphere and concrete slab is noticeably affected by air temperature. A sharp rise in local temperature results in the core temperature of element C to greatly increase. Element D responds with a more latent and shallow increase in core temperature, with element A plateauing. This validates Grove's (1989) suggestion that ambient temperatures could have a negative impact on temperature gains of blanket (insulated) curing. The hot water test (element C) is amplified by this local increase in heat, with the insulation (element B) having no noticeable response.

### 5.2. Transient Thermal Analysis

The finite element model generated for each combination of test proved to have a very weak correlation between the experimental data recorded. This was due to the complexity of the experiment with several unknown properties left to be determined.

The hot water film coefficient for instance, that provided optimal results, tended to be relatively low – between 20 to 60 W/m<sup>2</sup>°C (see *figure 4 (a)*). For the combination regime *figure 4 (b)* shows minimal variance in core temperature when a relatively low film coefficient is used. A relatively high thermal conductivity and low specific heat of concrete produce the best results. This was expected as a sharp increase in temperature followed by a decrease was required (see *figure 3 (b)*). The high thermal conductivity in this case enables a faster internal heat transfer, where a lower specific heat promotes a responsive change.

The lack of reinforcement modelled in the analysis may cause the thermal conductivity to be higher than the true value, however the holistic approach to modelling the thermal properties of the concrete could have included this.

The major inconsistencies derive from a dynamic air convection (wind speed and temperature) throughout the 21 hour curing period that acted with varying magnitudes on each surface of the pre-cast elements.

There were however some general patterns found in the generated data. Some sections of the experimental and computer generated curve for element A appear to have superposition like qualities of the separate curves generated for elements B and C. Suggesting both curing methods have a noticeable effect in combination.

## 6. Conclusions

We began by introducing a new curing regime using insulation and hot water applied to the exterior surface of concrete. With the aim to research the extent of accelerated strength gain and the heat it imparts to the concrete this combination method provides.

Experimenting with a portable system we have demonstrated a significant increase in heat of the concrete for independent curing tests of insulation, hot water and the combination. This translated into a significant increase in compressive strength from a 21 hour equivalent test to a period of 28 days for all tests compared to a control.

The following conclusions can be drawn:

- Hot water and insulation in combination maintain a noticeably higher compressive strength than each component separately and a control, over a 28 day period.
- For this concrete mixture and scenario, the insulation maintains a slightly higher average internal temperature than irrigating the surface of the concrete with hot water.
- Local air temperature can have a significant effect on the internal temperature of the hot water curing method.
- Both insulation and hot water tests converge in compressive strength quickly, reaching a similar strength near seven days.
- The effects of insulation and hot water on the thermal intake and strength of concrete will vary significantly depending on the constituents of concrete.
- Convection of air and hot water were sensitive to the model, and dynamic over 21 hours.
- Tests of hot water (55 °C) and insulation provided some superposition effects on the temperature and the magnitude of degree-hours accumulated for the combination curing method.

# Comparative Performance of Recycled Plastic and Polypropylene Commercial Fibres with Plain Concrete

Badr S. Al-Tulaian<sup>1</sup>, Mohammad J. Al-Shannag<sup>2</sup>, Abdulrahman M. Al-Hozaimy<sup>3</sup>

<sup>1</sup>Patent Specialist of Civil Engineering, Saudi Patent Office

<sup>2&3</sup>Professor of Civil Engineering, King Saud University

**Abstract:** Manufacturing of fibres from industrial or postconsumer plastic waste is an attractive approach with such benefits as concrete performance enhancement, and reduced needs for land filling. The main objective of this study is to investigate the effect of Plastic fibres obtained locally from recycled waste on plastic shrinkage cracking of concrete. The results indicate that recycled plastic RP fibre of 50 mm length is capable of controlling plastic shrinkage cracking of concrete to some extent, but are not as effective as polypropylene PP fibres when added at the same volume fraction. Furthermore, test results indicated that there was the increase in flexural strength of RP fibres and PP fibres concrete were 12.34% and 40.30%, respectively in comparison to plain concrete. RP fibres caused a significant increase in compressive strengths up to 13.02% compared to concrete without fibre reinforcement.

**Keywords:** Concrete, Plastic, Shrinkage Cracking, Compressive Strength, Flexural Strength, Toughness, RF Recycled Fibres, Polypropylene PP Fibres.

## 1. Introduction

Plastic shrinkage cracking of concrete is still a major problem in concrete members with large surface areas, such as slabs on grade, bridge decks and concrete pavements. Plastic shrinkage occurs in all fresh cement-based materials within the first few hours after they have been placed, Toledo et al. [1], especially during hot, windy and dry weather which can cause a fast rate of surface water evaporation. When the rate of evaporation exceeds the rate of bleed water rising to the surface, the concrete mixture will begin to shrink, Wang et al. [2]. If the shrinkage is restrained, tensile stress develops and can cause cracks.

The fibres provide bridging forces across cracks and thus prevent the cracks from growing. In addition, the large pores that are introduced at the fibre-matrix interfaces are believed to provide bleeding channels which supply water to replenish the water lost from the surface. As a results, the capillary stress between the solid particles, and hence the free plastic shrinkage potential, is reduced [3].

Saudi Arabian Basic Industries Company (SABIC) has been a leading force in the development of the Kingdom of Saudi Arabia plastic industries. There are around 450 thermoplastic processing units in KSA with an overall market demand of 400 ktpa (kilo ton per annual) polyethylene, 200 ktpa polyvinyl chloride (PVC), 100 ktpa polystyrene (PS), 70 ktpa polyethylene terephthalate (PET) and 30 ktpa polyester (PES) fibres, Alhozaimy et al. [4]. Polyethylene terephthalate (PET) is a plastic material commonly used in beverage containers and other products.

Study, Parviz et al. [5], demonstrated the effect of discrete reinforcement systems of recycled plastic fibres on enhancing the resistance of concrete to restrained shrinkage cracking and decrease the maximum crack width. They investigated that improvements in restrained shrinkage crack control and impact resistance was particularly significant and comparable to those of virgin fibres. Discrete reinforcement systems also delay the initiation of cracking. Alhozaimy and Alshannag [4] test results indicated a significant improvement in crack-arresting mechanism of the concretes reinforced with recycled plastic of low density polyethylene fibres (LDPE) compared to plain concrete. They observed that increasing the recycled fibre volume up to 3% caused no plastic shrinkage cracking of concrete slabs.

The use of recycled fibres from industrial or postconsumer waste could offer effective reinforcement for concrete and additional advantages of waste reduction and resources conservation. Limited researches have been conducted on the use of recycled fibres in concrete to control shrinkage cracking. This research provides a more comprehensive testing program to explore the various parameters influencing the performance of recycled plastic RP fibres as crack arrestors in concrete and compare their performance with that of commercial polypropylene PP fibres particularly under hot-dry environment.

## 2. Experimental Program

Ordinary Portland cement (Type I) was used. Coarse aggregates were crushed limestone obtained from quarries around Riyadh and were a blend of 3/4" (20 mm) and 3/8" (10 mm) sizes. The fine aggregate was a blend of crushed sand and red sand obtained from the crushed limestone. The specific gravity and absorption capacity of the coarse and fine aggregates were determined in accordance with (ASTM C 127) and (ASTM C 128), [6, 7]. The specific gravity of coarse aggregate of 3/4" (20 mm) and 3/8" (10 mm) sizes were 2.66 and 2.69, respectively and their absorption capacities were 1.13% and 1.48%, respectively. The specific gravities of the crushed sand and red sand were 2.64 and 2.66, respectively and their absorption capacities were 1.62% and 0.38%, respectively. The material properties of coarse and fine aggregates are given in Table 1.

The recycled Plastic RP fibres were obtained from small workshops operating in Jeddah. Process of recycling plastic includes; first, placing the plastic waste in a machine to be cut into small pieces. Second, these small pieces of plastic will be melted at a temperature depending on the plastic type. Third, the melted plastic will pass through perforated plate and extracted as a plastic wire with the width of 2.0 mm size. Finally, the plastic wires were cut into small pieces to be in the form of fibres. For the present study, recycled PET fibres of 2.0 mm width will be cut into 50 mm long pieces and used as reinforcing fibres for concrete at volume fraction 1.0%. commercial polypropylene PP fibres of 30 mm length at volume fraction 0.50% (Figures 1, 2) shows images of the manufactured recycled PET fibres and PP fibres, respectively. The basic properties of fibres are presented in Table 2.

**Table 1. Coarse and fine aggregate material properties**

Type	Specific gravity	Fineness modulus	Water absorption (mass %)	Unit weight (kg/m <sup>3</sup> )	Moisture content (%)
3/4"	2.66	7.05	1.13	1533	0.32
3/8"	2.69	5.83	1.48	1305	0.59
Crushed Sand	2.64	4.6	1.62	1580	0.55
Red Sand	2.66	1.02	0.38	1668	0.12

**Table 2. Properties recycled PET and Virgin PP fibres**

Fibre type	Strand shape	Specific gravity	Tensile strength (MPa)	Length (mm)	Width (mm)
RPF - (PET)	Flat	1.38	310	50	2.0
Virgin - (PP)	Circular	0.90	450	30	1.0

Fig. 1 : Picture of 50 mm long RP fibres used in the study.

Fig. 2 : Picture of Virgin PP fibres used in the study.

Plastic shrinkage cracking test plan, flexural strength and compressive strength tests were conducted for the various types of fibres. Two different series of RP fibres for concrete mixtures were used for casting ordinary concrete designated as R.P.C.3, R.P.C.4 and PP fibres as P.P.C.5, P.P.C.6 and plain mixture as N.F.C.1, N.F.C.2 without fibres were cast in the concrete laboratory as shown in Table 3. The mold of slab used in the test was a 1000 x 1000 x 100 mm, standard 100 mm of concrete cubes for compressive strength tests according to (BS 1881 Part 116), [8], 600 x 150 x 150 mm prisms for the flexural tests according to (ASTM C 78) and (JSCE-SF4), [9, 10] were used. For all mixtures, measurements of outdoor temperature during the time of casting ranged between 41°C to 45°C, relative humidity (RH) between 18% to 20 % and maximum wind speed 3.00 to 4.50 m/s. It was monitored for 24 h, during which time visible cracks appeared.

**Table 3. List of specimens and the number of specimens used for each combination.**

Design Mix.	Fibre volume fraction (%)	No. slabs Plastic shrinkage	No. specimens flexural strength	No. specimens compressive strength
N.F.C.1	----	2	2	6
N.F.C.2	----	2	2	6
R.P.C.3	1.00	2	2	6
R.P.C.4	1.00	2	2	6
P.P.C.5	0.50	2	2	6
P.P.C.6	0.50	2	2	6

The concrete mixes were prepared outdoor under hot-dry environment conditions to observe the plastic shrinkage cracking on the slabs. Proportions of mixtures ingredients used in this study were designed as given in Table 4. All mixtures were prepared in a rotary planetary mixer with capacity of 180 liters. The coarse and fine aggregate and absorption water were measured and placed into the mixer and mixed for 1.0 minute. After that the cement, the rest of the free water were added and mixed for three minutes followed by 2.0 minutes break and then another 3.0 minutes mixing was performed. Next, the fibres were added into the mixer and then mixed for three minutes.

**Table 4. Properties recycled PET and Virgin PP fibres**

Design Mix.	Fibre length (mm)	Fibre volume fraction (%)	Cement: Coarse Agg.: Fine Agg.: Water
N.F.C.1	----	----	1.00 : 2.40 : 2.66: 0.55
N.F.C.2	----	----	
R.P.C.3	50	1.00	1.00 : 2.40 : 2.66: 0.55
R.P.C.4	50	1.00	
P.P.C.5	30	0.50	1.00 : 2.40 : 2.66: 0.55
P.P.C.6	30	0.50	

The mix proportions of plain, RP fibres and PP fibres reinforced concrete used in this study are as follows:

Free w/c ratio = 0.55

In case of fibrous concrete the weight of RP and PP fibres for different volume fractions was calculated by Equation 1 as follows:

$$W_f = G_s \times \left(\frac{V_f}{100}\right) \times 1000 \quad (1)$$

Where,

$W_f$  : Weight of RP/ PP fibres ( $\text{kg/m}^3$ ).

$V_f$  = Volume fraction of fibres (%).

$G_s$  = Specific Gravity of RP/ PP fibres.

Using the above expression the weight of RP and PP fibres per  $1.00 \text{ m}^3$  of concrete is given in the Table 5.

**Table 5. Quantity of RP and PP fibres in fibrous concretes.**

Fibre type	Volume fraction $V_f$ (%)	Specific Gravity, $G_s$	Weight of Fibre ( $\text{kg/m}^3$ )
RP fibres	1.00	1.38	20.7
PP fibres	0.50	0.92	4.6

## 2.1 Tests on Fresh Concrete

### 2.1.1 Temperature and Slump Tests

Temperature of the materials of the mixtures fresh concrete was measured using the digital thermometer shown in Table 6. This temperature was determined in accordance with (ASTM C1064), [11] standard.

The digital thermometer was also used for measuring the temperature of the concrete. The slump test was used to measure workability of all the concrete mixes and was conducted in accordance with (ASTM C143), [12] as shown in Table 7. The slump of plain and fibrous concrete was determined at the concrete laboratory.

**Table 6. Temperature test for fresh concrete.**

Design Mix.	N.F.C.1	N.F.C.2	R.P.C.3	R.P.C.4	P.P.C.5	P.P.C.6
Cement Temp. °C	40.1	40.1	31.0	31.0	24.3	24.3
Coarse Agg. Temp. °C	40.3	40.3	30.1	30.1	34.6	34.6
Coarse Agg. Temp. °C	37.5	37.5	30.5	30.5	37.1	37.1
Crushed Sand Temp. °C	40.3	40.3	31.1	31.1	36.5	36.5
Red Sand Temp. °C	40.0	40.0	31.3	31.3	36.8	36.8
Water Temp. °C	23.0	23.0	22.5	22.5	22.0	22.0
Casting Temp. °C	32.1	32.1	28.6	28.6	29.1	29.1
Ambient Temp. °C	44.0	44.0	42.0	42.0	41.0	41.0

**Table 7. Slump test for fresh concrete.**

Design Mix.	Fibre volume fraction (%)	Fibre Length (mm)	Slump of Slab 1 (mm)	Slump of Slab 2 (mm)	Average Slump (mm)
N.F.C.1	Plain	0.00	75	85	80
N.F.C.2	Plain	0.00			
R.P.C.3	50	1.00	70	83	77
R.P.C.4	50	1.00			
P.P.C.5	30	0.50	75	90	82
P.P.C.6	30	0.50			

### 2.1.2 Wind Speed and Rate of Evaporation Tests

The anemometer device used for measuring the wind speed was placed on the surface of the mixture. This wind speed was determined in accordance with (ASTM D 5527), [13] standard. Plastic shrinkage cracking generally occurs in fresh concrete when the evaporation rate is high. High evaporation rates are caused by high temperatures, high wind speeds and low relative humidity.

The percentage of water evaporated was calculated as the ratio of water evaporated to the total water added to the mix. The rate of water evaporation was evaluated by recording the change in weight using a digital balance of 0.01-g sensitivity. The rate of evaporation investigate was measured by using Equation 2. The evaporation rate were recorded and presented in Table 8. A graphical method to estimate evaporation rate is described in (ACI 305R), [14]. The concrete temperature recorded was 29°C to 32°C and the average wind speed, ambient temperature and humidity were in the range of 3.00 m/s to 4.50 m/s, 41°C to 45°C and 18% to 20%, respectively. The evaporation rate for concrete slabs approaches 1.20 kg/m<sup>2</sup>/h, the chance of plastic shrinkage cracking occurring is high (ACI 305R).

**Table 8. The rate of evaporation recorded.**

Time	Weight of water (kg)	Loss water weight $L_w$ (kg)	Rate of Evaporation $R_{evp}$ (kg/m <sup>2</sup> /h)	Average of evaporation rate (kg/m <sup>2</sup> /h)
12:25	2.880	----	----	1.12
1:25	2.825	0.055	0.83	
2:25	2.730	0.095	1.43	
3:25	2.672	0.078	1.18	
4:25	2.612	0.070	1.06	
5:25	2.550	0.072	1.10	

$$R_{evp} = \frac{W_L}{A_{cont}} \quad (2)$$

Where,

$R_{evp}$  : Rate of Evaporation (kg/m<sup>2</sup>/h).

$W_L$  : Loss of water weight (kg).

$A_{cont}$  : Area of container (0.3 m , 0.22 m) .

## 2.2 Tests on Hardened Concrete

### 2.2.1 Compressive and Flexural Strength Tests

The compressive strength test was performed on a 100 mm cube specimen tested for concrete at right angles to the position of cast according to British Standard (BS 1881: part 116), [8]. Compressive strength test consisted of applying a continuous compressive axial load at a rate of 0.5 MPa/s until failure occurs.

Flexural strength was measured using prism specimens 600 x 150 x 150 mm under third point loading in accordance with (ASTM C 78), [9]. The toughness was calculated in accordance with (JSCE-SF4), [10] Japanese Standard . The specimens tested were turned on their sides with respect to their position as molded.

The specimens were loaded at a rate of 0.50 mm/minute using displacement control. The prisms were loaded in an Amsler press using a displacement rate of 0.50 mm/minute. The loads and mid span deflections were measured using 10 KN load cell and 25 mm LVDT respectively. The load-deflection data was recorded by using a data logger. The reading from the data logger was transferred to a computer to plot the load-deflection curve during testing.

The flexural strength ( $f_s$ ) was determined in accordance with (ASTM C 78), as an average value of three specimens, the flexural strength or modulus of rupture was calculated using simple beam bending Equation 3, using the first peak load value in the load-deflection curve, according to the following equation:

$$f_s = \frac{PL}{bh^2} \quad (3)$$

Where:

$f_s$  = The flexural strength in MPa.

$P$  = The peak load in N. (first peak for load-deflection curve with multiple peaks).

$L$  = The supported span in mm (450 mm).

$b$  and  $h$  = The width and the depth of specimen ( $b = h = 150$  mm for the tested prism).

Toughness ( $T$ ) is defined as the total energy absorbed prior to complete separation of the specimen. It was calculated as the area under the load-deflection curve up to a deflection of 1/150 times the span, which is equivalent to 3.0 mm for the prism specimen tested (span= 450 mm) as shown in Figure 3. Numerical approach (trapezoidal method) was used, to determine the area under the curve, by dividing the area under the curve into trapezoids. The toughness is calculated by summing up all the trapezoid areas up to 3.0 mm deflection. The toughness which is equal to the area under load-deflection curve up to 3.0 mm according to (JSCE-SF4) , [10] Japanese Standard.

Fig. 3 : Flexural characteristics testing setup.

## 2.2.2 Plastic Shrinkage Cracking Measurement

After casting the plastic shrinkage slabs described in results, the following day, the cracks on the hardened concrete surface were mapped to obtain pattern, length of cracking, crack width and total area of cracking. For mapping 10 mm grid was drawn on the surface of the slabs and the cracks on the slab were mapped on graph sheet. The width of each crack was measured at regular intervals along its length using a microscope as shown in Figure 4. The length of each crack was determined by placing a string along the crack and then measuring the length of string. The summation of product of average width and length of crack for all the cracks in a slab was calculated to obtain total crack area per square meter.

Fig. 4 : The microscope used for measuring crack width.

## 3. Results And Discussions

### 3.1 Plastic Shrinkage Cracking

All the plastic shrinkage slabs were placed outdoor in hot-dry environment condition during the month of September in Riyadh. The average wind speed, ambient temperature and humidity were in the range of 3.00 m/s to 4.50 m/s, 41°C to 45°C and 18% to 20% respectively. The evaporation rate for concrete slabs approaches 1.20 kg/m<sup>2</sup>/h, the chance of plastic shrinkage cracking occurring is high (ACI 305R), [14].

Plastic shrinkage cracks were mapped for all the slabs. These mapping patterns are presented in Figure 5. From these mappings, it is clearly seen that RP fibre with 1.00% and PP fibre with 0.50% concrete content exhibited less cracking.

The influence of adding different fibre types on crack measurements of plastic shrinkage in terms of the average crack width, maximum crack width, average crack length, total crack area and crack numbers is illustrated in Table 9. Average crack width was 0.27 mm/m, the maximum crack width was 0.40 mm for plain control specimens. Average crack length was 903 mm/m; total crack area was 254 mm<sup>2</sup>/m<sup>2</sup> and crack numbers were 2 cracks for plain control slabs.

A comparison of average crack width, crack length and total crack areas obtained for plain, RP fibre and PP fibre concrete is shown in Figures 6A thru 6C. The average crack width and total crack area decreased for both types of RP fibre and PP fibre. The significant reduction in plastic shrinkage cracks was obtained at a volume fraction of 1.00% RP fibre and 0.50% PP fibre concrete, there was no plastic shrinkage cracks in one of the slabs and cracks in the other was negligible. Plastic shrinkage cracking was shown to be connected with initial crack time. This result is clearly reflected in the data of initial crack time for three mixtures given in Table 10.

Fig. 5 : Plastic shrinkage cracking at 0.00% .

**Table 9. Plastic shrinkage of plain and RF fibres concrete slabs**

Design Mix.	Crack Measure	Slab No.1	Slab No.2	Average
N.F.C. 1&2 VF = 0%	Avg. Crack Width (mm/m)	0.21	0.32	0.27

### 3.2 Compressive and Flexural Strength of Concrete

The results for the plain, RP fibres and PP fibres concrete ( i.e. average of three cubes) compressive strength test are summarized in Table 11. The comparison of compressive strength at 7, 14 and 28 days for control, RP fibres and PP fibres contents of volume fraction 1.00% and 0.50% respectively. The results indicate an increase in compressive strength of RP fibre and PP fibre concrete compared to plain concrete.

The increase in compressive strength for concrete content of RP fibre and PP fibre at 7 days was 3.00% and 26.44% respectively, whereas the increase at 14 days was 10.70% and 24.14% respectively and at 28 days was 13.02% and 15.60% respectively, compared to control. The plain concrete specimens failed in a brittle manner and shattered into pieces. In contrast, all the RP fibres and PP fibres samples after reaching the peak load could still remain as integral piece, with fibres holding the mortar matrices tightly together.

**Table 11. Compressive strength of all concrete specimens**

Specimen	Design Mix.	Fibre Volume Fraction (%)	Compressive strength (MPa)		
			7-Days Average	14-Day Average	28-Day Average
Plain	N.F.C.1	0.00	25.15	29.00	34.95
	N.F.C.2	0.00			
Specimen with RPF	R.P.C.3	1.00	25.90	32.10	39.50
	R.P.C.4	1.00			
Specimen with PPF	P.P.C.5	0.50	31.80	36.00	40.40
	P.P.C.6	0.50			

The results for the plain, RP fibres and PP fibres concrete ( i.e. average of two prism) flexural strength test and toughness are summarized in Table 12. Load-deflection behavior under flexure for different fibres types of RP and PP concretes are presented in Figures 7A thru 7D. The curves presented in each of these figures represent plain and containing RP and PP fibres of concrete.

The results indicate an increase in flexural strength and toughness of RP fibre concrete compared to plain concrete. In each of these figures one curve represent the RP fibres and PP fibres concrete is plotted with the control. The plain concrete specimens broke into two pieces once the peak load was reached, with very little energy absorption. The fibres of concrete specimens, on the other hand, exhibited a virtual ductile behavior with RP fibres and PP fibres bridging the cracks.

**Table 12 Flexural strength and toughness of all concrete specimens**

Specimen	Design Mix.	Flexural Strength (MPa)	Average Flexural Strength (MPa)	Toughness (N.mm)	Average Toughness (N.mm)
Plain	N.F.C.1	3.81	3.97	17.95	15.11
	N.F.C.2	4.12		12.25	
Specimen with RPF	R.P.C.3	4.85	4.46	77.22	72.34
	R.P.C.4	4.05		67.63	
Specimen with PPF	P.P.C.5	5.52	5.57	38.24	38.25
	P.P.C.6	5.60		38.26	

**Fig. 7A: Comparison of flexural strength for plain**

**Fig. 7B: Flexural strength of plain concrete specimen.**

Fig. 7C: Flexural strength at 1.00% RP fibre, length 50 mm.

Fig. 7D : Flexural strength at 0.50% PP fibre, length 30 mm.

A comparison of flexural strength and toughness obtained for plain, RP fibres and PP fibres is shown in Figures 8A and 8B. The increase in flexure strength for RP fibres, at 1.00% volume fraction was 12.34%, whereas the increase in flexure strength for P.P fibres, at 0.50% volume fraction was 40.30% compared to control of concrete. The increase in toughness for R.P fibres, at 1.00% volume fraction was 379.00%, whereas the increase in toughness for P.P fibres, at 0.50% volume fraction was 153.00% compared to control of concrete.

The load-deflection curves of RP fibres and PP fibres specimens mainly consisted of three regions. First region is the region up to the point of maximum load called the pre crack (linear elastic behavior) region. Second region is between post crack and load stable regions, and third region is the load stable region. The second and third regions are the post crack regions. In contrast, load-deflection curves of the plain concrete specimens consisted of only first region up to the point of maximum load.

The flexural strengths of all the mixes obtained from the load–deflection relationships. The increase in flexural strength of RP fibres and PP fibres concrete were in range from 12.34% to 40.30% in comparison to plain concrete. Therefore, it may be concluded that the addition of RP and PP fibres to concrete affect the flexural strength significantly. The peak load in the in the third region was higher for mixes with higher volume fraction of RP fibres. The increase in the peak load for 0.50 % content PP fibre was 40.30% higher when compared with plain concrete of 0.0% RP fibre.

Fig. 8A : Comparison of flexural strength for all specimens.

Fig. 8B : Comparison of toughness for all specimens.

Toughness of fibrous concrete was calculated following (JSCE-SF4) guidelines, as the area under the load-deflection curve up to a specified deflection. In this study the limit on the final deflection was fixed at 3.0 mm. Because of the fibres bridging cracks in matrix, the toughness of fibre reinforced concrete was significantly higher than that of plain concrete. The RP and PP fibre also seems to affect toughness. Increasing the volume fraction of RP fibres to 1.00% caused a substantial increase in toughness compared to PP fibres at 0.50% volume fraction.

#### 4. Conclusion

This study investigated the performance of recycled plastic RP fibres as concrete reinforcement with commercially available polypropylene PP fibres. Also, To show the effect of recycled plastic RP/PP fibres

on the flexural strength, toughness and compressive strength of concrete. Based on the results of this investigation following conclusions are made:

- No plastic shrinkage cracks were observed in concrete slabs at 1.00% and 0.50% volume fraction of (recycled plastic) RP and (commercial Polypropylene) PP fibres, respectively.
- RP fibre showed a substantial increase in toughness and a slight decrease in flexural strength of plain concrete at a fibre volume fraction of 1.00% compared to PP fibres at fibre volume fraction of 0.50%.
- RP fibres caused a significant increase in compressive strengths, at the fibre volume fraction used up to 13.02% compared to concrete without fibre reinforcement.
- Based on this study, it is concluded that recycled plastic Polyethylene Terephthalate (PET) of 50 mm length may be used as a reinforcing fibres at 1.00 % volume fraction to control plastic shrinkage cracking and increase flexural toughness of concrete .

The proceedings contain 171 papers across 14 themes. All the papers included in the proceedings have been selected on the basis of at least two peer reviews which were provided by independent reviewers (referees) who were experts in the subject field of the paper.

The theme of the conference is Research into Practice. The Concrete Institute of Australia is an industry led association whose primary charter is to promote good practice in concrete construction. The theme is in line with this charter and is relevant in the current climate where the Australian industry is being asked for greater participation in R&D while the researchers are being asked to show greater impact and practical outcomes of their research. The proceedings contain papers from 20 different countries. Nearly half of them are from Industry and half from Researchers.
