

**27<sup>th</sup> Biennial National Conference of the  
Concrete Institute of Australia in conjunction with  
the 69<sup>th</sup> RILEM Week**

**concrete**  
30 August – 2 September  
Melbourne, Australia **2015**

**construction innovations:**  
RESEARCH INTO PRACTICE

## **Chair's Preface**

The proceedings contain 171 papers across 14 themes. All the papers included in the proceedings have been selected on the basis of least two peer reviews which were provided by independent reviewers (referees), who were experts in the subject field of the paper. We are grateful to the independent reviewers for their time and effort in reviewing the papers and providing reviews in a timely manner.

***Professor Jay Sanjayan***

Swinburne University of Technology

**Conference Chair**

Concrete 2015

Proceedings of the 27<sup>th</sup> Biennial National Conference of the Concrete Institute of Australia  
in conjunction with the 69th RILEM Week

*"Construction Innovations, Research into Practice"*

30 August – 2 September 2015, Melbourne, Australia

Published by the Concrete Institute of Australia

Suite 401, Level 4, 53 Walker Street, North Sydney NSW 2060, Australia

Tel: (02) 9955 1744

Fax: (02) 9966 1871

Email: [admin@concreteinstitute.com.au](mailto:admin@concreteinstitute.com.au)

Publication Date: 30 August 2015

ISBN: 978-1-943847-70-9

## **Organising Committee**

### **Chair**

Prof Jay Sanjayan, Swinburne University of Technology

### **Technical Program Committee Chair**

Dr Kwesi Sagoe-Crentsil, CSIRO

### **Committee Members**

David Millar, CEO, Concrete Institute of Australia

Prof Marita Berndt, Centre for Sustainable Infrastructure, Swinburne University of Technology

Simon Hughes, Westkon Precast

Fred Andrews-Phaedonos, Vic Roads

Vas Haitas, ITW Construction Systems

Shan Kumar, Hickory Group

Gary Wyatt, Calibre Consulting

Indubhushan Partnaikuni, RMIT University

Tuan Duc Hgo, The Melbourne University

Rebecca Gravina, RMIT University

### **Parallel Session Managers**

Chandani Tennakoon, Swinburne University of Technology

Max Un, Swinburne University of Technology

Behzad Nematollahi, Swinburne University of Technology

Rackel San Nicolas, University of Melbourne

### **Technical Committee and Reviewers**

Prof. Jay Sanjayan, Swinburne University of Technology (Conference Chair)

Dr Kwesi Sagoe-Crentsil, CSIRO (TC Chair)

Joanne Portella, EMS consultants

Prof Priyan Mendis, Melbourne University

Dr Rackel San Nicolas, Melbourne University

Behzad Nematollahi, Swinburne University of Technology

Dr Ahmad Shayan, ARRB Pty Ltd

Ahmad Mohd Ali, Swinburne University of Technology

Dr Pre de Silva, Australian Catholic University

Prof Riadh Al-Mahaidi, Swinburne University of Technology

Prof Emad Gad, Swinburne University of Technology

Prof Sujeeva Setunge, RMIT University

Prof Vijaya Rangan, Curtin University of Technology

A/Prof Faiz Shaikh, Curtin University of Technology

Dr Arnaud Castel, University of New South Wales

Prof Ian Gilbert, University of New South Wales

Dr Vinh Dao, University of Queensland

Dr Liza O'Moore, University of Queensland

Prof Hong Hao, Curtin University of Technology

Dr James Aldred, AECOM

Dr David Law, RMIT University

Dr Weena Lokuge, University of Southern Queensland

A/Prof Muhammad Hadi, University of Wollongong

Professor Hao Wang, University of Southern Queensland

Dr Sameh Salib, Ryerson University, Canada

Mr Prabir K Sarker, Curtin University

Chandani Tennakoon, Swinburne University

Fred Andrews-Phaedonos, Victoria Roads

Prof Marita Berndt, Swinburne University of Technology

Dr Michael Khrapko, RILEM

Chi Hou Un, Swinburne University of Technology

## **Table of Contents**

### **Keynote Presentations**

Ultra High Performance Ductile Concrete: The Delivery from Research into Practice Stephen Foster and Yen Lei Voo	1
Low Carbon Emission Geopolymer Concrete: from Research into Practice Jannie S.J. van Deventer and John L. Provis	12
Creep and Shrinkage of Concrete – from Theoretical Background and Experimental Characteristics to Practical Prediction Models Harald S. Müller Raphael Breiner and Vladislav Kvitsel	13

### **Construction Methods**

Concrete Hinges at Legacy Way Peter Boesch, Chin Cheah and Peter Miller	33
Challenges, Opportunities and Design Impacts for Different Construction Methods on Curtis Island LNG Jetties Jesper Jensen and Peter Kastrup	44
A Bond-Slip Modelling Approach for the Transfer Length of Pre-tensioned Concrete Rik Steensels, Lucie Vandewalle and Hervé Degée	55
Design for Construction Cockburn Gateway Stage 3 Case Study Bassam Matty	63
An Innovative Solution for Temporary Movement Joints in Concrete Floors Lance Rogers	73
Officer South Sewage Pumping Station – A Diaphragm Walling Case Study Marc Peril and Jaya Weerasinghe	83
Expansion and Mechanical Properties of Reactive Concrete incorporating Fused Thamer Kubat, Ahmad Shayan and Riadh Al-Mahaidi	94
Construction 3D Printing Laurie Edwards, Camille Holt, Louise Keyte, and Redmond Lloyd	101
The Application of Scattering-filling Stone Concrete on Highway Pavement Weiguo Shen, Xing Cheng, Liu Cao, Xinling Li, Chaochao Li and Guiming Wang	111
Preparation and Application of 3D Printing Materials in Construction Xiqiang Lin, Tao Zhang, Liang Huo, Guoyou Li, Nan Zhang, Baohua Wang	118

## **Repair and Retrofitting**

The restoration and repairs of the Sir William Goodman Bridge designed by Sir John Monash, Adelaide John Woodside and Leo Noicos	128
Condition Assessment and Structural Repair Solutions for the Renovation of the Sheraton Hotel at Doha, Qatar Satyajit Datar and Sajeev Kumar Krishnan	138
Adelaide Railway Station Façade Conservation Works Structural Engineering Aspects David Kennedy	147
A Variety of Remediation, Maintenance and Serviceability in its 15 Year Life Peter Kastrup and Andrew Turnbull	152
Design of FRP retrofitted concrete structures using AS5100 Part 8 Binh Pham	161
Investigation of Corrosion, Repair Assessment and Quality Assurance of a Basement subject to Saline Water Ingress Jonathon Dyson, Marton Marosszeky and Frank Papworth	167
Experimental Study on Anchorage Behaviour of the CFRP Grid in Mortar Bo Wang, Kimitaka Uji, Junlei Zhang, Atsushi Ueno, Kentaro Ohno and Tran Vu	177
Influence of Fiber Net Reinforced Mortar Repair Coating on the Crack Opening Resistance of Concrete Yoshinori Kitsutaka and Yukihiro Oyama	187
Performance of Fire-damaged Concrete Members Strengthened with NSM Laminates Embedded in Epoxy Adhesive Awad Jadooe, Riadh Al-Mahaidi and Kamiran Abdouka	193
Behavior of Squat Columns Strengthened with Fiber Reinforced Concrete Jacket Reza Hassanli and Minoru Kunieda	203

## **Failure Mode and Risk Analysis**

A Review of Limit State Design Principles and Practice Douglas Jenkins	218
Fasteners to Concrete: Failures and Solutions D. J. Heath, E. F. Gad and J. Lee	228
AEFAC Anchor Installer Certification Program Jessey Lee, David Heath and Emad Gad	238
Guide to Seismic Design & Detailing of Reinforced Concrete Buildings in Australia Scott Munter, John Woodside and Peter McBean	248

## Structures Research and Applications

Assessment of the Performance of a 24 Year Old Coating Applied to Concrete Bridge Piers Since Construction in a Saline Tidal Environment Fred Andrews-Phaedonos, Ahmad Shayan and Aimin Xu	259
Behaviour of Concrete Filled Steel Stub Columns During and After Fire Exposure Zhong Tao, Xing-Qiang Wang, Tian-Yi Song and Lin-Hai Han	268
Dynamic Performance Criteria for Suspended Courts at the National Tennis Centre Mark Sheldon and Benjamin Delaney	278
Flexural Response of GFRP-Reinforced Geopolymer Concrete Beams Ginghis B. Maranan, Allan C. Manalo, Warna Karunasena, Brahim Benmokrane and Priyan Mendis	287
An Experimental Study on the Long-Term Behaviour of Simply-Supported and Continuous Reinforced Concrete Slabs Md Mahfuzur Rahman, Gianluca Ranzi, Daniel Dias-da-Costa, Arnaud Castel and Raymond Ian Gilbert	297
Influence of environmental temperature and moisture conditions on the fatigue resistance of concrete Yasuhiro Koda, Shohei Minakawa and Ichiro Iwaki	307
An Approach for the Quantification of Ductility and Robustness of Reinforced Concrete Beams and Slabs R. Ian Gilbert, Stephen Foster and Ankit Agarwal	313
Experimental study of the mechanical behavior of shear-critical prestressed and reinforced concrete beams Kristof De Wilder, Guido De Roeck and Lucie Vandewalle	322
Development of a New Design Expression for the In-Plane Shear Capacity of the Partially Grouted Concrete Masonry Walls. Thangarajah Janaraj and Manicka Dhanasekar	332
Transient Heat Transfer Analysis of Reinforced Concrete Members Using a Discrete Crack Approach D. Dias-da-Costa, L. Godinho and G. Ranzi	343
In-Plane Behavior of Unbonded Post-Tensioned Concrete Walls Reza Hassanli	353
Concrete Slab and Footing Systems for Large Industrial Buildings. A Critical Overview of Current Design Methods for Reactive Clay Sites Anthony J Davis and Brian Ims	362

## **Fibres FRP Research and Applications**

Creep of Cracked Polymer Fiber Reinforced Concrete Rutger Vrijdaghs, Lucie Vandewalle and Marco di Prisco	373
Using FRP as Reinforcement in Precast Concrete Panels for Soil-Concrete Bridges Sameh Salib	382
Torsional Strengthening of Concrete Members Using Near-Surface Mounted CFRP Composites G. Al-Bayati, R. Al-Mahaidi and Robin Kalfat	390
Flexural Testing of Concrete Filled Fibre Reinforced Polymer Tubes (CFFT) with and without Internal Fibre Reinforced Polymer (FRP) Reinforcement Qasim S. Khan, Josiah S. Strong, M. Neaz Sheikh and M.N.S. Hadi	400
Durability Study of Textile Fibre Reinforcement Natalie Williams Portal, Nelson Silva, Katarina Malaga, Urs Mueller, Peter Billberg	408
Mechanical Properties and Post-crack Behaviours of Recycled PP Fibre Reinforced Concrete Shi Yin, Rabin Tuladhar, Tony Collister, Mark Combe and Nagaratnam Sivakugan	414
A Novel Ultra High Performance Fibre Reinforced Concrete Spandrel Cladding Panel Raafat El-Hacha, David Pesta, Gamal Ghoneim and Don Zakariasen	422
Upgrading the Dundas Point Boardwalk, Applecross with the use of GFRP Bar Reinforced Concrete Columns and Footings Joel Brown	433
A Design Methodology for Fibre Reinforced Concrete Slabs-on-grade Ravindra Gettu and Sunitha K Nayar	443
FRP Anchors for FRP-Strengthened Concrete Structures: Numerical Modelling Scott T. Smith, Jia-Qi Yang and Zhen-yu Wang	453
Joint Free Restrained Slabs – SFRC combined with mesh Alan Ross	459

## **Concrete Materials and Performance**

Neutron Pair Distribution Function Analysis of Synthetic Calcium-Silicate-Hydrate Claire E. White	471
Using Conventional Materials as Concrete Confinement Hua Zhao and Muhammad N.S. Hadi	476
Behaviour of Crumb Rubber Concrete Columns under Seismic Loading Osama Youssf, Mohamed A. ElGawady, Julie E. Mills, Xing Ma and Tom Benn	482
Sulfate Resistance Testing in Germany - Critical Review Johannes Haufe, Anya Vollpracht and Wolfgang Brameshuber	492

Linking New Australian Alkali Silica Reactivity Tests to World-Wide Performance Paul Rocker, James Mohammadi, Vute Sirivivatnanon and Warren South	502
Mechanical Properties of Mortar with Oil Contaminated Sand Rajab M. Abousnina, Allan Manalo and Weena Lokuge	514
Investigation into the Structural Properties of an Innovative Modified Concrete Negin Sharifi and Bijan Samali	523
Twisted Steel Micro-Reinforcement: Proactive Micro-Composite Concrete Reinforcement Luke Pinkerton, Kevin Fuller and Jeff Novak	533
Design of UHPFRC Mixtures to be used in Structures Subjected to Impact Loads Michael F. Petrou, Konstantinos G. Trezos and Anna L. Mina	543
Effect Rubberised Aggregates from Tyres on the Engineering Performance of M. Sonebi, R. Summerville and S. Taylor	552
The Effectiveness of Mineral Admixtures and Low Water to Cement Ratio in Concrete for Immobilizing Cesium, Sodium and Iodide from Radioactive Waste Irfan Prasetia and Kazuyuki Torii	559
Challenges contemporizing Australian Standards: Supplementary Cementitious Craig Heidrich	568
Effects of Chemical Admixtures and Aggregate Particles on Spatial Distribution of Cement Particles and Capillary Pores in Mortars Takuma Nakagawa and Shin-ichi Igarashi	578
The Effect of Type of Fly Ash on Mechanical Properties of Geopolymer Concrete M.P.C.M.Gunasekara, David W.Law and Sujeeva Setunge	586
Towards a More Sustainable Australian Cement and Concrete Industry James Mohammadi, Warren South and Des Chalmers	596
Steel, Concrete or Plastic? Support your Reinforcement! Scott Munter and Mark Turner	604
Performance of Architectural Concrete: New Approach Vyacheslav Falikman, Vyacheslav Deniskin and Alexander Vainer	611
Torsional Behaviour of Reinforced Concrete T-Beam Sections Douglas Anabalon	619
Effect of Ultraviolet Radiation on the Physical and Mechanical Properties of Polymer Matrix Wahid Ferdous, Allan Manalo, Thiru Aravinthan and Gerard Van Erp	630
Self-healing of Cementitious Composites via Coated Magnesium Oxide/Silica Fume Based Pellets Rami Alghamri and Abir Al-Tabbaa	637
Impact of Pore Structure of Lightweight Aggregates on Internal Curing Pietro Lura, Mateusz Wyrzykowski, Sadegh Ghourchian, Sakprayut Sinthupinyo and Clarence Tang	646

Reinforcing ordinary Portland Cement Mortar using Carbon Nanotubes Shu Jian Chen, Xiang Yu Li, Tong Bo Sui and Wen Hui Duan	652
The Significance of the Alkali Aggregate Reactivity Provisions in the VicRoads Structural Concrete Specification Section 610 Fred Andrews-Phaedonos, Ahmad Shayan and Aimin Xu	657
Long-term Experiments of Composite Slabs Using Recycled Coarse Aggregate Qinghe Wang, Gianluca Ranz, Yue Geng and Yuyin Wang	669
Implications of Alkali-Aggregate Reaction for three Concrete Bridges Ahmad Shayan, Aimin Xu and Fred Andrews-Phaedonos	679
Effectiveness of Traditional and Alternative Supplementary Cementitious Materials in Mitigating Alkali-Silica Reactivity Daniel Pospischil, Vute Sirivivatnanon, Uthayakumar Sivathasan and Kevin Cheney	694
The Use of Reaction Kinetics in Classifying Alkali Silica Reactivity Potential of Bob Bornstein, David Hocking, Johwelvic Bacolod and Vute Sirivivatnanon	704
Fresh and Early-Age Properties of Cement Pastes and Mortars Blended with Nickel Muhammad Ashiqur Rahman, Prabir Kumar Sarker and Faiz Ahmed Shaikh	712
Thermo-mechanical Behaviour of Epoxy Based Polymer Matrix Wahid Ferdous, Allan Manalo, Thiru Aravinthan and Gerard Van Erp	720
Development of an Acid Resistant Concrete Shamila Salek, Bijan Samali, Vute Sirivivatnanon and Georgius Adam	727
Effect of the Chemical Composition of Building Materials on Algal Biofouling Philippe Grosseau, Estelle Dalod, Alexandre Govin, Christine Lors, René Guyonnet and Denis Damidot	735
Expansive Behavior of Mortars - Containing Surf Clam Shell Powder at Early Age Akio Watanabe, Kazumi Hirokawa and Takashi Kondo	745
The use of Cementitious Coatings to Reinstat Low Nominal Cover on Reinforced Concrete Structures Neil Wilds	751
Behavior of Concrete after Exposure to Elevated Temperatures Yaman S. S. Al-Kamaki, Riadh Al-Mahaidi and Ian Bennetts	761
A Discussion on Service Life Prediction of Fly Ash Concrete Structures based on DuraCrete Methodology Zhuqing Yu and Guang Ye	770
Effect of Combined Fibres on Fire Resistance of Large Specimens Youngsun Heo and Byungyeol Min	779
Mechanical Properties of Fibre Reinforced High Volume Fly Ash Concretes Yashar Shafaei, Faiz Shaikh, Prabir Sarker and Salim Barbhuiya	788

## **Admixtures and Polymers**

Improving the Rheology of High Strength, very low W/C Ratio Concrete. 799  
Gary Boon and Tony Thomas

The Effects of Superabsorbent Polymers on the Water Vapour Sorption Properties of Cementitious Materials 805  
D.Snoeck, L.F.Velasco, A.Mignon, C.Vervaet, S.Van Vlierberghe, P.Dubruel, P.Lodewyckx and N.De Belie

Benefits of Water-Resisting Admixtures to Watertight Concrete 814  
Mohammadreza Hassani, Kirk Vessalas, Daksh Baweja and Zoe Schmidt

The Effect on Expansion of Wrapping Concrete Prisms with Cloth Saturated with Alkali Hydroxide 822  
Yasutaka Sagawa, Kazuo Yamada, Shoichi Ogawa, Yuichiro Kawabata and Masahiro Osako

Innovations in Admixtures for Piling Concrete 832  
Bruno D'Souza and Hairul Sarwono

Properties of Ultra-lightweight Concrete based on Protein and Surfactant foaming Agents 837  
Patrick Hartwich, Thomas Adams, Ali Shams, Anya Vollpracht and Wolfgang Brameshuber

Effect of Guar Gum Derivatives on Fresh State Properties of Portland Cement-Based Mortars 848  
Alexandre Govin, Marie-Claude Bartholin, Barbara Biasotti, Max Giudici, Valentina Langella and Philippe Grosseau

The Effect of Superplasticisers and Viscosity Modifiers on the Rheological Properties of Super Workable Concrete 858  
Greg Langton and Gary Boon

## **Durability and Serviceability**

Concrete Durability Performance Testing – The Approach Adopted in a Concrete Institute of Australia Recommended Practice 864  
W. Green and F. Papworth

A Discussion on the Autogenous Shrinkage Interpretation from the Experimental Shrinkage Measurement Based on the Australian Testing Procedure AS1012.13 875  
William A. Thomas, James Mohammadi and Warren South

Performance Test for Hydrophobic Impregnations for Protection against Chloride Ingress in Concrete 884  
Nelson Silva, Elisabeth Helsing, Katarina Malaga, Eva Rodum, Minna Torkkeli and Arvid Hejll

Durability of Concrete Caissons Made in Floating Docks 894  
Jose Vera-Agullo, Francisco Manuel Castro-Visos, Francisco Javier Larraz-Bordanaba, Claudio Troncone-Cusati, Juan Pedro Asencio-Varela, Nelson Silva, Urs Mueller and Katarina Malaga

Prescriptive versus Performance-based Design Approaches for Concrete Durability Hans Beushausen, Mark Alexander, Manuel Wieland and Stefan Linsel	904
Durability Performance of Crystalline-Modified Concrete Exposed to Severe Environment Farhad Nabavi	914
ISO 16204 and the Correct Solution to Fick Norwood Harrison	924
K-value for Carbonation of Concretes with Supplementary Cementitious Materials Christina Nobis and Anya Vollpracht	931
Feasibility of Digital Image Correlation Technique to Determine Mechanical Properties of Corroded Steel Rebars Ranjitha Rajagopal, Sameer Sharma, Radhakrishna G. Pillai and Sankara J.	939
Determination of Chloride Diffusion Coefficient of Concrete: Comparison of Bulk Diffusion and Electrical Field Method Aimin Xu and Ahmad Shayan	950
Frost Test and the Significant Influence of Small Amounts of Ions Dissolved in Surface Water Max J. Setzer	960
Durability Planning – a Formalised Approach in Concrete Institute of Australia Recommended Practice Rodney Paull and Frank Papworth	970
Time-dependent Stiffness of Concrete Members under Cyclic Loading Angus Murray, Raymond Ian Gilbert and Arnaud Castel	980
Role of Ettringite in Expansion and Cracking Potential in Steam Cured Precast Concrete Elements Johnson Mak, Paul Thomas, Kirk Vessalas and Daksh Baweja	990
Improved Sustainability by Design for Concrete Durability R. Doug Hooton	996
Exp-Ref: A Simple, Realistic and Robust Method to Assess Service Life of Reinforced Concrete Structures Roberto Torrent	1006
Durability Assessment of Concrete Immersed Tube Tunnel in Hong Kong-Zhuhai-Macau Sea Link Project Kefei Li, Quanwang Li, Pianpian Wang and Zhihong Fan	1016

## Geopolymers and Non-traditional Binder Concrete

Effect of MgO Incorporation on the Structure of Synthetic Alkali-activated Calcium Aluminosilicate Binders Brant Walkley, Rackel San Nicolas, Susan A. Bernal, John L. Provis and Jannie van Deventer	1026
Use of Geopolymer Concrete in Column Applications Weena Lokuge, Jay Sanjayan and Sujeeva Setunge	1033
Influence of Matrix Related Parameters on Strain Hardening Behavior of Engineered Geopolymer Composite (EGC) Behzad Nematollahi, Jay Sanjayan and Faiz Uddin Ahmed Shaikh	1041
EFC Geopolymer Concrete Aircraft Pavements at Brisbane West Wellcamp Airport Tom Glasby, John Day, Russell Genrich and James Aldred	1051
On Fly Ash Based Geopolymer Concrete and its Behaviour at Elevated Temperature Tian Sing Ng, Stephen J. Foster and Samantha Milojevic	1060
Development of Sugarcane Bagasse Ash Blended Geopolymer for use in Concrete Deepika S, Madhuri G, Bahurudeen A and Manu Santhanam	1070
Behaviour of Granulated Lead Smelter Slag-Based Geopolymer Concrete M. Albitar, M.S. Mohamed Ali, P. Visintin and M. Drechsler	1080
Influence of Binder on Alkali Reactivity of Aggregates in Geopolymer Concrete Chandani Tennakoon, Ahmad Shayan and Jay G. Sanjayan	1089
Rheological Properties of Sodium Carbonate Alkali-Activated Fly Ash/Slag pastes with Different Superplasticisers Ahmed Abdalqader and Abir Al-Tabbaa	1105
Direct Electric Curing of Alkali-Activated Concretes. Preliminary Study Maxim Kovtun, Julia Shekhovtsova and Elsabe Kearsley	1116
Investigation on Engineering Properties of Powder-activated Geopolymer Concrete Kamal Neupane, Daksh Baweja, Rijun Shrestha, Des Chalmers and Paul Kidd	1125
Alkali-Activated Foamed Concrete Elsabe Kearsley and Maxim Kovtun	1139
Alternative Concrete Materials from Industrial Waste Valle Chozas, Ignacio del Val, José Vera and Íñigo Larraza	1146
Progress Towards a Handbook for Geopolymer Concrete Marita Allan Berndt, Jay Sanjayan, Stephen Foster, Arnaud Castel, Pathmanatham Rajeev and Craig Heidrich	1156
Development of Low Shrinkage Water Repelling Foamed Concrete Kai Tai Wan, Honggang Zhu, Binmeng Chen and Chuanlin Hu	1166
A Resistivity-Based Approach to Indicate Chloride Permeability of Geopolymer Amin Noushini and Arnaud Castel	1172
Chloride induced Corrosion of reinforcing bars in Geopolymer concrete M. Babaee and A. Castel	1182
Specifying Fly Ash for Use in Geopolymer: A Conception of Reactivity Index Hao Wang, Zuhua Zhang, John L. Provis and Jin Zou	1188

## **Structural Monitoring and Assessment**

Evaluation of the Level of Damage of Concretes Affected by Expansive Reactions at Meso and Microstructural Scale. Relationship between Alkali-aggregate Reaction and Internal Sulfate Attack Esperanza Menéndez, Ricardo García Rovés and Nicanor Prendes	1197
The Impacts of Temperature and Salinity Variance on Service Life Modeling as a Result of Climate Change. Andrew Hunting, Sujeeva Setunge and David Law	1207
In situ and Laboratory Testing of Different Repair Materials. Lukovic, M., Gellweiler, W.A., Sierra Beltran, M.G., Blom, C.B.M., Savija, B., Zanten, van, D.C. Schlangen, E. , Ye, G. and Taffijn, E.	1217
Acid-soluble and Water-soluble Chloride – Testing Proficiency and Specification Warren South, Tony Thomas and Vute Sirivivatnanon	1225
Integrated Fracture-based Model for the Analysis of Cracked Reinforced Concrete Beams Tahreer M. Fayyad and Janet M. Lees	1233
Predicting Fire Induced Spalling in Concrete Structural Elements James M. de Burgh, Stephen J. Foster and Hamid R. Valipour	1243
In-situ Concrete Strength Assessment based on Ultrasonic (UPV), Rebound, Cores and the SONREB Method Frank Papworth, David Corbett, Reuben Barnes, Joseph Wyche and Jonathon Dyson	1253
Full Scale Concentric Punching Shear Testing of Two-way Floor with Bonded Post-tensioning and Studrails Fariborz Moeinaddini, Kamiran Abdouka and Andrew Barraclough	1263
Experimental Study on Carbon Fiber Reinforced Concrete for Strain Measurement of RC Portal Frame Fang-Yao Yeh, Kuo-Chun Chang and Wen-Cheng Liao	1273
<b>Early-age Concrete and Cracking</b>	
Temperature Monitoring of Concrete Elements for Insitu Strength Measurement and Prevention of Damage from Heat of Hydration Reuben Barnes, Frank Papworth, William Ward and Jim O'Daniel	1284
The Role of Dilation in Shrinkage Cracking of Concrete Suhaila Mattar and R.S. Al-Rawi	1295
High-absorptive Normal-weight Aggregates used as Internal Curing Agent Pericles A. Savva and Michael F. Petrou	1305
Tensile Properties of Early-Age Concrete Duy NGUYEN and Vinh T.N. DAO	1314
Experimental Study of Creep and Shrinkage in Early-age Concrete Inamullah Khan, Angus Murray, Arnaud Castel and Raymond Ian Gilbert	1325

## **Self-Compacting Concrete**

The Combined Influence of Paste Volume and Volumetric Water-to-Powder Ratio on Robustness of Fresh Self-Compacting Concrete 1335  
Farid Van Der Vurst, Steffen Grünewald, Dimitri Feys and Geert De Schutter

Instantaneous and Time-Dependent Behaviour of Reinforced Self-Compacting Concrete Slabs 1345  
Farhad Aslani, Shami Nejadi and Bijan Samali

Foam Concrete-aerogel Composite for Thermal Insulation in Lightweight Sandwich Facade Elements 1355  
Nelson Silva, Urs Mueller, Katarina Malaga, Per Hallingberg and Christer Cederqvist

## **Fib-C6**

Prefabricating in Unusual Environments 1364  
Marco Menegotto and Luciano Marcaccioli

Paddington Rail Station 1374  
George Jones

PCI Design Awards Program 1382  
Jason Krohn, Daniel Roman and Karla Vazquez

Sustainability of Structures with Precast Elements 1391  
D. Fernández-Ordóñez, B. González-Rodrigo, J. Ramírez and R. Valdivielso

## **Major Projects Case Studies**

Christchurch Art Gallery Foundation Strengthening and Building Re-Level 1400  
James O'Grady, William Lindsay and Russell Deller

Design of Berthing Dolphins on Curtis Island LNG Jetties 1408  
Jesper Jensen, Peter Kastrup and Matt Hodder

Lady Cilento Children's Hospital 1418  
Ken Gallie and Darryl Feodoroff

Documentation of Bridge Deck Construction Using Industrially Produced Internally Cured, High Performance Concrete 1430  
Timothy J. Barrett Albert E. Miller and W. Jason Weiss

## Posters

Comparative Performance of Recycled Plastic and Polypropylene Commercial Fibres with Plain Concrete Badr S. Al-Tulaian, Mohammad J. Al-Shannag and Abdulrahman M. Al-Hozaimy	1440
Finite Element Modeling of Shape Memory Alloy Confined Reinforced Concrete Khaled Abdelrahman and Raafat El-Hacha	1449
Modelling the Reactivity of Nano-silica in Cement Paste Madhuwanthi Rupasinghe, Rackel San Nicolas and Priyan Mendis	1457
A Study on the Estimation of ASR Expansion Based on CPT Kazuo Yamada, Shoichi Ogawa, Yuichiro Kawabata, Yasutaka Sagawa, Masahiro Osako and Takamasa Ochiai	1465
Enhancing Mechanical and Durability Properties of Recycled Aggregate Concrete George Dimitriou and Michael F. Petrou	1472
Effects of Silane Impregnation on Drying Shrinkage of Cement-based Compounds Pedram H. Mojarrad and Gary Boon	1482
Fresh Property and Matrix Distribution for Amorphous Steel Fiber Reinforced Byoungil Kim and Sea Hyun Lee	1488
Application of FRP Composite to Self-anchored Cable-stayed Bridge for Emergency Disaster Relief Fang-Yao Yeh, Kuo-Chun Chang, Yu-Chi Sung, Hsiao-Hui Hung	1495
Quick Uplift Rehabilitation for Differential Sunken Concrete Structure of Slab Ballastless Track Xinguo Zheng, Weichang Xu, Fei Cheng, Zhiyuan Zhang, Youneng Wang and Jing	1505
Investigation of Strain and Energy Ductility in SFRP-Wrapped Concrete Cylinders Nisreen Salameh, Raafat El-Hacha, and Khaled Abdelrahman	1510
The Possibility of using Inhibitors in New Repair Materials Vit Cerny, Rostislav Drochytka, Jiri Bydzovsky and Pavel Dohnalek	1518
Numerical Investigation of the Flexural Performance of RC Beam Strengthened with Iron-Based Shape Memory Alloys Bar Hothifa Rojob and Raafat El-Hacha	1528
Development of Double-Slotted Beam-Column Connection for the Seismic Design of Structures Fadi Oudah and Raafat El-Hacha	1547
Development of a Finite Element Analysis Design Tool for Future Study of a Novel Hybrid Steel-Free Multi-Girder Bridge Deck System Donna Chen and Raafat El-Hacha	1554
Investigation of Strength and Thermal Intake of Concrete Curing Through Means of Heated Water and Insulation Applied to the Exterior Surface Jamie Warr	1564
Comparative Performance of Recycled Plastic and Polypropylene Commercial Fibres with Plain Concrete Badr S. Al-Tulaian, Mohammad J. Al-Shannag, Abdulrahman M. Al-Hozaimy	1574

# Keynote Presentations

# ULTRA-HIGH PERFORMANCE DUCTILE CONCRETE: THE DELIVERY FROM RESEARCH INTO PRACTICE

Stephen Foster<sup>1</sup> and Yen Lei Voo<sup>2</sup>

<sup>1</sup>Professor and Head, School of Civil and Environmental Engineering, UNSW Australia

<sup>2</sup>CEO and Director, Dura Technology Sdn Bhd, Perak, Malaysia

**Abstract:** With the opening of Shepherd's Gully Bridge 150 km north of Sydney in 2005, Australia was amongst the leaders in the world in the utilisation of ultra-high performance concrete (UHPC) for road bridge construction. Ten years on, not one more bridge has been constructed and the uptake of UHPC technologies has been, at best, limited. In contrast, Malaysia's first bridge was opened in 2010 and in the time since a further 47 bridges have been completed, with many more under construction and on the drawing boards. Road bridges with spans as little as 12 metres and large as 58 metres are operational and of 100 metres are being built. Around the globe, UHPC is seeing slow, but steady, take up in many countries with more than 100 operational bridges worldwide. The question is asked "why has Australia gone from leading the world in the application of UHPC technology to watching from a distance" and "what is the future of UHPC for developing sustainable and resilient infrastructure"? This paper provides examples of two Malaysian UHPC bridges, the 51.0 metre span UHPC-composite deck Rantau Negeri Sembilan Bridge completed in December 2013 and the 100 metre span integral-deck precast segmental box girder bridge completed May 2015.

**Keywords:** Ultra-high performance, ductile, fibre, segmental, bridge, sustainable.

## 1. Introduction

One of the major breakthroughs in concrete technology of the 1990s was the development of ultra-high performance fibre reinforced concrete (UHPFRC), also known as the reactive powder concrete (RPC), by Richard and Cheyreyzy (1994, 1995). Compressive strengths and flexural strength of over 180 MPa and 40 MPa, respectively, have been reported. Since then, extensive research studies have been undertaken by academics and engineers alike with the view to industrialise this technology as an alternative for sustainable construction. While its take-up in practice has received gradual acceptance in many countries, this has not been the case in Australia. In the years 2004 and 2005, Australia was amongst the world leaders in development of UHPFRC for road bridge construction, through VSL Australia and their product Ductal. In the time since, and despite significant potential, the uptake of the technology has stalled, if not stopped in Australia.

The first major structures adopting UHPFRC technology were footbridges. In 1996, the 60-metre single span Sherbrooke Pedestrian Bridge was constructed, crossing the river of Magog, province of Quebec, Canada (Lachemi et al., 1998). The walkway deck, serving as the top chord to the truss, consists of 3.3 metre wide by 30 mm thin UHPFRC slabs. The web members are of a composite design involving UHPFRC placed in thin walled stainless steel tubing. April 2002 saw the construction of the Seonyu Footbridge (the Footbridge of Peace) in Seoul, South Korea (Behloul and Lee, 2003). Constructed by Bouygues Construction, the bridge is an arch with a 120 metre span supporting a 30 mm thick RPC deck. The structure required about one-half of the quantity of concrete that would have been used with traditional construction. At a similar time to the construction of the Seonyu bridge was the 50 metre footbridge constructed in Sakata (Sakata-Mirai footbridge), which is located in the north-western region of the island of Honshu, Japan (Tanaka et al., 2011). Other examples from Japan include the 36.4 metre span segmental construction Akakura Onsen Yukemuri Bridge (completed in 2004), the 64.5 metre span Hikita Footbridge (completed in 2007), the 81.2 metre span Mikaneike Footbridge (completed in 2007) (Tanaka et al., 2011, Musha et al., 2013). In the time since the construction of the Seonyu and Sakata-Mirai footbridges, UHPFRC bridges for pedestrian traffic have been constructed in France, New Zealand, Spain, Germany and elsewhere (Toutlemonde and Resplendino, 2011).

Internationally, private and governmental bodies are increasing their attention and initiative towards utilising performance advantages of UHPFRC, together with its being demonstrated as one solution towards more sustainable construction (Ng et al., 2012; Voo and Foster, 2010). UHPFRC is a highly workable material that may be used to form complex shapes, with reduced mass and reduced material. Figure 1 shows a 2.5 metre high UHPFRC retaining wall segment; Figure 2 shows the UHPFRC façade

elements of the Museum of European and Mediterranean Civilisations, Marseille, France and constructed in 2013.

The first road bridges to be constructed using UHPFRC technology appeared in 2005, with four bridges constructed at around the same time (Voo et al. 2014). One of these was the 16 metre span, 21 metre wide, precast pre-tensioned I-girder bridge at Shepherd's Gully Bridge (Figure 3) located 150 km north of Sydney and constructed by VSL Australia (Foster, 2009, Rebentrost and Wight, 2011). The girders for these bridges were fabricated by VSL using the facilities of the Heavy Structures Laboratory at UNSW Australia. At this time, Australia was at the cutting edge of research into use of UHPFRC with doctoral theses by Voo (2004), Warnock (2005), Ngo (2005) Malik (2007) and Menefy (2007). The significance of such technology lies not only in the great enhancements in concrete strengths, leading to lighter weight construction and more efficiency of materials, but also in the contribution to sustainability through lower carbon footprints (Voo and Foster, 2010).

**Figure 1. Precast UHPFRC 2.5 metre high retaining wall segment.**

(b)

**Figure 2. (a) Museum of European and Mediterranean Civilisations - Marseille, France; (b) UHPFRC façade:**

**Figure 3. Shepherd's Gully Bridge, NSW, Australia constructed 2005: (a) 15 metre span 4 lane road traffic bridge (b) underside showing I-girders.**

In 2008, the world's first segmental UHPFRC composite deck road bridge was constructed; a single-span 46.0 metre ground support equipment (GSE) bridge was built over a road connecting the south and north apron in the extension of the Tokyo International Airport project. At the time, the road bridge was the largest UHPFRC road bridge in the world (Tanaka et al., 2011).

While construction of UHPFRC bridges in Australia has stalled, since 2006 Dura Technology Sdn Bhd (DTSB) has been pioneering research on the optimal uses of UHPFRC in bridge construction in Malaysia. During several years of research and development, DTSB has been collaborating with the Malaysia Works Ministry to design and build UHPFRC bridges, with a particular emphasis for bridges in rural areas where sourcing materials, site access and construction method are major constraints when using the conventional technology. From 2010 to now a total of 47 UHPFRC bridges have completed; a further 13 are in advanced stage of construction and another 15 are in the early stages of production. By the end of 2015, 75 bridges are due to be completed; 58 of these bridges are of segmental construction and 17 are pre-tensioned girders having spans of less than 22 metres.

In most cases UHPFRC precast bridge construction can be demonstrated to realise the following advantages (Voo and Foster, 2010, Voo et al., 2014):

- immediate and life-cycle cost saving;
- enhancement in design/service life of structures;
- low maintenance due to their high durability;
- reduced overall construction time and risk;
- reduced consumption of raw material;
- lighter superstructure dead weight permitting smaller and lighter substructure and foundations;
- reduced man-power and smaller plant;
- higher quality than in-situ wet work and precast high performance concrete structures; and
- lower impact on the construction site due to shorter-duration of temporary works.

In this paper, firstly, the mix design and mix performance properties of the Malaysian UHPFRC are outlined; next, two of the more than 40 bridges that have been completed are briefly discussed, the first the Rantau, Negeri Sembilan bridge, the largest single span composite deck UHPFRC bridge constructed to date, and the second the 100 metre span Batu 6 bridge, the world's longest UHPFRC single-span box-girder road bridge.

## **2. DURA Ultra-High Performance Fibre Reinforced Concrete**

There are many variations in mix design of UHPFRC with a number of commercial products in the marketplace (eg. Ductal, BSI, Taktl, myUHPC, Florida, etc). The mix design used in the beams in all bridges designed and constructed by DURA is given in Table 1; the material used to produce UHPFRC consists of Type I Ordinary Portland cement, densified silica fume containing more than 92% silica dioxide (SiO<sub>2</sub>) and with a surface fineness of 23,700 m<sup>2</sup>/kg and washed-sieved fine sand with a particle size

range between 100  $\mu\text{m}$  and 1000  $\mu\text{m}$ . A polycarboxylic ether (PCE) based superplasticizer is used. Two types of steel fibres are utilised in the mix; both manufactured from 2500 MPa high carbon steel wire. Type I steel fibre are straight in shape and are supplied with dimensions of 20 mm length by 0.2 mm diameter. Type II steel fibre is hooked-end and have dimensions of 25 mm long by 0.3 mm diameter. One percent of each fibre type is used; a total of 2%, by volume. Benchmark values for the specification of the UHPFRC are a 28 day characteristic cube compressive strength of 150 MPa and flexure strength of not less than 20 MPa; heat curing is applied for a period of 48 hours at a temperature of 90°C. The mechanical properties of the DURA UHPFRC are presented in Table 2.

**Table 1. Mix design of standard DURA UHPFRC.**

Ingredient	Mass (kg/m <sup>3</sup> )
DURA-UHPFRC Premix	2100
Superplasticizer	36-40
High strength steel fibres	158
Free water	168
3% moisture	32
Targeted W/B ratio	0.16
Total air voids	< 4%

**Table 2. Material characteristics of DURA UHPFRC.**

Characteristics	Standard	Value
Specific density, $\delta$	BS1881-Part 114 – 1983	2350 – 2450 kg/m <sup>3</sup>
Cube compressive strength, $f_{cu}$	BS EN 12390-3-2009	Min. 150 MPa (characteristic) Min. 160 MPa (mean)
Creep coefficient at 28 days, $\phi_{cc}$	AS1012.16 – 1996	0.2 – 0.5
Post-cured shrinkage	AS1012.16 – 1996	< 100 $\mu\epsilon$
Modulus of elasticity, $E_o$	BS1881-Part 121 – 1983	40 – 50 GPa
Poisson's ratio, $\nu$		0.18 – 0.2
Split cylinder. cracking strength, $f_t$	BS EN 12390-6 – 2000	5 – 10 MPa
Split cylinder ultimate strength, $f_{sp}$	ASTM C496 – 2004	10 – 18 MPa
Flexural strength or Modulus of rupture, $f_{cf,3P}$	BS EN 14651-2005 (Three-point test on notched specimens)	20 – 35 MPa
Rapid chloride permeability	ASTM C1202 – 2005	< 200 coulomb
Chloride diffusion coefficient, $D_c$	ASTM C1556 – 2004	0.05 – 0.1 $\times 10^{-6}$ mm <sup>2</sup> /s
Carbonation depth	BS EN 14630 – 2006	< 0.1 mm
Abrasion resistance	ASTM C944-99 – 2005	< 0.03 mm
Water absorption	BS1881-Part 122 – 2011	< 0.2 mm
Initial surface absorption	BS1881-Part 208 – 1996	< 0.02 ml/(m <sup>2</sup> s) (10 min) < 0.01 ml/(m <sup>2</sup> s) (120 min)

### 3. Rantau, Negeri Sembilan Bridge

The first example presented is the Rantau, Negeri Sembilan Bridge, which on 20 May 2013 became the world's longest single span UHPFRC-composite deck bridge, breaking the record of its predecessor, the 50 metre Kampung-Linsum bridge (see Voo et al., 2011). The project cost was MYR6.5 million (A\$2.1 million), which includes the construction of the new four lane road, river protection works, road furniture, earthwork, 400 metre by 16 metre wide approach pavement works, in addition to that of the bridge structure. The four lane wide bridge consists of five DURA UBG1750 beams with a conventional concrete cast in-situ deck (Figure 4). Being one of the busiest road accesses between the towns of Seremban and Port-Dickson, on the day of launching the existing road, and bridge, could not be closed to traffic for periods of more than 15 minutes at a time. The seven segments (2  $\times$  5.8 metres and 5  $\times$  8.0 metres) making up the 51.6 metre long beams were delivered from the factory to a site adjacent to the

construction, where they were assembled and stressed together. The girders were next transported the short distance to the new bridge site, utilising the existing bridge, and were lifted by two 500 tonne mega cranes in a single lift and placed on their abutments (Figures 5a and 5b). The whole launching process took just five hours to complete. There were no major disruptions to the heavy traffic and by 5 pm normal activity around the site was resumed and launching was complete. The composite deck slab was subsequently cast and the completed bridge is shown in Figures 5c and 5d.

The 18.3 metre wide Rantau, Negeri Sembilan Bridge remains the largest single span composite-deck bridge in plan area constructed to date; the longest span is held by the 58 metre span single lane Kampung Merdeka Bridge, completed in June 2015. The largest multi-span bridge is the 5 span, 200 metre long by 17 metre wide CFS Bridge, completed February 2015.

#### 4. Batu 6 Bridge

The second example presented is the 100 metre span, integral-abutment box girder Batu 6 Bridge, located at Batu 6, Gerik, Perak, Malaysia. The construction cost was RM6.3 million (A\$2.2 million), which includes the foundation/piling, substructure (included wing-wall and approach slabs), superstructure, temporary works, road furniture, earthwork, 600 metre long by 6 metre wide approach road works and slope protection. The bridge was due for completion in February 2015; however, on December 22<sup>nd</sup> 2014, just one day before the planned pouring of the first of the integral abutments, the pour that would join the bridge to its foundations, saw the worst floods in Malaysia in decades with more than 100,000 people displaced.

The bridge is constructed of 40 – 4.0 metre high precast segments (Figures 6 and 7a), with each segment matched cast in the factory and delivered to site for placement and tensioning. The thickness of the webs between segment ends is 150 mm; the webs are locally thickened at the matched joints to accommodate the shear keys. The 36 middle segments each weight 16.5 tonnes, the segments second from the end 18 tonne and the end segments 20 tonne. With 26 tonnes of prestressing cable, 52 tonnes for the wearing surface and 20 tonnes for railings and ancillary fixtures, the total weight of the bridge is 770 tonne. For construction of the bridge falsework and positioning of the segments, crane access was available from one bank only and required the largest crane available; a 550 tonne crawler crane with a boom length of 108 metres. Even then, the last end segments at Abutment B could not be lifted into position and an innovative strategy was needed. To this end, a rail system was developed on the falsework to locate the precast segments to the accuracy needed for threading of the tendons. Figures 7b – 7d show the placement of the UHPFRC precast box segments. The 40 segments were placed over a period of 18 days (including two rest days). On day 11 of placement, five segments (12.5 metres of bridge) were positioned and aligned in a single day.

Figure 6. Batu 6 Bridge cross section.

The stage 1 prestressing work began on day 19 and the bridge was stressed on day 33 (29 November). On days 34 to 38 the strand ends were cut and grouting was completed (Figure 7e); the average prestress on the section ( $P/A$ ) is 17.1 MPa compression, the stress at the top and bottom of the section at mid-span is 19.3 MPa (compression) and 15.0 MPa, respectively. The calculated theoretical hog was 34.8 mm; the measured hog was 50 mm. After 7 days, the hog had reduced due to creep by 7 mm to 43 mm, consistent with predictions. Stage 2 stressing will be undertaken after completion of the integral abutment works.

(h)

**Figure 7. Batu 6 Bridge: (a) factory cast segments; (b)-(d) placing of segments; (e) after stage 1 stressing; (f) during flood; (g) shifting of girder on abutments downstream; (h) after completion of Abutment A.**

On 29 December 2014, from an unplanned release of water from Bersia Dam, the river Perak rose to a level of 3.0 metres above the soffit of the 4.0 metre tall girder (Figure 7f). This placed an extreme lateral pressure on the member, a load for which it had not been designed! The bridge, which had its first stage stressing a month before, carried the load without damage but had moved on its abutment 1.2 metres downstream, with the edge of the girder moving to within 50 mm of the edge of the abutment, and had tilted by 5 degrees (Figure 7g); it had come precariously close to topping into the river! On 20 January 2015 the flood waters had subsided to below the soffit of the girder and planning for restoration works began.

On 12 February the construction authority gave approval for the proposed remediation plan and work began shortly after. The girder was first lifted using hydraulic jacks and Teflon bearing plates were placed between the girder and the pile cap. The bridge was then repositioned by jacking laterally against a temporary structure that had been constructed around the pile caps for this purpose. The casting of integral Abutment A was undertaken over the days between 30 March and 3 April, 2015 (Figure 7h) and Abutment B is between 13 to 17 April. With the completion of construction in May mid-2015, the 100 metre span Batu 6 Bridge became the world's longest single span UHPCFRC integral-box road bridge (Figure 8).

**Figure 8. 100 metre span Batu 6 Bridge – completed May 2015.**

## **5. Concluding Remarks**

With the opening of Shepherd's Gully Bridge near Newcastle, Australia was at the lead of industrialisation of the latest in research in cementitious materials technology and in the utilisation of ultra-high performance concrete for road bridges – ten years ahead, not one more bridge has been constructed. The question that should be asked is: "where will we be in 2025"? In contrast, based on research begun in Australia and with Australian research training, Malaysian engineers built their first UHPC bridge in 2010; in the short time since, 47 more bridges, road and pedestrian, have been built. Similarly in other parts of Asia (particularly Japan) and in Europe (particularly France) some remarkable structures are being developed utilising UHPC technology.

In 2005 the German Government, through the German Research Foundation, invested €12 million (A\$16.7) in a programme that involved 34 research projects at more than 20 research institutes (Schmidt, 2012). Similarly, in 2007 the Korean Institute of Construction Technology (KICT) invested WON\$12 billion (\$A14 million) into research into UHPC for cable-stayed bridges in their Super 200 program (Kim et al., 2012). The US Federal Highway Administration (FHWA) began investigating the use of UHPC in 2001, with the first structure, the 33 metre Mars Hill road bridge in Iowa, constructed in 2006 (Graybeal, 2011). This compares to a general lack of investment in cementitious materials technology research throughout Australia by government, industry and, indeed, universities. Will we be looking for inspiration from overseas for the years ahead; will again Australia be at the lead or remain followers? It is time that that a new paradigm is found that unlocks the talent invested in Australian research institutions and brings the benefit more directly to Australian industry and the Australian economy.

# Low Carbon Emission Geopolymer Concrete: from Research into Practice

Jannie S.J. van Deventer<sup>1</sup> and John L. Provis<sup>2</sup>

<sup>1</sup>CEO, Zeobond Group, P.O. Box 23450, Docklands, Victoria 8012, Australia

<sup>2</sup>Professor, Department of Materials Science and Engineering, Sir Robert Hadfield Building, Mappin Street, Sheffield, S1 3JD, United Kingdom

**Abstract:** Geopolymers have received increasing attention in the literature and are rapidly gaining application in the construction industry. Nevertheless, there are obstacles to their wider adoption, including the lack of a long service track record, inflexible standards based implicitly or explicitly on the chemistry of Portland cement, questions about the applicability of durability testing, and the absence of many geopolymer precursors from the supply chain. Recent developments in nanostructural analysis and modelling of phase assemblages have provided insight into the nature and likely durability of the formed calcium aluminosilicate phases. This also provides indications that some accelerated durability testing methods will need to be modified to allow for the particular development of geopolymer gels at early age. The life-cycle analysis (LCA) of geopolymers needs to be conducted with caution regarding the origin of alkali activators, and for suitable mix designs an LCA will show significant reduction in CO<sub>2</sub> emissions compared with Portland cements. A case is made for the development of cement and concrete standards based on performance instead of prescription. It is shown here how a step by step approach involving all stakeholders, and by taking into account the drivers for adoption, has led to the commercialisation of geopolymers.

**Keywords:** geopolymer, nanostructure, durability, standards, commercialisation.

## 1. Introduction

Numerous papers have outlined the high CO<sub>2</sub> emissions of the Portland cement industry, mainly as a result of the calcination of the enormous quantities of limestone which must be processed to meet global demand for construction materials. Several alternative binder systems have been proposed as a means to reduce the CO<sub>2</sub> emissions of cement manufacturing; these include alkali-activated materials and geopolymers, calcium aluminates, sulphoaluminates, supersulphated slag cements, and magnesium-based binders. There has been much discussion of the term 'alkali-activated materials' versus 'geopolymers,' as coined by Joseph Davidovits (1), and while this is not the place to continue this debate, the term "geopolymers" will be used here to indicate all materials that are activated by alkalis.

The history of geopolymers, the binder chemistry, microstructure, different precursor materials, and engineering properties have been discussed extensively, especially in a recent RILEM report (2). The focus here will be to show how recent research on nanostructure has deepened our insight into phase assemblage and durability of geopolymers, that a critical analysis is required of durability testing methods, that the CO<sub>2</sub> footprint of geopolymers is a function of the origin of alkali activators, that there is a strong case for performance-based standards, and that despite obstacles, commercial adoption of geopolymer concrete has been achieved. In most commercial geopolymer concretes, Supplementary Cementitious Materials (SCMs) like fly ash from coal combustion and ground granulated blast furnace slag are used as precursors. Unless otherwise specified, the shortened terms 'fly ash' and 'slag' will be used here for these materials.

## 2. Understanding Phase Assemblage

### 2.1 Nanostructural Characterisation

The nanostructure of geopolymers is strongly dependent on the available Ca content of the precursors used in their formulation, with high-Ca systems based on materials such as blast furnace slag being dominated by a calcium aluminosilicate hydrate (C-A-S-H) gel with a tobermorite-like structure, while low-Ca systems such as those based on metakaolin or Class F fly ash tend to generate an alkali aluminosilicate (N-A-S-H) gel with a highly cross-linked, disordered pseudo-zeolitic structure (3). These gels can coexist in binders based on blends of high-Ca and low-Ca precursors, although the stability of the gel co-existence at high alkalinity is still the subject of some discussion (4).

Key analytical techniques which provide information about geopolymer gel structure include Fourier transform infrared (FTIR) and nuclear magnetic resonance (NMR) spectroscopy. Magic angle spinning (MAS) NMR studies of geopolymers often investigate  $^{27}\text{Al}$  and  $^{29}\text{Si}$  nuclei, and yield information about the coordination states of Al and Si. The information obtained through this method has been key to unlocking the details of the network structures of both C-A-S-H and N-A-S-H gels in geopolymers (3).

Particularly for low-Ca systems, FTIR spectroscopy provides information about the connectivity within Si-O-(Si,Al) frameworks, which can be observed via shifts in the infrared absorption peak corresponding to the Si-O-(Si,Al) asymmetric stretching vibration (3). Recent studies have also used in-situ time-resolved FTIR spectroscopy (5,6), and spatially-resolved infrared microscopy (6), the latter based on synchrotron radiation, to provide new insight into how the availability of silica (7) and alumina (8) controls gel structure.

Pair distribution function (PDF) analysis involves the calculation of interatomic distance correlations from 'total scattering' X-ray or neutron data, and can be applied to both ordered and disordered materials. This technique has shown differences in ordering between the C-A-S-H gels formed by hydration of tricalcium silicate and in alkali-activation of blast furnace slag (9). This is mainly because of the low Ca/Si ratio and the high Al content of the gel produced in slag-based geopolymers, which increases the likelihood of cross-linking between the silicate chains within the tobermorite-like gel (10).

A key question to be answered is whether the alkali metal cations in geopolymers are in fact structurally incorporated into C-A-S-H, or whether they are instead mainly sorbed onto its surface. This question is difficult to answer, particularly in view of the complexity in defining the 'surface' of such nano-scale particles (3), and so in some ways becomes a partly philosophical question. Nonetheless, Myers et al. (11) showed that the extent of alkali uptake by these gels is determined essentially by gel chemistry rather than being controlled by the available surface area. Thus, incorporation of the alkalis into the fundamental gel structure is important, and this may provide at least a partial explanation for the differences in PDF analysis results between slag-based geopolymers and tricalcium silicate hydration products, as mentioned above (9). Incorporation of alkali cations into the interlayer space of the C-A-S-H gel is inducing additional structural disorder in the gel (3).

## **2.2 Modelling**

The nanostructural and chemical complexity and disordered nature of geopolymers mean that it is difficult to study their phase assemblage by instrumental analysis alone, which is why there is increasing focus on thermodynamic and kinetic modeling in this field of research. The availability of appropriate structural models is essential in enabling the correct interpretation of spectroscopic data for C-A-S-H and N-A-S-H gels, as the models provide the necessary structural constraints which guide and validate the complex process of spectral deconvolution for quantification of individual sites. It is only in this way that structural parameters such as Ca/(Al+Si) ratios and mean chain lengths can be calculated from appropriately deconvoluted spectra. In recent examples of advances in this area, Myers et al. (10) implemented a structurally-based framework by which crosslinking degrees can be calculated in tobermorite-like C-A-S-H gels, and Richardson (12) also provided a crystal chemical model to describe layer spacings in these gels.

Krivenko (2,13) showed how the formation of sedimentary rock from weathered rock components could be used as a conceptual model for synthesising artificial materials such as geopolymers, which provides support for the durability of these concretes. Geochemical-type thermodynamic models have been successful in describing the phase assemblages formed in Portland cement and other Ca-rich systems, but until recently have not fully described the alkali metals and Al which are known to play important structural roles in the C-(N)-A-S-H gels in geopolymers. This gap has been filled by the thermodynamic model of Myers et al. (11) which describes this phase as an ideal 8-member solid solution, and can accurately describe solubilities in the full quaternary  $\text{CaO-Na}_2\text{O-Al}_2\text{O}_3\text{-SiO}_2$  aqueous system, as well as the pore solution chemistry of high-Ca geopolymers. This provides confidence in the long-term phase stability of the C-(N)-A-S-H gel and accompanying secondary phases, as the observed phase assemblages are consistent with predictions made from a thermodynamic basis. Unfortunately, such models are not yet available for N-A-S-H type gels, as the thermodynamics of this type of gel are much less well defined. It is envisaged that further developments in modelling of phase assemblage will aid in the prediction of phase changes over time, hence durability and in-service life, not just for geopolymers but also blended Portland cements.

The question is thus whether the currently available test methods for durability, which have been designed mainly for Portland cement systems, are applicable to geopolymers. Even for Portland cement systems

the prediction of service life based on accelerated testing remains problematic, so the prediction of service life for geopolymer concrete is a more challenging objective not yet achieved. The sections below review recent progress on the application of accelerated durability testing methods to geopolymers.

### **3. The Case for Durability of Geopolymers**

#### **3.1 Carbonation Testing**

The general assumption that a decrease in the alkalinity of concrete will always increase the susceptibility to corrosion of steel reinforcement requires further investigation and validation, especially when the chemical environment of the steel is different between various classes of concretes. The process of atmospheric carbonation is known to proceed differently in geopolymers compared with Portland cements (14). In Portland cement pastes, atmospheric  $\text{CO}_2$  dissolves in the pore solution and reacts rapidly with portlandite to form  $\text{CaCO}_3$ , and then once the portlandite is consumed, further  $\text{CO}_2$  decalcifies the C-S-H gel to form  $\text{CaCO}_3$  and silica gel (15). In contrast, the carbonation of geopolymer slag paste occurs first in the alkaline pore solution and then directly in the C-A-S-H gel because of the lack of portlandite, leaving an Al-containing siliceous gel in addition to  $\text{CaCO}_3$  (16).

While carbonation causes a loss of strength in geopolymer concrete (17), the hydrotalcite-type phases present in most slag-based geopolymers have been observed to bind carbonate ions and retard the progress of carbonation (18). The mechanism of strength loss in low-Ca gels induced by carbonation requires further research; the carbonation of low-Ca geopolymer gel mainly involves crystallisation of alkali carbonate or bicarbonate salts from the alkali-rich pore solution (19), with very little nanostructural alteration observable in the binder gel itself, as decalcification cannot happen in the absence of significant levels of calcium (16).

The most rapid carbonation of concretes occurs at relative humidities between approximately 50-70% (20), which is optimal for transport of  $\text{CO}_2$  into the pore solution, and so this is the condition specified in most testing standards. Unfortunately, exposure of immature concrete to relative humidities in this range can also result in significant drying shrinkage and microcracking (20), which contributes to the rapid carbonation of geopolymers in accelerated tests. The question arises whether such accelerated tests are representative of in-service natural carbonation conditions.

Xu et al. (21) evaluated the natural carbonation of in-service concretes older than 35 years as applied in the former Soviet Union, where the binders were based on alkali carbonate-activated metallurgical slags. In general, a carbonation depth of less than 8 mm was identified in these specimens, demonstrating the satisfactory durability of these materials against natural carbonation (2). Bernal et al. (22) showed that the depth of carbonation in a set of slag-geopolymers exposed to ambient conditions for 7 years was much lower than would be predicted through accelerated carbonation testing of specimens formulated to the same mix designs, demonstrating that the exposure conditions used in accelerated testing do not replicate the phenomena that take place under natural service conditions. In a recent study of in-service geopolymer concrete in the Netherlands it was shown that after 2 years the carbonation depths were comparable with those of blended Portland cement concrete containing slag or fly ash (23).

There appears to be a discrepancy between the results of accelerated carbonation testing of geopolymers, and the carbonation rates observed in-service under ambient conditions. This is attributed in large part to the thermodynamic differences between accelerated and natural carbonation conditions, which lead to different processes controlling the carbonation rates observed under different conditions. Accelerated carbonation testing over-predicts carbonation rates under actual service conditions, partly due to damage of the immature gel structure, and partly due to changes in alkali carbonate phase equilibria when the  $\text{CO}_2$  level is increased (17,24). Consistent with this observation regarding the importance of geopolymer binder maturity, accelerated carbonation testing of slag-geopolymer concretes showed that for carbonation depths less than ~8 mm, the carbonation process appeared to be predominantly chemical reaction controlled, and the rate-controlling step was close to first order with respect to  $\text{CO}_2$  (25). Beyond this point, where a more mature binder was being carbonated, diffusion control appeared to be more significant. This may indicate that as the geopolymer samples age the refinement of the pore structure of geopolymers means that diffusion of  $\text{CO}_2$  is limited by the carbonation reactions that can take place. This may partly explain the discrepancy outlined above.

It is also noteworthy that the chemistry of the precursors in geopolymer reactions may significantly affect carbonation behaviour. Bernal et al. (18) identified a strong interdependency between the formation of secondary phases, especially hydrotalcite-type phases, and the carbonation rate of the binder, as well as the chemistry and structure of the C-(N)-A-S-H type gels. A reduced content of MgO in the slag accelerates the early reaction process during alkali-activation, but reduces the overall extent of reaction which can be reached, and favours formation of C-A-S-H products with higher Al uptake, high chain length, and a lower degree of crosslinking. Conversely, the presence of more Mg reduces the Al/Si ratio in the C-(N)-A-S-H, as Al is instead bound through the formation of hydrotalcite. Under natural exposure conditions, hydrotalcite plays a clear role in determining the rate of carbonation by taking up CO<sub>2</sub> and preventing it from penetrating further into the material (18). The relationship between Ca/Si ratio and carbonation depth in geopolymers is not as evident as is the case for Portland cement.

### **3.2 Chloride Ingress**

The discussion about the corrosion of steel reinforcement in concrete has in general been focused mainly on the ratio of hydroxyl ions to chloride ions. However, the local oxidation-reduction potential is equally important in determining whether or not the steel will corrode. Much more needs to be done to understand these complex phenomena, not just in the case of geopolymer concrete but also in blended Portland cement concrete and other new binders which may have redox environments different from those of plain Portland cement. Nevertheless, the ingress of chloride is a major contributor to steel corrosion, especially in marine environments and in cold areas where de-icing salts are used.

Accelerated test methods aim to predict the time taken for the chloride to penetrate the concrete and initiate corrosion of the steel. The rate of ingress of chloride ion into concrete is a function of its diffusivity, hence the pore size and tortuosity, as well as its adsorption onto the pore walls. In general, geopolymers tend to show reduced chloride ingress compared with Portland concrete or even blended cements (2). However, as shown below, the interpretation of accelerated test data is complicated by the strong influence of the composition of the pore solution, which is a function of the nature of both the geopolymer precursor and the activator. This can yield unexpected results when comparing results obtained through tests such as the 'rapid chloride permeability test' (RCPT) with microstructural measurements for the same mixes (26). For example, mercury intrusion measurements have shown that sodium silicate-activated slag mortars exhibit much lower porosity and finer pore structure than when sodium carbonate or sodium hydroxide are used to activate the same slag in similar mix designs, but RCPT results revealed a much higher charge passed by the silicate-activated slag mortars. Thus, for slag-geopolymers the chemistry of the pore solution appears to contribute more to the electrical conductivity than does the pore structure, and the RCPT method may not always be accurate in predicting chloride resistance to ingress.

Bernal et al. (27) also found that the correlation between the RCPT and direct diffusion tests for determining chloride diffusion coefficients for geopolymer concretes was poor. It seems that the nature of the geopolymer gel hydration products strongly affects chloride ionic transport (28), but a full description of these processes has not yet been published. In high-Ca geopolymers, the C-A-S-H reduces porosity, while in low-Ca systems the N-A-S-H, which is more porous (29), appears to contribute significantly to higher chloride binding (28). The inherent deficiency of the RCPT method has led many workers to apply more advanced accelerated chloride migration tests such as the Nord Test method NT Build 492 (30), or long-duration chloride ponding tests such as ASTM C1543 (31). These tests use the colour change induced by spraying a silver nitrate solution onto a laterally split sample surface to provide a measurement of the chloride penetration depth, which is more appropriate than a pure electrical measurement as long as the pore solution chemistry is taken appropriately into account when defining the chloride concentration corresponding to the point of the colour change.

### **3.3 Sulphate Attack**

The mechanism of sulphate attack in geopolymer concrete is markedly different from that in Portland cement due to differences in phase chemistry of the hydration products, and specifically the absence or low concentrations of AFm phases, which are the Portland cement hydrate product most susceptible to sulphate-induced expansive processes, in geopolymers. From the summaries published by Shi et al. (32) and by RILEM TC 224-AAM (2) it can be concluded that geopolymers appear to resist expansion to a

higher degree than regular Portland cement under exposure to most sulphate solutions, and even show performance superior to that of sulphate-resistant Portland cement in the presence of sodium sulphate solutions. This is because sodium sulphate can be used as an activator in higher-Ca geopolymers (33), and thus can enhance the structural evolution and densification of the binding phases rather than inducing damage (32). However,  $MgSO_4$  exposure of calcium-containing geopolymers induces significant loss of compressive strength due to decalcification of the C-A-S-H, and gypsum and/or ettringite can also be formed as degradation products (34). To date, there has been little detailed investigation of the sulphate resistance of Ca-free geopolymer binders, but the expansive processes which take place in Ca-rich materials are unlikely to occur, and so the possible reduction in magnesium sulphate attack in geopolymer concrete which can be designed with very low permeability is worthy of further research.

### **3.4 Alkali-Aggregate Reaction**

Geopolymer concrete contains high levels of alkali as an intrinsic part of its binding phases, so there are valid – and widely asked – questions regarding whether alkali-aggregate reaction (AAR) is a concern for the durability of geopolymer concrete structures. In an interpretation of recent research, Provis et al. (3) concluded that, although AAR can occur in geopolymers, AAR in general does not contribute to deleterious expansive phases as is the case in Portland cement-based systems. In fact, AAR is close in nature to many geopolymer-forming reactions and when controlled correctly, could be expected to contribute substantially to longer term strength development through the formation of a strong and intimate paste-aggregate bond.

Based on the relationships between alkali-silica reaction expansion and slag content of Portland-slag cement, it has been observed that deleterious expansive processes would not be predicted to happen at slag contents higher than 80%, even at an alkali content over 4% (32). The reason for this behaviour is that the replacement of a high fraction of Portland cement with Al-rich supplementary cementitious materials will result in the formation of C-A-S-H with a low Ca/Si ratio, and this product can bind more alkali ions than C-S-H with a higher Ca/Si ratio, thus offering the potential to inhibit AAR. According to Provis et al. (3), many researchers have confirmed that AAR does indeed occur in slag-geopolymers, as significant amounts of AAR reaction product are able to be observed by electron microscopy around the interfaces between aggregate and paste, but the overall expansion of the specimens was in almost all cases less than that of conventional Portland materials tested in parallel, across a variety of testing protocols. In geopolymers containing low-Ca fly ash or metakaolin blended with slag, the expansion of the specimens was less than in solely slag-based specimens (3), and samples containing low levels of Ca demonstrated very small or negligible expansion, even with alkali-reactive aggregates.

The widely used accelerated mortar bar test (ASTM C1260) (35) for screening AAR-susceptible aggregates was designed for Portland-based reactions and may not be directly suitable for application to geopolymers (3), although in a practical sense it is unlikely that this test will be rapidly replaced due to its popularity and the lack of a validated alternative method specific to geopolymers. In the ASTM C1260 test, the mortar bars are cured for only 24 h (which is far from sufficient for almost all geopolymer formulations), then submerged in water for 24 h (inducing leaching of alkalis from the geopolymers and hindering further reaction (2)), and afterwards in 1 M NaOH solution at 80°C. Alternative curing regimes are therefore often applied to geopolymer mortars in variants of this testing methodology, but this does render the test non-compliant with the ASTM standard and causes problems in comparing the results between various published studies. Additionally, the alkali level of 1 M NaOH used in the immersion step of this test is actually lower than the intrinsic alkali content of most geopolymer binders (36), and thus the contribution of the external alkalis may be very limited (3). Clearly, the quantification of AAR for geopolymer concrete requires further investigation.

## **4. The Case for Performance-Based Standards**

In most jurisdictions, cement and concrete standards currently follow a cascade of dependency where the base standards assume and prescribe that Portland cement is the key binder, and is only aided by SCMs. Only a few standards do not prescribe the minimum level of Portland content of the cementitious materials, but most standards such as the European framework standard EN 206-1 prescribe a minimum Portland content for different applications or exposure classes. This prescription is highly inhibitive to

innovation and presents a formidable challenge to the commercial adoption of new cementitious binders, including geopolymers. When Portland cement is no longer the key binder and various non-Portland binder chemistries could be used instead, a prescriptive standards framework becomes inappropriate.

Prescriptive standards give users, including structural engineers, concrete specialists, contractors, asset owners and insurance companies, a sense of security. A key question in a dispute about concrete quality is whether the cement, the fresh concrete and the in-situ cast or precast concrete elements have all been manufactured according to the applicable standards. That often allows a shifting of the blame for a material or element failure to a specific party in the value chain. In contrast, if a performance standard is used instead, either for the cement binder, the wet concrete or the concrete elements, it places the onus for technical performance on the producer. Many producers find this situation a culture shock, which impedes attempts to change the standards framework from a prescriptive to a performance basis. Despite claims to the contrary, many vested interests are served by the current prescriptive and Portland-based framework. If the construction industry is serious in migrating to a performance framework of standards, it will allow the wider adoption of geopolymer concrete, and enable the industry to reduce its CO<sub>2</sub> footprint significantly. Moreover, such a shift will allow the utilisation of a wide range of precursors, provided that they are safe to use; this prohibition of intrinsically hazardous materials (which includes a significant fraction of unprocessed non-ferrous metallurgical slags as well as most unprocessed incineration ashes) must fundamentally be encoded in the standards documents, and should not dilute the 'non-prescriptive' philosophy of standardisation any more than is absolutely necessary.

A highly significant set of questions do arise regarding which performance testing and durability testing methods should be used in order to specify performance criteria. The discussion above shows the challenge of developing testing methods for durability that are independent of initial binder phase assemblage. In a critical review of performance-based approaches, Alexander and Thomas (37) explained that it is possible to relate service-life prediction models to durability testing, even when it is known that the diffusion parameters in concrete are complicated by several factors, including interaction between the diffusing species and the matrix and the reduction of diffusion coefficients with age. It is noteworthy that South Africa has developed a suite of durability index tests – oxygen permeability, sorptivity, and chloride conductivity – and these are linked to service-life models for the relevant deterioration mechanisms in reinforced concrete structures (37).

## **5. Geopolymers with Low CO<sub>2</sub> Emissions**

There have been a wide range of reported outcomes regarding the environmental performance of geopolymer concrete compared with Portland cement based concrete (38). Some authors report an 80% reduction in CO<sub>2</sub> emissions for geopolymer binders compared with blended Portland cement based on an independent lifecycle analysis (LCA) (39), while others like Habert et al. (40) have reported values which are more similar to that of Portland cement. The bulk of the CO<sub>2</sub> emissions attributed to geopolymeric binders are due to the production of the alkali activator(s), and it is here where caution is required in drawing conclusions.

There are various pathways to the production of sodium silicate, generally based on Na<sub>2</sub>CO<sub>3</sub> as a Na source. The different available processes for conversion of Na<sub>2</sub>CO<sub>3</sub> (or NaOH) and SiO<sub>2</sub> to sodium silicate, via either furnace or hydrothermal routes, differ by a factor of 2-3 in CO<sub>2</sub> emissions, and up to a factor of 800 in other emissions categories (41). It is therefore essential to state which of these processes is used as the basis of any LCA. Moreover, the best available data for emissions due to sodium silicate production were published in the mid 1990s (41), so improvements in emissions since that time have not been considered. Sodium carbonate itself can be produced via two main routes, which vary greatly in terms of CO<sub>2</sub> emissions. The Solvay process, which converts CaCO<sub>3</sub> and NaCl to Na<sub>2</sub>CO<sub>3</sub> and CaCl<sub>2</sub>, has emissions between 2–4 t CO<sub>2</sub> per tonne of Na<sub>2</sub>CO<sub>3</sub>, depending on the energy source used. Conversely, the mining and thermal treatment of trona for conversion to Na<sub>2</sub>CO<sub>3</sub> has emissions of around 0.14 t CO<sub>2</sub> per tonne of Na<sub>2</sub>CO<sub>3</sub> produced plus a similar level of emissions attributed to the electricity used. This indicates an overall factor of 5–10 difference in emissions between the two sources of Na<sub>2</sub>CO<sub>3</sub> (38). A similar situation is likely to exist in the production of NaOH, where various different processes are in use in different parts of the world; there will also be significant differences in the non-CO<sub>2</sub> emissions profile (particularly regarding mercury) between these processing routes.

Unfortunately, a high alkali activator addition is sometimes used in geopolymer concrete to compensate for the lack of reactivity of some precursors at low temperature, slow initial strength development, poor aggregate and particle grading design, and the deficiency of at least a portion of highly reactive precursors. When precursors could be custom ground, various precursor materials are available in the supply chain, alkali activators are better matched to the precursors, reagents are added to enhance dissolution and phase formation, and appropriate plasticisers are used to reduce water content, the achievement of high performance with a significantly lower alkali activator addition is possible, resulting in cost savings and greatly reduced CO<sub>2</sub> emissions.

## **6. Pathway to Commercial Adoption**

It is essential that the right drivers are in place to enable the commercial adoption of a new construction material. Usually, a substantial reduction in CO<sub>2</sub> emissions can be a driver for demonstration projects, or for inclusion as an innovation component as part of a larger project, but in general it is not a sufficient driver for widespread adoption. For the latter to happen, the strongest driver will be cost reduction, but enhanced technical performance such as enhanced resistance to aggressive media and fire, or utilisation of waste precursors to create a new value chain, may also be drivers.

Irrespective of the above drivers and the favourable CO<sub>2</sub> emissions of correctly designed geopolymer concrete, it is essential to gradually build industry confidence in geopolymers from a technical and commercial perspective. There are only a few examples of geopolymers in long term structural applications that can demonstrate the long service life of this emerging construction material (2), but confidence has been strengthened by recent large scale structural applications in Victoria, Queensland and South Africa. In Portland cement concretes, substantial technical advances since the 1970s have led to new engineering applications and cost reduction, most notably the chemical and mineral admixtures which are used to improve the properties of almost every concrete now produced in the developed world. For geopolymer concrete as an emerging technology, such advances are not yet available at the same level, which presents a challenge for wider commercial adoption beyond demonstration projects. The implementation of such advances is often dependent on scale and hence availability in the supply chain, so close collaboration is required between technology providers, materials suppliers, concrete manufacturers, contractors, asset owners, consulting engineers and regulatory authorities to build market confidence, achieve wider adoption and guide further research.

Regulatory progress has been made in Australia by VicRoads, that has recognised geopolymer concrete as being equivalent to Portland cement-based concrete for a range of applications. Nevertheless, geopolymer cement is not recognised as a binder in its own right in the Australian standards for structural concrete, and likewise in most other international standards frameworks. Beside the challenge associated with relating accelerated durability testing data to in-service life predictions as outlined above, there is also the question of whether existing structural engineering design methods calibrated for Portland-based concrete are applicable to geopolymer concretes. Laboratory research outcomes on these questions have given some comfort and certainly have supported commercial adoption, but it is indeed the success of in-service construction applications that has given the confidence to early adopters to continue with the technology. It is essential that research continues, not just on phase assemblage and durability, but that the industry should collaborate more with researchers in developing appropriate structural design methods and work towards the prediction of service life.

It has been necessary to build confidence in geopolymer concrete from scratch in each new market, as consumers wish to see success under local conditions. Small 'low risk' projects, where the cost of replacement is low if performance is not met, must first be completed to build confidence before more complex projects are tackled. The key challenge is often the availability of suitable precursors at the right price for demonstration projects in a new location, which is a more challenging situation technically and commercially than when there is a suitable supply chain at scale. This is the equivalent of building a car from components compared with delivery from an assembly line. These challenges are often underestimated by both researchers and experienced concrete professionals. Nevertheless, commercial adoption of geopolymer concrete has been achieved in selected applications (2). Recently, there has been an increase in interest in commercial application of geopolymers in new markets, with the driver being valorisation of fly ash in Australia, India and South Africa, a push to further reduce CO<sub>2</sub> emissions in

Europe, the Middle East and China, improved technical properties and if possible, cost reduction, in most markets.

## **7. Could Different Precursors be Used?**

Most of the published research on geopolymers has focused on SCM precursors like metakaolin, blast furnace slag and coal fly ash. According to Provis et al. (3), recent studies have greatly extended the sources and types of precursors, which may include non-ferrous slags, coal gangue, red mud, mine tailings, catalyst residue, coal bottom ash, rice husk ash, palm oil fuel ash, other biomass ash, municipal solid waste incinerator ash after removal of heavy metals, waste glass, waste ceramic, paper sludge ash, sludge resulting from water treatment, calcined clays, and natural minerals including natural pozzolans. Many of these precursors vary in reactivity over time, and could be more challenging than using fly ash and blast furnace slag. A bigger challenge is consistency of supply, associated with bringing these materials into the supply chain at a useful volume, which could pose a logistical challenge. In the same way as there is reluctance by Portland cement users to shift to geopolymers in fear of the unknown and the higher perceived risk, there is reluctance by geopolymer concrete producers familiar with using fly ash and slag to shift to other precursors. It takes a substantial amount of effort and time to prove again to the market that geopolymers made from new precursors perform well and are durable.

## **8. Conclusions and Final Remarks**

Geopolymers, or alkali-activated materials, have progressed from a laboratory research phase to industrial application in various structures and in different countries. Although further work is required to introduce a wider variety of precursors into the cementitious supply chain, and confidence building in the market will be ongoing, geopolymer concrete now offers a high-volume, affordable, and low-CO<sub>2</sub> alternative to Portland cement. Progress on the modification of existing accelerated durability testing methods and the development of methods to predict service-life will lead to the development of a performance standards framework, which is essential for the utilisation of various precursors in geopolymer cement. Such a framework will greatly enhance market adoption as it will simplify specification of geopolymers by structural engineers and reduce perceived risk, which will expand the scale of the supply chain, reduce costs and justify more expenditure on research, leading to further improvements in the technology.

Substantial progress has been made on the analytical characterisation and phase modelling of geopolymers at the nano-scale. Nevertheless, as is still the case with Portland cements, the link between nano-structure, microstructure and macroscopic/engineering behaviour of these materials remains a research challenge. This task is particularly challenging, because these materials are heterogeneous on every length scale from nanometers to centimeters, are crystallographically disordered, are multiphase, and are formed from precursors that are themselves often difficult to characterise. Further insight into the phase assemblage and nano-structure of geopolymers of industrially-relevant composition will aid the development of improved accelerated durability testing methods and service-life prediction, which will help to build further confidence in the market. There is a need to generate more data to describe the engineering behaviour of geopolymer concrete under different ambient conditions, so that existing structural design methods can be recalibrated. For this to happen in a productive manner, it is essential that structural engineers and materials scientists collaborate more closely.

<sup>1</sup>Prof. Dr.-Ing., Director, <sup>2</sup>Dipl.-Ing., Research Assistant and <sup>3</sup>Dr.-Ing., Research Associate, Materials Testing and Research Institute (MPA Karlsruhe), Karlsruhe Institute of Technology (KIT), Germany

**Abstract:** This contribution focuses on the newly developed creep and shrinkage models being included in the *fib* Model Code 2010. Emphasis will be paid to the background of these models and the underlying principles of constitutive behaviour and related modelling of modern structural concretes. Concerning shrinkage one of the main characteristics of the new model is the subdivision of total shrinkage into the components basic shrinkage and drying shrinkage. Furthermore, the creep deformation is introduced as the sum of the components basic creep and drying creep. The time-development functions of all deformation components were adjusted in order to predict properly the particular kinetics associated with the related mechanisms and the ambient conditions. The models will be briefly discussed in view of their prediction accuracy and application in the analysis and design of concrete structures. Finally, a brief outline on the microstructural mechanisms of concrete deformation behaviour will be given.

**Keywords:** Creep, shrinkage, prediction models, *fib* Model Code 2010.

## 1. Introduction

In the framework of the development of the new *fib* Model Code for Concrete Structures 2010 (MC 2010) creep and shrinkage prediction had to be revisited. The main reasons were that the models being included in the former CEB-FIP Model Code 1990 (MC 1990) reflect the knowledge of the 80s of the last century. Furthermore, some types of concrete being applied in practice today may differ considerably from those of that time. Finally, the fact that personal computers were not available to designers, when MC 1990 was developed, had some effect on the type of models being selected at that time.

While the mentioned weaknesses of the former MC 1990 models are overcome by the new models in MC 2010, one basic characteristic has been maintained. This concerns the consideration of the effect of the composition of concrete by means of the substitute parameter compressive strength of concrete. There are different reasons for that being indicated subsequently.

It is well known that the behaviour of structural concrete subjected to different types of loadings and actions depends primarily on its composition and its age. Modern concretes represent a five component system. They are composed of mineral aggregates like natural sand and gravel, cement, water, additions and admixtures. While the admixtures like plasticizer or air-entraining agents are added only in small quantities, additions like fly ash, stone dust, silica fume or finely ground blast furnace slag are often added in large amounts to the concrete mix. Depending on the reactivity of the additions and the water/cement or water/binder ratio, respectively, the properties of concrete can vary considerably, e.g. the compressive strength between approximately 5 and 200 N/mm<sup>2</sup>, see also *fib* Bulletin 51 [1].

It appears neither possible nor does it make any sense until today to develop code-type models, which take into account quantitatively all the parameters of the composition of concrete. The reasons are twofold. First, at the stage of structural analysis and design usually only the concrete strength, the dimensions of members, the exposure conditions and some other actions are known to the designer but not any details of the concrete composition. Second, too less systematic experimental data are available to cover all aspects of the effects of the composition of concrete and to derive reliable models. On the other hand, the strength of concrete may be used as a reasonable substitute parameter for the pronounced effect of the concrete composition. Hence this key parameter, in particular the compressive strength at the age of 28 days, partly complemented by information on the type of cement and the use of high amounts of additions in combination with the age of concrete, constitute the fundamental internal parameters to be used for code-type modelling of concrete. However, this simplification is also a source of the scatter which can be observed when the predictions of code-type models are compared with experimental data (see e.g. sections 4 and 5).

It has also to be kept in mind that the type of mineral aggregates used for concrete exerts a major effect on its deformation characteristics. Even if the aggregates may be characterised as quartzite material, their stiffness may vary considerably, depending on the place where the aggregates have been dug. This is another uncertainty in predicting creep and shrinkage, which is hardly to overcome unless tests are carried out.

Subsequently the newly developed creep and shrinkage models for MC 2010, including the approach to predict elastic strains, will be briefly presented and discussed. Their constitutive background will be explained and major features of the constitutive behaviour will be shown. In addition the prediction accuracy of the new models and possibilities for further improvement will be indicated. Temperature effects are not dealt with.

## 2. Definition of strain components of concrete

Concrete shows in addition to elastic deformations at loading both stress-dependent and stress-independent long-term deformations. The total strain  $\varepsilon_c(t)$  occurring at time  $t$  in a concrete member subjected to a sustained uniaxial stress at time  $t_0$  (age at loading) and at constant ambient humidity and temperature may be expressed by Eq. (1):

$$\varepsilon_c(t) = \varepsilon_{ci}(t_0) + \varepsilon_{cc}(t, t_0) + \varepsilon_{cs}(t) \quad (1)$$

where  $\varepsilon_{ci}(t_0)$  is the stress-dependent initial strain (elastic strain) at the time of stress application,  $\varepsilon_{cc}(t, t_0)$  is the creep strain at a concrete age  $t \geq t_0$  and  $\varepsilon_{cs}(t)$  is the shrinkage or swelling at a concrete age  $t$ .

This subdivision of the total strain into strain components, being a matter of convention, has been selected for MC 2010 [2]. One of the underlying key issues results from the fact that only overall deformations can be observed and measured on a single specimen, which means that the load- and time-dependent components cannot be separated. A second identical specimen is required in order to capture the shrinkage component that occurs after loading of the first specimen. In order to determine the load-dependent strains by subtraction of shrinkage strains the hypothesis has to be applied that the loaded and the unloaded specimen show the same shrinkage. This is very probably not the case, however, the hypothesis may neither be proven nor discarded by experiments. Further conventions are necessary to separate creep and elastic strains, or in general terms, time-dependent and instantaneous deformations considering both the age at loading and any later stage. Most usual is the procedure to measure the elastic strains (or the modulus of elasticity) on a separate specimen at the age at loading.

There are different approaches for creep prediction models where in particular the elastic strain is not distinctly separated from the creep strain, see e.g. [3]. However, it is of some advantage in the practice of design to use the descriptive parameters like elastic strain or creep strain, being connected with the modulus of elasticity of concrete and the creep coefficient. Basically, there is no restriction concerning the prediction accuracy of any models as long as the definitions for the strain components are consistent with the related derivation of the individual strain components from experimental data.

## 3. Elastic strains and modulus of elasticity

The initial elastic strain  $\varepsilon_{ci}(t_0)$  according to Eq. (1) may be directly related to the modulus of elasticity  $E_{ci}(t_0)$  applying Hooke's law, i.e.  $E_{ci}(t_0) = \sigma_c(t_0)/\varepsilon_{ci}(t_0)$ . Hence  $E_{ci}(t_0)$  is the tangent modulus of elasticity. At the age of  $t_0 = 28$  days,  $E_{ci}$  may be estimated from the subsequent Eq. (2), which is given in MC 2010 [2]:

$$E_{ci} = E_{c0} \cdot \alpha_E \cdot \left( \frac{f_{cm}}{10} \right)^{1/3} \quad (2)$$

In Eq. (2)  $E_{c0}$  is a constant in *MPa*,  $\alpha_E$  takes into account the effect of the aggregate type, and  $f_{cm}$  is the mean compressive strength of concrete in *MPa* at the age of 28 days. If  $f_{cm}$  is not available from tests, it can be estimated from the characteristic strength  $f_{ck}$  by means of the relation  $f_{cm} = f_{ck} + 8$  *MPa* [2].

By definition  $E_{ci}(t_0)$  and  $E_{ch}$ , respectively, do not contain any viscous or plastic deformations. However, at least at first loading of conventional structural concrete members, some plastic deformations due to micro-

cracking are observed, often termed as initial plastic set. Its magnitude decreases with the increase of the strength of concrete.

As a matter of convention, this initial plastic deformation is considered as part of the creep strain  $\varepsilon_{cc}(t, t_0)$  in MC 2010, i.e. it is included in the prediction of the creep function, see section 5. In cases where in practice at the design of a concrete structure creep effects are not considered and only an elastic analysis is carried out, a reduced modulus of elasticity  $E_c$  (secant modulus of elasticity) according to Eq. (3) should be used which takes into account the initial plastic strain:

$$E_c = \alpha_i \cdot E_{ci} \quad (3)$$

Herein  $\alpha_i = 0.8 + 0.2(f_{cm}/88) \leq 1.0$ , see MC 2010 [2]. For concrete grades higher than C80, the initial plastic strain may be neglected and  $\alpha_i = 1.0$  is calculated.

## 4. Shrinkage

### 4.1 Modelling

The shrinkage of concrete  $\varepsilon_{cs}(t, t_s)$  is usually defined as the load-independent strain or volume change (volume reduction) of concrete when concrete is subjected to drying, i.e. when hardened concrete evaporates at constant ambient environment. From a physical point of view various types and components of shrinkage may be subdivided [1]. However, as long as normal strength concrete is considered only the deformation caused by drying (drying shrinkage) is of practical significance. Hence for many decades this deformation of concrete, termed as shrinkage  $\varepsilon_{cs}(t, t_s)$  and achieving negative strain values of up to approximately 0.08 %, has been described by a simple product-type formula, see e.g. MC 1990 [4]:

$$\varepsilon_{cs}(t, t_s) = \varepsilon_s(f_{cm}) \cdot \beta_{RH} \cdot \beta_s(t - t_s) \quad (4)$$

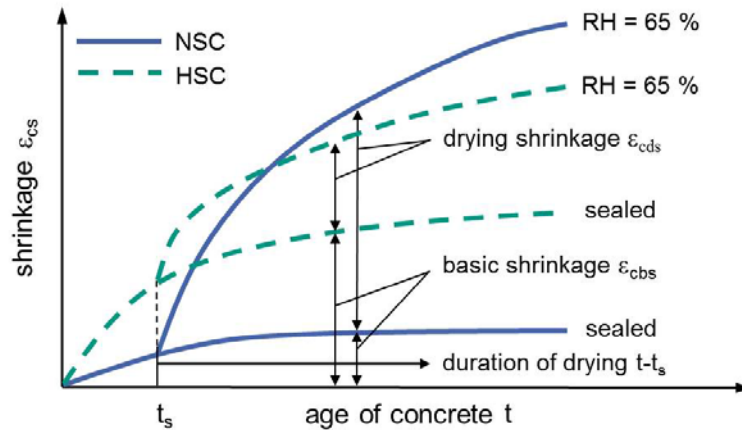

where  $\varepsilon_s(f_{cm})$  is a monotonic decreasing function with increasing strength,  $\beta_{RH}$  takes into account the average ambient humidity and the notional member size, and  $\beta_s(t - t_s)$  describes the development of shrinkage over time by means of a hyperbolic function. Here  $t - t_s$  is the duration of drying, i.e.  $t$  is the concrete age and  $t_s$  is the concrete age at the beginning of drying.

When high strength concrete is considered, which is the case in MC 2010, this type of formula can no longer be kept. The reason becomes clear from Fig. 1, where besides the drying shrinkage component also the basic shrinkage component is shown. Basic shrinkage is observed on sealed concrete specimens, i.e. when a concrete is prevented from drying. This particular shrinkage primarily results from self-desiccation and to a much lower extent from chemical shrinkage which both are associated with the hydration process.

While for normal strength concrete the basic shrinkage  $\varepsilon_{cbs}$  is very small ( $\varepsilon_{cbs} < 0.05 \cdot \varepsilon_{cs}$ ), compared to shrinkage or total shrinkage, respectively, for high strength concrete this component may become very large ( $\varepsilon_{cbs} \gg 0.05 \cdot \varepsilon_{cs}$ ), and even exceed the drying shrinkage component. Hence, a new approach for shrinkage must clearly distinguish between basic shrinkage  $\varepsilon_{cbs}$  and drying shrinkage  $\varepsilon_{cds}$ , and is formulated as a sum of both components in MC 2010:

$$\varepsilon_{cs}(t, t_s) = \varepsilon_{cbs0}(f_{cm}) \cdot \beta_{bs}(t) + \varepsilon_{cds0}(f_{cm}) \cdot \beta_{RH} \cdot \beta_{ds}(t - t_s) \quad (5)$$

Herein  $\varepsilon_{cbs0}(f_{cm})$  and  $\varepsilon_{cds0}(f_{cm})$  give the notional coefficient of basic and drying shrinkage, respectively. The functions  $\beta_{bs}(t)$  and  $\beta_{ds}(t - t_s)$  describe the time-development of the particular shrinkage component by means of an exponential function and a hyperbolic function, respectively, see MC 2010 [2].

**Figure 1. Total shrinkage subdivided into the components basic shrinkage  $\epsilon_{cbs}$  and drying shrinkage  $\epsilon_{c ds}$  for normal strength concrete (NSC) and high strength concrete (HSC). Note that the figure is not scaled.**

It should be noted that the term basic shrinkage is introduced in MC 2010 in analogy to the well-established term basic creep which describes the creep occurring when a loaded member is prevented from drying (see section 5). In the literature basic shrinkage is often termed as autogenous shrinkage or intrinsic shrinkage. Furthermore, the summation approach given by Eq. (5) represents a certain simplification as there is an interaction between basic shrinkage and drying shrinkage. However, for the sake of simplicity, and as the average prediction accuracy appears to be unaffected, this summation of individual strain components has been adopted.

While within MC 2010 detailed formulas are given to calculate the total shrinkage and its development with time, in many practical cases of design only the final value of shrinkage is of interest. Those final values of shrinkage (shrinkage after 50 years (service life) of drying) are given in Table 1. The final shrinkage values for other concrete grades and member sizes may be obtained roughly by linear interpolation.

**Table 1. Shrinkage values  $\epsilon_{cs,50y} \cdot 10^3$  after a duration of drying of 50 years for the concrete grades C20, C50 and C100**

Concrete grade	Dry atmospheric conditions (RH = 50%, indoors)			Humid atmospheric conditions (RH = 80%, outdoors)		
	Notional size $2A_c/u$ [mm]					
	50	150	600	50	150	600
C20	-0.68	-0.67	-0.53	-0.40	-0.39	-0,31
C50	-0.56	-0.56	-0.46	-0.37	-0.36	-0.31
C100	-0.48	-0.47	-0.42	-0.37	-0.37	-0.34
$A_c$ = cross-section [mm <sup>2</sup> ]; $u$ = perimeter of the member in contact with the atmosphere [mm]						

It should be noted that the difference in total shrinkage between normal strength concrete and high strength concrete is rather small from a practical point of view. However, the magnitudes of the individual components are different. Considering shrinkage after 50 years of drying for normal strength concrete C20, the basic shrinkage amounts to 7 % of the total shrinkage whereas this value increases up to 53 % for high strength concrete C100. While the drying shrinkage causes eigenstresses over the cross-section, the basic shrinkage does not, as it is uniformly distributed.

## 4.2 Prediction accuracy

The new prediction model for shrinkage of normal strength and high performance concrete in MC 2010 was developed and optimized on the basis of 168 different long-time shrinkage experiments. These data sets have been carefully selected and show a reasonable spread of the effecting parameters. Based on a procedure being defined in [5], a coefficient of variation of  $V = 32\%$  has been determined.

As the selected data sets cover a broad range of shrinkage under various conditions, the parameter  $V$ , indicating originally the quality of the regression analysis, may also be considered as a measure of the prediction accuracy of the shrinkage model given in MC 2010. For this reason comparisons with any other models, considering  $V$  and  $F$  in view of evaluating the prediction accuracy, would make only sense, if the other models would have been optimized applying the same data base.

For design purposes often only the final value of the shrinkage strain is of relevance which can be obtained by an extrapolation of the respective experimental data set. The mean prediction error  $F$ , indicating the average deviation between extrapolated and predicted final shrinkage values and being determined according to [5], amounts to  $F = 22\%$ .

## 4.3 Improvement of the shrinkage prediction

The prediction of the notional basic shrinkage coefficient  $\varepsilon_{cbso}(f_{cm})$  may be improved, if more detailed information on the type of cement, applied additives like silica fume, fly ash or blast furnace slag would be taken into account. Regarding the time-function of basic shrinkage no significant improvement of the overall prediction accuracy was obtained, when introducing the compressive strength as an affecting parameter.

The same aspects hold also true for modelling the notional coefficient and the time-development of the drying shrinkage component. Some further improvements might be obtained, if the parameter beginning of drying  $t_s$  would be introduced in the formulae. This holds true for both normal and high strength concrete. However, within typical durations of moist curing in practice, no significant effect of this parameter on the magnitude of shrinkage can be observed.

A general problem in finding an optimized prediction accuracy for shrinkage results from observed differences in the magnitude of shrinkage depending where the experimental investigation has been carried out. It is clearly evident from the shrinkage data included in the RILEM database [10] that the concretes investigated in the United States show always higher shrinkage deformations than comparable concretes in European investigations. This may partly be attributed to differences in the types and compositions of the cements and to some typical differences in the composition of the concretes (concretes according to EN 206 have a lower cement content than typical American concretes). In this context it should be noted, that the given prediction model for shrinkage is unbiased, i.e. the model has been optimized using all data sets included in the data base. Nevertheless, this may result in an underestimation of shrinkage of concretes outside of Europe up to approximately 20 %.

The prediction accuracy of the model could be improved without modifying the basic approach, if the parameter compressive strength of concrete is replaced by parameters describing the composition of concrete such as the water/cement-ratio, the cement content, the content and the type of additions and admixtures, etc. The reasons why such an approach has not been chosen for MC 2010 is explained in section 1.

If shrinkage is a decisive parameter in the design of concrete structures the most significant improvement of the prediction accuracy may be obtained by some short-term shrinkage tests on the particular concrete. The notional coefficients of autogenous and drying shrinkage, which are the most uncertain parameters of the model, may then be determined from the measured shrinkage data.

## 5. Creep

### 5.1 Modelling

The creep of concrete  $\varepsilon_{cc}$  is defined as the stress-dependent strain developing over time after the occurrence of the initial elastic strain when concrete is subjected to constant mechanical loads [1], [2]. For practical reasons creep is expressed by the so-called creep coefficient  $\varphi$ , which gives the ratio of creep strain and elastic strain at the concrete age of 28 days under the same stress  $\sigma_c(t_0)$ , i.e.  $\varphi(t, t_0) = \varepsilon_{cc}(t, t_0) / \varepsilon_{ci}(t_0 = 28d)$ , where  $t$  is the age of concrete and  $t_0$  is the age at loading in days. Hence  $\varphi(t, t_0)$  may be written as:

$$\varphi(t, t_0) = \frac{\varepsilon_{cc}(t, t_0)}{\sigma_c(t_0)} \cdot E_{ci} = \frac{\varepsilon_{cc}(t, t_0)}{\varepsilon_{ci}(t_0 = 28d)} \quad (6)$$

It has to be pointed out that in this definition of  $\varphi(t, t_0)$  the initial elastic strain at the concrete age of 28 days  $\varepsilon_{ci}(t_0 = 28d)$  is used, which can also be expressed by means of the modulus of elasticity at the age of 28 days, i.e.  $\varepsilon_{ci}(t_0 = 28d) = \sigma_c(t_0) / E_{ci}$ , where  $E_{ci}$  is the tangent modulus of elasticity at the concrete age of 28 days. Some confusion might be caused, as sometimes in the literature the creep coefficient is defined as  $\varphi^*(t, t_0) = \varepsilon_{cc}(t, t_0) / \varepsilon_{ci}(t_0)$ , where  $\varepsilon_{ci}(t_0)$  is the initial elastic strain at the time at loading  $t_0$ . Note, that  $\varphi^*(t, t_0)$  and  $\varphi(t, t_0)$  may differ considerably, in particular if  $t_0 \ll 28$  days. It is of veritable advantage to use  $\varphi(t, t_0)$  instead of  $\varphi^*(t, t_0)$  as it has been done also in former CEB Model Codes, see e.g. [6].

The total load-dependent deformation of structural concrete, i.e. the sum of elastic strain and creep strain per unit stress, is described by the creep function  $J(t, t_0)$ , see MC 2010:

$$J(t, t_0) = \frac{1}{E_{ci}(t_0)} + \frac{\varphi(t, t_0)}{E_{ci}} \quad (7)$$

Herein the creep function is connected with the descriptive values of  $E_{ci}(t_0)$ ,  $E_{ci}$  and  $\varphi(t, t_0)$  being defined above. The creep function has the dimension [1/MPa] and gives itself no descriptive value to the engineer in contrast to the creep coefficient which clearly indicates the relation between creep strain and elastic strain. Some other models for creep describe the creep function in a different way without using the descriptive parameters included in Eq. (7), see e.g. [3]. However, it has to be stated clearly that any type of expressing the creep function is correct as long as the total load- and time-dependent strains per unit stress are described as observed in experiments. This holds true for Eq. (7) as the definitions of the descriptive parameters  $E_{ci}(t_0)$ ,  $E_{ci}$  and  $\varphi(t, t_0)$  – being themselves derived from the experimental data – are absolutely consistent.

While in MC 1990 the creep coefficient  $\varphi(t, t_0)$  is modelled by a simple product-type approach applying a uniform deformation kinetics,

$$\varphi(t, t_0) = \varphi_0 \cdot \beta_c(t, t_0) \quad (8)$$

for MC 2010 a product type approach with a distinct separation into the deformation components basic creep and drying creep has been chosen. This approach is written as follows:

$$\varphi(t, t_0) = \varphi_{0,b} \cdot \beta_{bc}(t, t_0) + \varphi_{0,d} \cdot \beta_{dc}(t, t_0) \quad (9)$$

In Eq. (8)  $\varphi_0$  is the notional creep coefficient reflecting the effects of various parameters on the magnitude of creep such as the age at loading, concrete strength, type of cement as well as the member size and ambient conditions, see MC 1990 [4]. The coefficient  $\beta_c(t, t_0)$  describes the time-development function of creep, being of the same hyperbolic type as Eq. (11), however with a constant exponent of 0.3. In Eq. (9)  $\varphi_{0,b}$  and  $\varphi_{0,d}$  represent the notional basic creep coefficient and the notional drying creep coefficient, respectively, both reflecting parameters affecting the magnitude of creep, see MC 2010 [2]. The coefficients  $\beta_{bc}(t, t_0)$  and  $\beta_{dc}(t, t_0)$  describe the time-development functions of basic creep and drying creep, respectively, see the subsequent Eqs. (10) and (11):

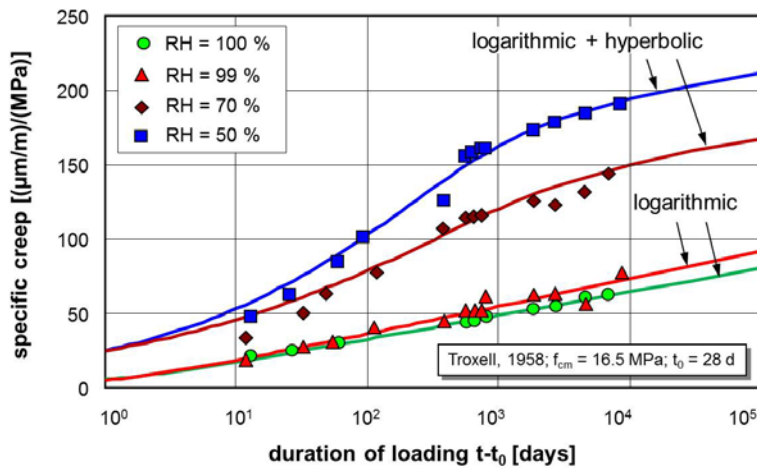

$$\beta_{bc}(t, t_0) = \ln \left( \left( \frac{30}{t_{0,adj}} + 0.035 \right)^2 \cdot (t - t_0) + 1 \right) \quad (10)$$

$$\beta_{dc}(t, t_0) = \left[ \frac{(t - t_0)}{\beta_H + (t - t_0)} \right]^{\frac{1}{2.3 + \frac{3.5}{\sqrt{t_{0,adj}}}}} \quad (11)$$

Herein  $t_{0,adj}$  is the adjusted age at loading,  $t - t_0$  is the duration of loading and  $\beta_H$  takes into account the member size and environmental conditions; for details see MC 2010 [2].

Note, that the basic creep is defined as the creep which occurs when concrete is prevented from drying (concrete loses no water), while drying creep is the additional creep which develops when concrete undergoes a drying process while being under load. This separation of the total creep into the components basic creep and drying creep, now realised in MC 2010 in contrast to MC 1990, became indispensable due to the fact that creep of normal strength concrete and high strength concrete should be covered best by one single model, and that the different deformation kinetics of these components should be considered properly. This is demonstrated in Fig. 2, which gives long-term experimental creep data for basic creep (RH = 100 % and RH = 99 %) and creep under drying conditions (RH = 70 % and RH = 50 %) together with a best-fit approximation.

The logarithmic function for basic creep (Eq. (10)) describes creep as an infinite on-going deformation process while the hyperbolic function for drying creep (Eq. (11)) approaches a finite value. Due to the addition of both components (see Eq. (9)), creep of concrete is now described as an infinite on-going process in MC 2010 in contrast to the approach given in MC 1990.

**Figure 2. Time-development of creep. Experimental data of Troxell et al. [7] and approximation by different types of time functions.**

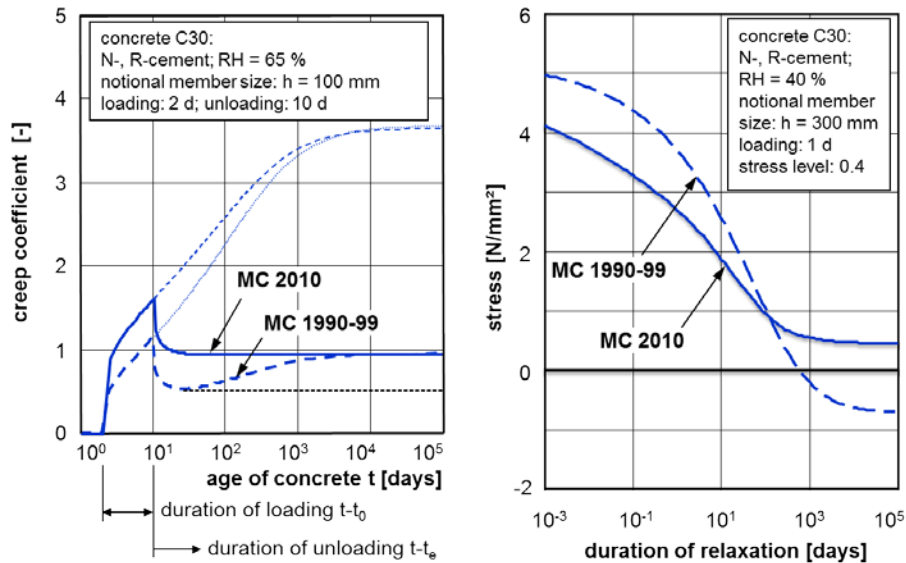

Comparing the different creep approaches of MC 2010 and MC 1990, respectively, it should be noted that the creep model in MC 1990 was valid up to the concrete grade C80. As high strength concrete up to the concrete grade C120 entered the practice only a few years after MC 1990 has been released, a modification of this creep (and shrinkage) model became necessary. This modification, where the main characteristics of the creep approach of MC 1990 have still been kept, is termed as MC 1990-99 and is given e.g. also in [1]. The actual creep model in MC 2010 now explicitly separates creep into the components basic creep and drying creep as described above while neither MC 1990 nor MC 1990-99 did.

When product-type creep approaches – their main feature is the product of the ageing function (age at loading) and the time-development function – are used in combination with the principle of linear superposition to describe creep deformations under variable stresses, some weaknesses could become evident under certain conditions, e.g. if a large member is loaded at a very young age. This is illustrated for the MC 1990-99 model in Fig. 3, left and right, considering the cases of creep recovery upon total unloading and relaxation. There a strain reversal and a change in sign, respectively, can be observed under the mentioned loading conditions. These weaknesses are nearly completely overcome by the new creep model in MC 2010 with the help of the exponent of the hyperbolic function in Eq. (11). In addition, this exponent also improves the prediction accuracy of creep development.

These weaknesses of the models MC 1990 and MC 1990-99, which were already known at the time when the models were developed (MC 1990 in the middle of the 80s of the last century), have been accepted in order to keep the approach as simple as possible and to facilitate hand calculations being typical at that time. On the other hand it was clearly stated that the creep prediction model of MC 1990 should only be applied for variable stresses and strains in combination with the effective age adjusted modulus method, see Eq. (12):

$$E_{c,eff}(t, t_0) = \frac{E_{ci}(t_0)}{1 + \rho(t, t_0) \cdot \varphi(t, t_0)} \quad (12)$$

Herein  $E_{c,eff}(t, t_0)$  is the effective age adjusted modulus and  $\rho(t, t_0)$  is the relaxation coefficient. If only final deformations or stresses are of interest,  $\varphi(t, t_0) = \varphi_{\infty}$ . Furthermore,  $\rho(t, t_0)$  may be assumed as  $\rho(t, t_0) = \text{const} \approx 0.8$  for the sake of simplicity. By means of Eq. (12) the creep analysis is reduced to an elastic analysis, and the fore-mentioned problems are overcome. For further details and background information see [8].

**Figure 3. Prediction of creep recovery (left) and stress relaxation (right) applying the principle of linear superposition in combination with the creep models given by MC 1990-99 and MC 2010.**

In many practical cases it is sufficient to know the final (corresponding to the service life) value of the creep coefficient. Those values are given in Table 2. The final creep coefficient for other concrete grades and member sizes may be obtained by linear interpolation.

## 5.2 Prediction accuracy

Corresponding to the shrinkage model, also the creep model has been optimized on the basis of a data bank, which includes in total 379 different long-time creep experiments of 39 different researchers. Compared to the large amount of publications on creep worldwide this number might appear rather small. However, one should keep in mind that strong selection criteria have been applied for data to be included

in the data base. In addition own experience in running creep tests since more than 40 years at the KIT helped to identify critical data suffering from certain experimental weaknesses.

Furthermore, when developing and optimizing a creep model it is not decisive to use as much data as can be found. It is more important to have a reasonable spread of the creep affecting parameters in the data sets. A higher number of selected data within the same range of criteria does not necessarily result in a better prediction model, but may well result in better looking statistical parameters for the accuracy like the coefficient of variation or the mean prediction error. Some more information on shrinkage and creep data bases may be found in [9].

As the result of the optimization of the MC 2010 creep prediction model a coefficient of variation of  $V = 27\%$  has been obtained for the creep function according to a procedure being described in [5]. This value may also indicate the prediction accuracy, as explained for shrinkage in section 4. In various practical cases, only the final value of the creep function or the creep coefficient is of relevance. The mean prediction error  $F$  for the creep function, determined according to [5], was found to be  $F = 27\%$ .

It is generally observed that after short durations of loading or drying (for shrinkage) the prediction error is higher than after long durations of loading and drying. Due to the inherent scatter of creep and shrinkage deformations, the weaknesses of a model simplifying the reality and the general uncertainty caused by randomness of material properties and environment, the prediction of deformations is inevitably associated with a high probability of a more or less considerable error, see also [9]. For concrete structures being very sensitive to creep it is recommended to run related tests.

**Table 2. Creep coefficients  $\varphi(50y + t_0, t_0)$  after 50 years of loading for the concrete grades C20, C50 and C100**

Concrete grade	Age at loading $t_0$ [days]	Dry atmospheric conditions (RH = 50%, indoors)			Humid atmospheric conditions (RH = 80%, outdoors)		
		Notional size $2A_c/u$ [mm]					
		50	150	600	50	150	600
C20	1	7.7	6.2	5.0	4.8	4.2	3.7
	7	5.5	4.5	3.7	3.6	3.1	2.8
	28	4.3	3.5	2.8	2.8	2.5	2.2
	90	3.4	2.8	2.2	2.2	1.9	1.7
	365	2.5	2.0	1.6	1.6	1.4	1.2
C50	1	3.5	2.9	2.5	2.4	2.2	2.0
	7	2.5	2.2	1.9	1.8	1.7	1.5
	28	2.0	1.7	1.4	1.4	1.3	1.2
	90	1.6	1.3	1.1	1.1	1.0	0.9
	365	1.1	1.0	0.8	0.8	0.7	0.7

	7	1.4	1.2	1.1	1.1	1.0	1.0
	28	1.1	0.9	0.8	0.8	0.8	0.7
	90	0.8	0.7	0.7	0.7	0.6	0.6
	365	0.6	0.5	0.5	0.5	0.4	0.4

$A_c$  = cross-section [mm<sup>2</sup>];       $u$  = perimeter of the member in contact with the atmosphere [mm]

### **5.3 Improvement of the creep prediction**

It may come as a surprise to the informed layperson that research on concrete creep will continue to be facing significant challenges with regard to the further development of concrete constructions and the associated requirements for engineering models but also when considering the large number of remaining open questions in this area.

One of the many examples in this regard is the influence of varying ambient conditions on the magnitude of creep, which the KIT research activities are focussing on (see also [11]). This is of practical relevance, which is illustrated by the fact that almost all of the tests were carried out under constant ambient conditions, while by contrast, varying temperatures of structural components between -20 and +60 °C and varying ambient humidities between 30 and 100 % are not uncommon, even if only Central Europe is considered.

Furthermore, the creep models up to the date had predominantly been developed on creep experiments with higher ages at loading which holds also true for the new creep model given above. Nevertheless, in view of the large natural scatter of creep deformations the given model may be applied with sufficient accuracy also for younger concretes. However, regarding the limited number of experiments available on very young concretes, this previously insufficiently investigated behaviour and the prevailing nonlinear effects have recently been studied [12] to allow for improved predictions in the cases of very early loading (e.g. pre-stressing) of members.

The accuracy of the creep function depends on both the appropriate choice of the modulus of elasticity and the prediction accuracy of the creep coefficient itself. As long as no information is available on the concrete composition the modulus of elasticity at the age of 28 days may be estimated according to section 3 assuming the factor  $\alpha_E$  equal to 1.0. However, it is well-known that even for a given strength, the modulus of elasticity depends on the stiffness of the aggregates. The creep prediction may therefore be considerably improved by choosing factor  $\alpha_E$  according to the type of aggregates. Additionally, the modulus of elasticity at the age at loading does not only depend on the type of cement but also on the water/cement-ratio and the amount and type of additions.

Some attention has to be paid to the combination of ageing and time-development functions (product-type approach) when using the principle of superposition for the calculation of creep recovery or stress relaxation. Under certain conditions irrational results such as a strain reversal after complete unloading or a change in sign of stress relaxation may be obtained [5]. This weakness was tremendously reduced in *fib* Model Code 2010. However, some very special cases may be found, where these errors might occur to a rather small extent.

The logarithmic approach for the prediction of basic creep could be further optimised by introducing an additional exponent, which links the duration of loading  $t-t_0$  in Eq. (10) with the age at loading  $t_{0,adj}$ . It would enable a better adjustment to experimental data, i.e. it would result in slightly improved statistical parameters. However, a strain reversal after complete unloading will occur again, as the derivation of the function would be different for loading and unloading.

It may be generally stated that without modifying the given approaches, the prediction accuracy can probably be slightly improved if the parameter concrete compressive strength is replaced by parameters providing more detailed information on the concrete composition. However, a very significant improvement of the creep prediction may only be obtained if the notional creep coefficients, which are the most uncertain parameters of the model, are estimated on the basis of some short-term tests on the concrete to be used in the building or structure.

## **6. Understanding and controlling concrete creep and shrinkage deformation behaviour on the microstructural level**

The deformation behaviour of concrete as described by the models presented above can be traced back to partially reversible and irreversible changes in the microstructure of the material resulting from hygral changes and/or a mechanical loading. A detailed understanding of the mechanisms behind the long-term deformation behaviour would open up the chance to directly control and thus reduce the total deformation. However, the available knowledge on microstructural processes triggered e. g. by a drying or a mechanical loading of a building element is very limited. Today it is generally accepted that both shrinkage and creep of concrete are primarily a result of the deformation of the hardened cement paste, whereas the aggregates rather hinder this deformation process. Further it is known that the presence of water within the paste is a

prerequisite for deformations to occur. Therefore it is essential to understand the whereabouts and physical binding of water in the gel structure.

A large fraction of water is bound in hydrate phases such as calcium-silicate-hydrate (C-S-H) and calcium-hydroxide (CH), which form during the hydration process. According to Jennings, two different types of C-S-H, a low density (LD C-S-H) and a high density (HD-) C-S-H species have to be differed [13]. Despite their chemical binding, the water molecules bound in the C-S-H phases possess a certain mobility [14] and act as sliding plane allowing large irreversible shear deformations to occur. Feldman and Sereda identify this process as the dominating mechanism of concrete creep [15]. Newer computer simulations seem to confirm a significant contribution of this process to the total creep deformation [16]. In between the hydrate phases, water molecules are bound by van-der-Waals forces, resulting in a thermodynamic equilibrium, which however is disturbed by a mechanical loading of the sample [17]. So far it is unclear, to which extent these water layers act as sliding planes and contribute to the long term deformation behaviour. A great number of authors such as Powers, Wittmann or Bažant however identified processes on this level as the dominating mechanisms with regard to the creep deformation [17, 18, 14, 19]. Finally, depending on the w/c-ratio of the concrete, large fractions of water are stored in the capillary pores of the hardened cement paste. The role of this fraction of water with regard to concrete creep and shrinkage is still widely unknown.

All of the above model representations have in common that they essentially lack information on the mechanical behaviour of the microstructural constituents of the cement paste. Progress in this context can be expected from creep tests with in-situ small-angle X-ray scattering measurements [20]. Further, Vandamme and Ulm were able to conclude on the elastic properties and the creep modulus of the LD C-S-H and HD C-S-H phases using the statistical nano-indentation technique [21]. By implementing this data in a micromechanical model and combining it with data on the content of the individual phases in the concrete, they were able to show a good agreement with macroscopic creep results. Using this approach, a totally new class of creep models will become available in the future.

## 7. Summary and conclusions

In this paper it is shown which developments in structural concrete technology forced to modify the MC 1990 models for creep and shrinkage which have been applied with much success worldwide over two decades. One major point is the use of high strength concrete in practice nowadays. Concerning shrinkage, a model which should cover the characteristics of ordinary and high strength concrete must subdivide total shrinkage into the components basic and drying shrinkage, which is now realized in *fib* MC 2010. Similar to shrinkage also creep has to be subdivided into the components basic creep and drying creep. Hereby the time-development functions were adjusted in *fib* MC 2010 in order to predict more reliable the particular kinetics associated with the ambient conditions. On the other hand some basic features connected with diffusion-type processes and for reasons of practical application have been maintained also for the new models. The prediction accuracy of both models, being optimized applying an extended data bank, may be considered as rather good. Nevertheless creep and shrinkage tests are recommended when a structure is very sensitive to these deformations.

Considering future developments and improvements of the prediction models, respectively, some statistical evaluations indicate that there is only a very limited room left. Probably the consideration of the water/binder-ratio – if it is exactly known at the stage of design – might be associated with a minor improvement concerning the prediction accuracy. However, in view of the complexity of the composition of modern concretes and due to the pronounced effect and the variability of the characteristics of the type of aggregates, it makes hardly sense to go beyond using the substitute parameter compressive strength of concrete in prediction models. If the prediction accuracy achieved by the models is considered to be insufficient in view of the sensibility of the structure against deformations, tests have to be carried out. If these tests are run using the same concrete as applied for the structure, all effects concerning the concrete composition and the type of aggregates and cements are covered best, and the creep and shrinkage characteristics may be derived from the experiments with a coefficient of variation of approximately 10 %. Then these particular test results may be incorporated in the *fib* creep and shrinkage models by suitable algorithms to allow for the prediction of any deformation of this concrete under any given conditions. The development of these algorithms is underway.

Finally, significant progress in the next years is to be expected in understanding the microstructural mechanisms of creep and shrinkage. This knowledge will eventually allow the concrete engineer to develop concretes with significantly reduced long-term deformation tendency.

# Construction Methods

# Concrete Hinges at Legacy Way

Peter Boesch<sup>1</sup>, Chin Cheah<sup>2</sup> and Peter Miller<sup>3</sup>

<sup>1</sup>Bridges Manager of Cardno (NSW/ACT) Pty Ltd, <sup>2</sup>Bridges Engineer of Cardno (NSW/ACT) Pty Ltd,  
<sup>3</sup>Design Manager, Transcity JV

**Abstract:** Legacy Way is Brisbane City Council's 4.6km road tunnel that will connect the Western Freeway at Toowong with the Inner City Bypass (ICB) at Kelvin Grove and is being constructed by Transcity Joint Venture.

The tunnels are driven from west to east requiring below ground box structures to facilitate TBM launch and TBM extraction respectively. The boxes are constructed using the Cut and Cover method. A significant innovation is the design and construction of the Eastern Cut and Cover box structure.

For the Eastern Cut and Cover roof, post-tensioned cast in-situ T-girders were used. The connection to the substructure, i.e. the secant pile walls, was achieved utilising a concrete hinge located between the T-girder support and a capping beam on top of the secant piles. Concrete hinges have been used in the past, as outlined in the NAASRA 76 standard, but design rules do not exist in the current standards. Often concrete hinges are used at the supports of arches to support significant axial compression forces while achieving a moment free connection. At Legacy Way, concrete hinges are used to reduce the fixity and therefore load transfer from the roof into the walls whilst achieving a maintenance free connection without bearings. Additional compression capacity was required in the throat of the hinge which was realised by post-tensioning the connection with high-tensile steel stress bars.

**Keywords:** Concrete Hinge, Cut and Cover Tunnel.

## 1. Introduction

The design and construction of Cut and Cover structures have the particular challenge of designing roof to wall connections without bearings and movement joints as those elements cannot be replaced once the structure is backfilled. The solutions adopted at the Legacy Way tunnel project are discussed, especially the solution for the Eastern Cut and Cover at Kelvin Grove, where post-tensioned girders and post-tensioned concrete hinges are used to provide a durable structure that minimises whole of life costs and improves sustainability.

## 2. Principal approach to design of cut and cover structures.

Cut and cover structures are often designed as cast in-situ reinforced concrete boxes. For the construction of these boxes from the bottom up, additional shoring is required as shown in Figure 1.

Another option is to use the required shoring, (diaphragm walls and secant pile walls) as walls of the permanent structure. To achieve a watertight structure the roof must be fixed to the walls. If the span between supports for these roofs is large, or if the backfill on top of the structure adds significant weight, the roof will need to be prestressed to gain

**Figure 1. Cut and Cover box.**

additional capacity and reduce deflection. Prestress, shrinkage and creep and backfill result in significant long term effects on the structure, resulting in high moments in the corners if the structure is designed as a fixed, continuous frame.

Achieving a high quality structure and speedy construction are important requirements. Consequently, precast, prestressed Super-T girders were initially used for the design of the Cut and Cover structures at Legacy Way. The girders were made integral with the secant pile walls, cast in-situ curtain walls, connecting pile caps and topping slab. An image of this solution is shown in Figure 2.

**Figure 2. Top down construction Legacy Way.**

The demand for precast, prestressed Super-T-girders was high and supply was identified as an issue. Consequently, another option was investigated which utilised cast in-situ, post-tensioned girders in a top-down construction. From previous experience, it was known that timing of the post-tensioning, backfill and excavation of the roadway was critical for the design of corners of the structure. A solution was sought which would allow rotation while transferring vertical and shear forces. With such a solution, bending moments in the corners of the structure would be negligible and would not govern the design of the piled walls. Bearings could not be used as their replacement would be impossible in service because the structure is covered.

Concrete hinges were considered a possible solution as they would transfer loads and still allow a degree of rotation. However, design rules for those hinges published in the 1970s have not been updated and most research into this construction type generally dates back to the 1930s to 1960s.

### 3. History of concrete hinges

**Figure 3. Salginatobelbridge.**

The background of construction utilising concrete hinges, their history, invention, applications and design rules, are described below.

#### 3.1 Invention and applications

Hinge connections for concrete bridges were initially used in 1880 in an arch bridge for a railway in Eastern Germany. These connections were first called rolling joint connections and their use for the support of concrete arches was well established. However, their construction proved to be very elaborate. Further developments in 1885 and 1933 introduced plumb plates between concrete blocks to

simplify construction. By the early 1900s, Mesnager introduced reinforced concrete hinges using crosswise reinforcement through the throat of the hinge and in 1910 Freyssinet proved that reinforcement can be omitted through the throat with the design based on compression and concrete confinement (Marx (1).

Documented testing of concrete hinges was undertaken by Parsons (2), Kluge (3) and Base (4). Tested specimens were generally based on the Mesnager-type-hinge and included reinforcement through the throat of the hinge. It was generally found that high compression forces and substantial corresponding

shear forces could safely be transferred. An example is the Salginatobelbridge built in 1929/1930 and is shown in Figure 3

Sims (5) emphasized the favourable use of concrete hinges in northern England for motorway bridges in mining subsidence areas. His research concluded that reinforcement through the throat should be avoided to reduce the risk of shrinkage cracks. Leonhardt (6) undertook considerable research resulting in design guidelines for concrete hinges. He found that unreinforced concrete hinges can be successfully utilised if the confinement reinforcement in both adjoining concrete blocks is thoroughly detailed. This research work suggests no throat reinforcement is necessary if the shear force is smaller than 0.12 x axial force. If the shear force is between 0.12 x axial force and 0.25 x axial force, straight reinforcement is suggested. If the ratio of shear force to axial force is larger than 0.25 a concrete hinge is not recommended unless additional measures are taken. These measures include prestressing of the throat to achieve additional compression.

### 3.2 Design rules

In Australia, there are no design rules for concrete hinges in current standards. The last code that covered concrete hinges was the 1976 NAASRA Bridge Design Specification. This approach described is largely based on a technical memorandum by the British Highways Agency (7) for the design and use of Freyssinet concrete hinges. It is very specific in regards to permissible axial forces and the shape of the notch either side of the throat. An image of the required notch shape is included in Figure 4.

Figure 4. Typical shape of notch. British Highways Agency (7)

Basic rules as set out in NAASRA 1976 (8) are:

- No tensile forces in throat
- $f'_{c \text{ min}} = 40\text{MPa}$ ;
- Maximum aggregate size 10mm;
- Shear across throat 1/3 of co-existing axial load;
- Required short-term and long-term rotations can be accommodated without tensile stresses in the throat;
- Bending moments transmitted by the hinge is acceptable;
- Throat width "a" shall be not less than 50mm;
- Throat thickness at end of parabolic section between "a/2" and "a/3"; and
- Basic allowable stress  $P/a = \min (2 f'c \text{ or } 100\text{MPa})$ .

The high allowable stress is based on the confinement stresses of the concrete as included in current design standards for the design of bearing pressures, for example AS 5100.5, section 12.3 (9).

Further literature on the use of concrete hinges suggests that tensile forces in the throat may be allowed over a width of up to half the width of the throat. Forces and moments around the hinges are illustrated in Figure 5.

Figure 5. Forces on the throat. Leonhardt (6)

Leonhardt (6) derived a maximum allowable rotation for the hinge of:

$$\alpha \leq 12800000 \frac{N}{a \cdot b \cdot E} \quad (1)$$

With a = width of throat [mm], b = length of throat [mm] and E = Young's modulus [MPa].

### 3.3 General design detailing

From testing of concrete hinges as well as the design rules for concrete exposed to high bearing pressures it is known that the high compression forces through the throat cause bursting forces either side of the hinge. From testing it was found that the bursting force  $Z_1$  as shown in Figure 6 equals approximately  $0.3 \times$  the vertical force  $N$  (Marx (1)). This approximation is very close to the bursting force calculated in accordance with AS 5100.5, section 12.2.4 (9) which is given as:

$$T = 0.33 P (1 - k_r) \quad (2)$$

Where  $k_r$  is the ratio of the depth or breadth of an anchorage bearing plate to the corresponding depth or breadth of the symmetrical prism.

The provision of sufficient reinforcement to cater for the above bursting forces was found to be critical for the capacity of concrete hinges and is therefore an essential part of the design process.

Figure 6. Bursting stress at concrete hinges. Leonhardt (6)

### 4. Design for Legacy Way

The design approach outlined above is particularly favourable for the case of concrete hinges with high axial forces such as would be found in the foundations of arch structures. For those arches, the hinge is oriented on an angle to achieve the highest possible direct axial force. At Legacy Way, secant piled walls are utilised for shoring and to support the roof structure. Locating the hinge at the lower foundation level was therefore not possible. The only practical solution was to locate the hinge at the top of the pile cap as shown in Figure 7 to allow cast in-situ construction of the throat and adjoining concrete blocks.

The roof was designed utilising cast in-situ post-tensioned T-girders. Post-tensioning of those girders was only possible once the rest of the structure was cast and hence, post-tensioning would create a significant shear force in the throat. Additionally, thermal effects during construction and in service had to be considered for the calculation of the shear forces. Consequently, the design shear force exceeded the design axial compression

in the throat. Since the advantages of allowing rotations in the support to reduce the bending moments at the top of the secant piles was considered significant, an option of introducing additional axial forces by post-tensioning the throat was agreed to be the best solution.

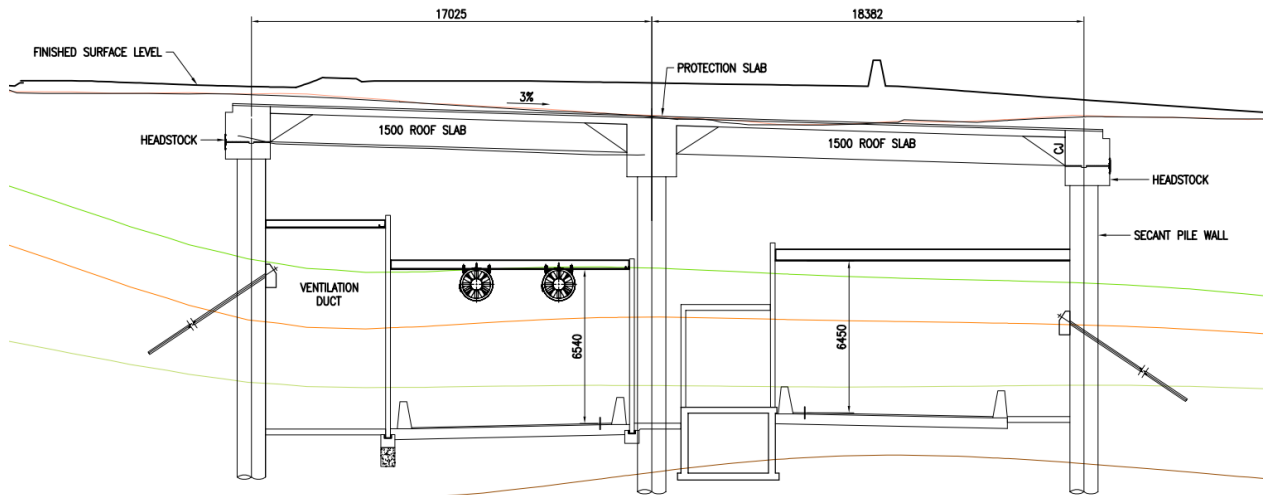

Figure 7. Typical arrangement of hinge.

**Figure 8. Typical geometry.**

Internal forces from post-tensioning, creep and shrinkage and thermal effects were calculated in a global model and a typical layout is shown in Figure 8. The design shear force was calculated to be 612kN/m and hence the resulting vertical force P was required to be 1836kN/m. The corresponding rotation angle was found to be  $\phi=0.0008$  rad.

In accordance with NAASRA section 8.12.4.2, the throat width required to eliminate tensile forces in the throat is calculated as follows:

$$E'\phi \leq 2Kh_e \cdot \frac{P}{a^2} \Leftrightarrow a \leq \sqrt{2Kh_e \cdot \frac{P}{E'\phi}} \quad (3)$$

with:  $K=1.5$ ,  $h_e=125\text{mm}$ ,  $E=39162\text{MPa}$ , the throat width  $a$  is hence calculated to 148mm

On that basis the throat width was chosen to be 150mm.

The shape of the notch shown in the NAASRA code was found to be impractical for construction and the rule was considered unnecessarily prescriptive. Instead, a simplified version was designed and detailed. It comprised a 12.5mm radius and a horizontal 25mm joint material comprising a closed cell compressible filler. Details of the solution are included in Figure 9.

Initially, it was planned to cast the pile cap and girders in one operation. However, access to the throat to ensure a high quality execution was considered an issue. Also, generally the concrete was planned to comprise 20mm aggregate but, for the throat, 10mm aggregate was planned to be used. Consequently, it was decided to construct the throat in several stages. Initially, the pile cap was constructed with a block out to form the hinge. In a second step the construction joint was prepared and the hinge area cast. Finally, the post-tensioned girders were cast, encapsulating the hinge area. The construction staging is described in more detail in the sections in Figure 9 and 10 and with photos and more detailed information in section 5.

**Figure 9. Stressbar details.**

**Figure 10. Cross section details with construction staging.**

As detailed in section 3.2 bursting reinforcement is required in addition to the typical beam and headstock reinforcement. A detail of this reinforcement is included in Figure 11.

**Figure 11. Reinforcement details at the concrete hinge.**

## 5. Construction phase

The construction sequence is a critical aspect of the design of the concrete hinges to ensure the design intention is met. However, there were also a number of construction constraints and difficulties during the works including narrow width between the construction platforms, accessibility, limited lay down and storage areas and close proximity of the active Inner City Bypass. The Cut and Cover structures also had to be constructed early to ensure timely completion for TBM arrival, which put further constraint on the construction program.

The designers recognised this and, working with the construction team, focused on a way to combine innovative construction techniques with appropriate technical design solutions. The chosen construction sequence allowed the concrete hinge to be built off line to minimise traffic disruption to the Inner City Bypass.

The outline of the construction sequence has been divided into three stages as follows:

- Stage 1: Construction of the lower capping beam
- Stage 2: Construction of the concrete hinge and T Girder
- Stage 3: Stressing of the stress bars

### 5.1 Stage 1

The construction methodology for the lower capping beam was carried out in the following sequence:

- Construct blinding level to the lower capping beam and outside secant piles to give a flat and stable working space.
- Place and position capping beam reinforcement and bursting reinforcement.
- Erect formwork to the edges of the capping beam and install adequate falsework to support the forms off the ground.
- Install waterproofing membrane to manufacturer's specification.
- Erect scaffolding system to support the stress bars.
- Install high tensile steel stress bars including lower bearing plates and lock nuts.
- Form 55mm recess at the hinge centerline.
- Cast lower capping beam.
- Strip forms at hinge recess and provide wood float finish to the rest of the pile cap outside of the hinge recess.
- Green cut and apply concrete retarder to the hinge recess.

**Figure 12. Stress bars supported by scaffolding system.**

**Figure 13. Completion of stage 1 works.**

The stress bars were supported by a specifically designed scaffolding system as shown in Figure 12. The system was made using a closed frame slimshor system spaced at 2.5m centres. The frames were erected either side of the capping beam formwork. Each bay supports the weight of 4 stress bars. The longest steel stress bar was approximately 2.4m long and had to be lifted into position using machinery. Franna cranes were used to lift the stress bars into position and all slinging operations were carefully carried out by a competent dogman and rigger. The site surveyor provided the necessary support to ensure the set out of each stress bar was within the design tolerance and concentric with the throat centerline. Accurate placement of stress bars is required to eliminate any potential eccentric force on the hinge from the prestressing bars. The scaffolding system also provided the required support and bracing to the stress bars to ensure that the verticality and position of the stress bars were maintained at all times until the lower capping beam had been cast.

The capping beams were cast in 20m lengths to expedite the construction program, as requested by the construction team. To meet the project requirement of a maximum target concrete crack width of 0.2mm, additional reinforcement was placed. In addition, a low heat concrete mix was designed and imposed limit on the concrete placement temperature of 32 degree Celsius was in place to ensure the target concrete crack width can be achieved. A photo of the completed stage 1 works is included in Figure 13.

## 5.2 Stage 2

The Stage 2 works were more complex and the following procedures were adopted (Refer Figure 14 and 15 and diagrams in section 4):

- Form concrete nib above construction joint and cast 150mm wide x 125mm deep concrete nib.
- Place backing rod, compressible filler board and FC sheeting.
- Install stress bar bursting reinforcement and form grout pocket.
- Install T girder HDPE ducts and reinforcement.
- Install remaining waterproofing membrane.
- Erect formwork.
- Cast T girder roof slab.

Concrete with maximum aggregate size of 10mm was placed in the concrete nib forms from wheelbarrows as shown in Figure 14. The concrete was compacted through vibration transmitted from the formwork. The concrete nib surface was then screeded prior to commencement of the concrete curing.

To reduce the potential for early shrinkage and plastic cracks of the concrete nib, the concrete nib was covered in wet hessian and kept continuously damp for seven days after pour. The hinge is the critical item of the design and all construction risks were evaluated with the construction team to ensure the integrity of the design was not compromised. Wet hessian was therefore selected over the application of a curing compound because it was considered to be a more effective way of minimising evaporation in the hot Brisbane weather and thereby ensuring proper cement hydration and curing of the concrete.

**Figure 14. Forming and casting of concrete nib. Figure 15. Wet hessian applied on concrete nib.**

Due to the amount of the bursting reinforcement required for both the stress bars and the T girder tendons, the closed compressible fillers were under immense downward pressure from the weight of the steel reinforcement. Fibre cement (FC) sheeting was used to distribute the pressure adjacent to the hinge and prevent the closed cell compressible filler being crushed. This layer of the FC sheeting was placed above the compressible filler board adjacent to the hinge. The spacing of the fibre concrete bar chairs was also reduced to avoid excessive bearing stress on the compressible filler.

## 5.3 Stage 3

The Stage 3 works involved the setting up, stressing and grouting of the stress bars and these activities were undertaken after casting of the roof and edge beams. The following procedure was adopted:

- Install upper bearing plates, nuts and washers.
- Set up stressing equipment.
- Tension the stress bars up to design load after T girder concrete strength has achieved 35MPa.
- Tighten the permanent nut against the washer and bearing plate.
- Grout stress bars and infill pocket with shrinkage compensated cementitious grout.

- Stress T girder tendons.
- Grout T girders tendon and infill pockets.

A 200t capacity bar jack was used on site to stress the bars. The jack was connected to a hydraulic pump via hydraulic hoses and fitting which were powered by a site generator. A steel stool which was connected to the jack was placed on top of the infill pocket to allow access to the nut once the bar is stressed. A coupler and an additional pull bar were used to connect the stress bars to the jack. Once all equipment was fitted together, the bar was stressed to the required design load. The permanent nut was then fully tightened against the washer and bearing plate before the jack was released. Each bar was fully stressed before the jack was disassembled and moved to the next bar. See Figure 17 & 18 for details.

Figure 17. Stress bar infill pocket.

Figure 18. Stress bar stressing arrangement.

#### 5.4 Completed structure

Following construction of the roof, water proofing was provided to the top of the structure and the structure was backfilled. Excavation underneath the roof was carried out in parallel with roof construction. The excavation was carried out in stages to allow the progressive installation of water beams and prestressed anchors before full excavation depth was reached. The progressive excavation resulted in additional loads being applied onto the hinge joint. Due to the capacity for rotation, the additional loads applied are limited to shear forces and minor moments in the throat. The bending moments in the secant piles are largely due to earth pressure following excavation and prestressing forces when the ground anchors are stressed. A photo of the completed structure is shown in Figure 18.

Figure 18. Completed structure.

## 5. Conclusions

Design and construction of the cut and cover structures of the Legacy Way Project in Brisbane have required the provision of rigid or semi-rigid solutions and provision of structures without bearings and movement joints which would require later maintenance or replacement. Allowing rotations at the roof support while also providing a low maintenance structure resulted in a solution comprising secant pile walls, pile caps, a post-tensioned roof structure and a concrete hinge connection between sub and superstructure. It has been shown that a highly durable and sustainable structure was constructed.

However, there are no current design standards in Australia for this support type and the most recent codes date back nearly 40 years. In addition, the details provided in 1976 lack practicality on site and are over prescriptive. It is recommended that this support type be reassessed for current use in structures, in particular to address current whole of life and sustainability discussions. Since concrete hinges have been detailed for design and construction in previous versions of the Australian bridge design standard, consideration should be given to the re-introduction of this form of support. Finally, it appears prudent to carry out further testing of concrete hinges in particular since construction materials and the associated technology have changed significantly over past decades and these new materials could result in an improved design and construction approach.

# Challenges, Opportunities and Design Impacts for Different Construction Methods on Curtis Island LNG Jetties

Jesper Jensen<sup>1</sup> and Peter Kastrup<sup>2</sup>

<sup>1</sup>Engineer, Arup

<sup>2</sup>Queensland Maritime Leader and Senior Engineer, Arup

**Abstract:** The demand for energy in South East Asia and the Pacific region has seen vast growth in gas exploration across the continent of Australia. With the approval of a number of liquefied natural gas (LNG) export facilities across the Australian seaboard, Arup Australasia has put its multi-disciplinary capabilities to full use in the delivery of a number of LNG Jetties in Gladstone, Queensland in a design and construct collaboration with contractor John Holland Group (JHG).

Marine construction methods often influence the permanent works design for which the importance of early constructability considerations is significant. The temporary works design and planning across the three projects required particular attention during the detailed design phase. Careful coordination between Arup's structural design team, John Holland's construction planning team and temporary works designers was vital in achieving a solution that achieved both the design intent and that could be constructed safely and efficiently.

As the projects were delivered in a high labour cost environment, pre-fabricated solutions were considered to be preferable. Where possible, a large number of precast and prefabricated elements were transported to site and installed on the driven steel piles. Adopting this type of modular construction meant that the temporary works were minimised where possible. The precast elements worked as permanent formwork for a large number of in-situ concrete pours above water.

The permanent walkways were utilised for temporary access allowing concreting dolphin pile caps by line pump instead of transporting agitators by barge at significantly increased transportation cost and with impacts on the concrete mix design.

## 1. Introduction and Project Background

In 2010, the Queensland Government approved the Queensland Curtis LNG (QCLNG), Gladstone LNG (GLNG), and Australia Pacific LNG. The project partners across the three projects are (at the time of writing):

- QCLNG – QGC(BG), China National Offshore Oil Corporation (CNOOC)
- GLNG – Santos, PETRONAS, Total, KOGAS
- Australia Pacific LNG – Origin, ConocoPhillips, Sinopec

Bechtel was awarded as the engineering, procurement, and construction contractor of the three jetties. John Holland Group (JHG) was awarded the marine subcontracts, including procurement, fabrication, construction and commissioning of the structural, mechanical and electrical components of the product loading facility. JHG appointed Arup in a Design and Construct (D&C) collaboration for the permanent works design of the three liquefied natural gas (LNG) jetty facilities. Arup was also the engineer of record during construction, certifying that the works met the design intent.

With three different project stakeholders, the projects are considered as three separate projects. As such, each project required an individual assessment of the project-specific design requirements, geotechnical profile, and environmental conditions. Examples of impacts on constructability include different levels of the structures, which combined with different geotechnical supports leading to different requirements for member sizes and reinforcement. The three LNG plants are located on the south-western shoreline of Curtis Island and are only accessible by water. The three project sites are illustrated in Figure 1.

Figure 1. Top left: Overview of the Curtis Island LNG plants (from the bottom; Australia Pacific LNG, QCLNG and GLNG). Top right: GLNG. Bottom left: Australia Pacific LNG. Bottom right: QCLNG. @Bechtel

### 1.1 Concept Considerations

Constraints associated with constructing over water forms one of the defining considerations in the structural form selection. Early understanding of the contractor methodologies, plant preference and availability and programme needs are imperative to developing the optimum solution. The assessment of vertical piles vs. raked piles and reinforced concrete (RC) superstructure vs. steel frame were the major considerations during scheme development. Example considerations are summarised in Table 1 and Table 2 below.

Table 1. Examples of Pile Selection Comparison

Item	Advantages	Disadvantages
Vertical Piles	Simpler to install than raked piles.	Complex pile to superstructure connection to accommodate lateral loads.
	Flexibility to adjust rock sockets to manage geotechnical uncertainty.	
Raking Piles	Increased structural efficiency due to the ability of the pile to resist the lateral forces partially as an axial load.	Rely on increased certainty of ground conditions due to the difficulties to extend raked sockets.
	More robust structure than the vertical pile scheme.	Increased complexity of installation. Floating plant may not be practical. Pitch can be difficult to control when driven to seams of hard or firm material.

**Table 2. Examples of Superstructure Selection Comparison**

Item	Advantages	Disadvantages
RC Super-structure	Can be constructed in stages to satisfy the maximum crane lift capacity.	Availability of quality concrete and restrictions on concrete delivery to off shore location.
	Ability to accommodate pile installation out of tolerances.	Heat of hydration concerns with large concrete pours.
	Standard formwork allow quick installation of form base and reinforcement fixing.	Labour intensive. Practical issues when form is within tidal zone. Setting out cast-in items is a challenge.
	Permanent precast formwork save on temporary works, on site steel fixing, and removal of formwork.	Staged pours may be required. Preparing the horizontal construction joint can be challenging.
	Precast fabricated in a controlled environment, which give opportunity for improved appearance. Where marine grade precast concrete is used for the critical exposed sides and soffit, it may be possible to use in-situ concrete with lower durability and strength.	Consideration should be given to tidal variations in relation to the temporary support scheme.
	Increased control of material quality with steel truss typically fabricated off site in a controlled environment.	In-situ welding will likely be required for connection to piles – or a sleeved option may be preferred. Difficult to install with raked piles incl. sleeved option.
Steel Super-structure	Prefabrication can reduce in-situ labour and construction time significantly.	Reduced ability to accommodate piles installed out of tolerances.
	If no design corrosion allowance, full steel section can be utilised for structural capacity.	Potential vortex induced vibrations during transportation may be governing.

Early collaboration with the client to understand the ancillary functional requirements of the dolphins such as furniture, early Arup input during fender selection and involvement with the contractor to understand the constructability needs, was key to a successful scheme development.

## 2. Piling

The high variability of the ground conditions in Gladstone Harbour at Curtis Island and concerns over geotechnical risk governed the contractor's early decision to adopt a vertical pile solution. This was chosen over raking piles for the ease of installation and flexibility. Vertical piling also meant that more costly jack-up barge mobilisation would not necessarily be required. A traveler was utilized to install the trestle piles (and headstocks, pipe rack modules and deck units, refer Section 3). The use of a traveler allowed for the piling to be done independently from the water and intertidal area, which reduces risk of downtime due to wind, waves, tides and currents. Examples of the vertical piling is shown in Figure 2.

The vertical piling decision had a major influence on the structural jetty design, which is discussed in the following sections of this paper.

**Figure 2. Example of LNG Jetty Piling (from Australia Pacific LNG). Left: Piling using Traveler. Right: Piling using Floating Barge. @Arup**

### **2.1 Rock Socket/Anchor**

Due to the design criteria, loading and structural layout, some of the dolphin piles were subject to tension forces, which required rock sockets/anchors to fully transfer the design forces to the ground. Arup and JHG assessed options such as RC rock sockets and post-tensioned grouted rock anchors. The geotechnical conditions meant that the RC rock socket was deemed the most effective and flexible option. The bored in-situ concrete rock sockets could be practically extended where required to counteract the ground condition variability and manage geotechnical uncertainty.

This constructability decision impacted on incorporating this element into the pile design. When included in the dolphin pile analysis the RC rock socket attracted not only axial force, but also shear and bending moment and the connection detail to the steel liner had to be developed. To transfer the forces from rock socket to liner, Arup and JHG developed a solution using internal shear beads, which were designed to a size not protruding past the pile shoe to mitigate risk of damage during pile driving. In turn, this detail led to requirements for cleaning of the rock socket and bottom part of liner to ensure adequate concrete placement and bond.

### **3. Trestle**

As per Section 2, a traveler was utilized on all three projects to install the trestle piles, headstocks and deck units. This constructability decision impacted the pile and headstock permanent works design.

The crane on the traveler is used to lift piles, headstocks and deck units hence the reaction forces from these load cases were incorporated in the design of piles and headstocks. In addition, the deck units were transported from land to the traveler using a self-propelled modular transporter (SPMT), which the deck units were also designed for.

Arup and JHG assessed headstock options including a box section slotted into the pile and box section placed directly on top of the pile. Due to the preference for not cutting the slot in the pile, design loadings and criteria including a significant corrosion allowance, it was decided to adopt the steel box section welded to the top of the pile.

Although adopted for the abutment headstock, a typical concrete headstock was not preferred due to constructability considerations such as maximizing headstock installation time, traveler speed and practical design aspects requiring a steel section for load capacity at the critical locations.

Concrete deck units were designed for the temporary works load cases (in addition to permanent load cases) including the lifting case and to provide compression throughout the cross section. Arup and JHG developed the design of the deck units to fit within the lifting capacity of the crane proposed for the traveler.

### 3.1 QCLNG

The QCLNG trestle was designed for a typical span of 24 m. Images from QCLNG are shown in Figure 3.

Figure 3. QCLNG Trestle. Left: Headstock (Anchor Bent) During Welding to Pile. Right: One Deck Unit Installed. @Arup

### 3.2 GLNG

GLNG trestle is the longest of the three jetties. This jetty was designed for a typical span of 18 m. Figure 4 shows the GLNG trestle at two different construction stages.

Figure 4. GLNG Trestle. Left: Typical Bent View without Pipe Rack Modules. Right: View after Pipe Rack Module Installation. @Arup

### 3.3 Australia Pacific LNG

Australia Pacific LNG trestle is the shortest of the three jetties and a 24 m typical span was adopted, refer images in Figure 5.

**Figure 5. Australia Pacific LNG Trestle. Left: Traveler Trestle Construction. Right: Completed Trestle Roadway. @Arup**

## 4. Loading Platform

The loading platform size and deck level varied between all three projects. JHG preferred a universal pile size to facilitate using the same piling equipment across all three projects. A concrete superstructure was adopted for all three projects and the designs were in all cases heavily governed by the constructability requirements. Wind forces on loading arms were also governing cases. The vertical pile arrangement meant that a relatively large quantity of reinforcement was required for the pile cap or headstock. Detailed space proofing was prepared considering piling and precast tolerances and cast-in temporary works members.

### 4.1 QCLNG

Precast pile caps were used on QCLNG. Primary precast deck planks were then placed on top of the pile caps followed by secondary precast deck planks placed to create the full soffit of the platform. However, one area of the deck had to be completed first such that JHG could install a crane here to facilitate the rest of the loading platform construction, refer Figure 6. A detailed staged analysis was performed to overcome the challenge of designing the precast including pile caps and in turn, assess and advise of allowable crane pad locations for an in-complete platform.

**Figure 6. QCLNG Loading Platform. Left: Pile Caps and Part Installation of Primary Precast. Right: All Precast Installed and Crane Working from a Section of the Platform. @Arup**

#### **4.2 GLNG**

The GLNG loading platform was designed and built with precast headstocks spanning in the direction of the quay line. Precast deck planks span the headstocks to complete the concrete soffit, refer Figure 7. This design avoided the need for pile caps, however requiring larger lifts than QCLNG.

The platform was built partly using a crane on a floating barge and partly using the traveler crane once it had reached the platform location.

**Figure 7. GLNG Jetty Loading Platform. Installation of Secondary Precast Deck Planks. @Arup**

#### **4.3 Australia Pacific LNG**

The Australia Pacific LNG loading platform was designed and constructed in a similar way to GLNG. Precast headstocks were placed directly on top of the piles without the use of concrete pile caps. Secondary precast planks span the headstocks to create the permanent soffit of the structure.

**Figure 8. Australia Pacific LNG Jetty Loading Platform during Construction. @Arup**

## **5. Dolphins**

The dolphin design was also heavily influenced by the construction method decisions. A main factor was whether or not to adopt a precast shell or use a conventional temporary formwork strategy for the reinforced pile cap. Another key component was the pile plug, which is a reinforced concrete plug within the top of the piles. The construction of these structures was challenging and was done in different ways on the three projects. Due to the vertical pile arrangement, a large quantity of reinforcement was required within the pile cap, which proved challenging when also having to account for piling tolerances and cast-in items such as fenders, mooring hooks and internal temporary works members.

### **5.1 QCLNG**

For the berthing dolphins, the pile extends into the cap. On QCLNG it was decided to prefabricate the pile plug reinforcement cage and attach this to the top part of the pile, which also had externally welded shear keys. This assembly was then welded with full penetration butt welds onto the pile at the surveyed level. Temporary works members was also incorporated into this assembly and facilitated less work over water when subsequently installing the temporary formwork. For QCLNG Arup and JHG further developed a modular concept for the pile cap reinforcement, which was another measure adopted to reduce work done over water, refer Figure 9.

**Figure 9. Left: Berthing Dolphin Pile Plug Prefabricated Assembly. Right: Modular Reinforcement Being Lifted into Pile Cap. @Arup**

## **5.2 GLNG**

The construction methodology Arup and JHG developed for GLNG was different to the other projects in a number of ways. A precast shell (soffit and sides) was utilized to avoid the need for temporary formwork over the water (temporary supports to the piles in the tidal zone were required to land the shell). Instead of traditional round reinforcement bars, a predominantly steel plate based reinforcement concept was adopted to provide less congestion within the cap. This steel plate arrangement was fully prefabricated off site and lifted into the cap in two pieces, refer Figure 10. The precast shell also facilitate the early installation of the walkways to utilize this access for staff and concrete pumping from trucks on the loading platform rather than by barge.

**Figure 10. Precast Berthing Dolphin Shell before and After Reinforcement Installation. @Arup**

## **5.3 Australia Pacific LNG**

The Australia Pacific LNG dolphins were designed and built using standard formwork. For the mooring dolphins the pile plug reinforcement cage extended fully into the pile cap and had to be designed to allow for the temporary works supports, refer Figure 11.

JHG also utilized early installation of walkways on the Australia Pacific LNG dolphins to improve access for staff and concrete pumping practicalities. This was also a critical factor in being able to reduce the time

from concrete batching to the point of discharge. This was important to control the placement temperature during the summer months.

**Figure 11. Left: Berthing Dolphin Construction. Right: Mooring Dolphin Pile Plug Temporary Works Assembly. @Arup**

## **6. Modular Reinforcement and Clash Detection**

The opportunity to develop modular reinforcement and clash detection for the berthing dolphins was identified early in the projects. A 3D BIM model was developed to ensure that sufficient space was provided for all specified bars. As the projects were delivered in a high labour cost environment, pre-fabricated modules were developed for the reinforcement cage. The model was developed by Arup and transferred to JHG for construction. Adopting this type of modular construction had a positive impact on the critical path of the construction programme. In addition to the coordination of temporary works and the reinforcement, it was also a priority to develop a solution maintaining a safe working environment. An example of the 3D BIM model is shown in Figure 12.

**Figure 12. Design BIM 3D Modular Reinforcement and Clash Detection Model. @Arup**

## **7. Conclusion**

Arup was expecting the design of these marine structures to be governed in a large part by the construction methodology decisions made by JHG. As per the examples in this paper, a number of critical design aspects had different impacts, challenges and opportunities across each of the three projects. The successful design and construct delivery of these projects is a demonstration of the positive collaborative relationship between the design team and contractor. Early engagement and an aligned understanding of the constraints helped in paving the way to designing efficient structures while incorporating innovative marine construction techniques. First gas was shipped from Curtis Island on 5 January 2015 from QCLNG. GLNG and Australia Pacific LNG are expected to commence shipping later in 2015.

**Figure 13 Methane Rita Andrea LNG Vessel at the QCLNG Berth (first vessel to ship gas from Curtis Island). @QGC**

## **8. Acknowledgements**

This paper is published with the permission of John Holland Group, Bechtel, QCLNG, GLNG, and Australia Pacific LNG. The authors acknowledge the encouragement of these parties in supporting this paper. Many people have contributed to these projects. The authors thank everyone involved and for the opportunity to deliver such challenging projects.

# A Bond-Slip Modelling Approach for the Transfer Length of Pre-tensioned Concrete

Rik Steensels<sup>1</sup>, Lucie Vandewalle<sup>2</sup> and Hervé Degée<sup>3</sup>

<sup>1</sup> PhD candidate, Hasselt University

<sup>2</sup> Professor at faculty of civil engineering, KU Leuven

<sup>3</sup> Professor at faculty industrial engineering, Hasselt University

**Abstract:** In this paper, a bond-slip relation at the prestress strand-concrete interface for pre-tensioned concrete is developed. The bond-slip behaviour is based on the confinement model developed by Den Uijl in order to properly address the influence of the nonlinear concrete material behaviour around the strand and the influence of the geometrical properties of the beam on the confinement of the prestress strand. Furthermore, this bond-slip behaviour is implemented in a finite element model to evaluate the transfer length of prestressed beams. The numerical model is compared to experimental results of two independent researchers and good agreement is achieved. This paper also presents the influence of several calibration constants of the bond-slip model on the resulting transfer length of the beam.

**Keywords:** Pre-tensioned concrete, bond-slip, confinement, transfer length, pre-stressed concrete.

## 1. Introduction

The transfer length of a prestressed element is an important parameter for the design of the anchorage zone reinforcement. In pre-tensioned elements, the driving phenomenon for the determination of the transfer length is the bond behaviour between the prestress tendons and the surrounding concrete. Overall, current evaluation of the transfer length is performed using empirically determined formulae based on experimental data (1). Furthermore, they often only take into account a couple of parameters like the prestressing force or the diameter of the prestressing strand. However, the bond behaviour governing the transfer length is influenced by an extensive amount of parameters ranging from geometric parameters, which determine the confinement of the concrete, to material parameters like the Young's modulus and the tensile strength of the concrete mixture. Furthermore, additional influences like the manner in which the prestress tendons are detensioned or the presence of additional confinement reinforcement around the prestressing strand impact the behaviour of the bond strength between steel and concrete and therefore also affect the transfer length. This study involves an implementation of a bond-slip relation based on the confinement model as described by Den Uijl (2). The bond-slip relation will be applied in a nonlinear finite element model to ascertain a numerical evaluation of the transfer length for concrete elements with different geometrical and prestressing conditions based on the experimental work of Mitchel et al.(3) and Oh et al.(4). The aim of this study is to achieve a numerical model which accurately describes the transfer of the prestressing force from the prestress tendon to the concrete, taking into account the geometrical and material properties of the element.

## 2. Modelling the bond behaviour

### 2.1 Bond mechanism of 7-wire strands

The bond mechanism describing the behaviour of 7-wire strands differs quite extensively from that of a plain wire as can be seen in figure 1. The bond strength can be attributed to three aspects; cohesion between steel and concrete, mechanical resistance and friction between steel and concrete. The effect of cohesion however is very small and thus of insignificant influence (5,6). Mechanical resistance is primarily of importance when deformed bars are examined due to the fact that concrete ribs will be formed and the associated bearing stresses will have a significant impact on the bond stresses. However when a 7-wire strand slips, it will follow the helical grooves in the surrounding material without substantial shearing off of the concrete (6).

The frictional aspect of bond carries the most weight when studying 7-wire strands. The friction can again be subdivided in three aspects, more specifically the poisson contraction, the 'lack of fit' and the pitch effect (7). Due to the stretching of the strand during the prestressing stage, the cross section of the strand

will narrow according to the Poisson ratio of steel. However when the strand is cut during detensioning,

**Figure 1. Bond-slip relation of strand vs plain wire**  
the

**Figure 2: 'Lack of fit'**

**Figure 3. Torsional moment attributed to pitch effect**

stress in the strand will decrease again at the end faces of the element and the cross section will want to expand radially to its original diameter. This expansion is partially restricted due to the surrounding concrete and causes a wedge-like shape of the 7-wire strand at the end faces of the element. Additionally, further bond strength can be attributed to the cross sectional properties of the strand. In a 7-wire strand, the middle wire has a larger diameter than the surrounding ones (figure 2). This causes the surrounding wires to leave a gap which is helically shaped along the length of the strand. Due to this 'lack of fit', cement particles form a small, helically shaped, concrete rib along the length of the strand. The additional compressive stresses which result when detensioning occurs further enhances the bond behaviour at the interface between concrete and steel. This increase in bond is known as the 'lack of fit' effect (7,8).

The final contribution to the bond behaviour is attributed to the pitch effect. When a 7-wire strand is released, it changes its pitch along its length. This pitch-change will be restricted by the concrete and consequently cause a torsional moment which further increases the bond strength of the strand (figure 3). However, the importance of the pitch effect is contested by several researchers, Stocker and Sozen (9) concluded that, due to low torsional stiffness of the strand, the frictional aspect of the pitch is small compared to other influences. This was contested by Russel and Burns (10) who stated that the boundary conditions of the test setup of Stocker and Sozen prevented them from effectively measuring the influence of the effect of the pitch change. Den Uijl lastly concluded from pull out and push in tests that frictional influence for prestress strands is greater than the effects which can be contributed to merely the Poisson effect and the 'lack of fit' of the strand. The third influence was denoted as the pitch effect without a clear mechanical explanation (2,7,11). The contribution of the wedging effect due to the Poisson ratio and the frictional forces to the bond are known as the Hoyer effect (12).

The bond phenomena described above cause a radial compressive pressure  $\sigma_{rr}$  at the strand-concrete interface. According to Tepfers (5), the bond stress  $\tau$  can now be calculated using a dry friction law.

$$\tau = \tau_0 + \mu \sigma_{rr} \quad (1)$$

Where  $\tau_0$  is the initial bond strength caused by cohesion at the steel-concrete interface and  $\mu$  is the friction coefficient denoting the relation between the radial compressive pressure and the bond stress.

## 2.2 Confinement model

Based on the work of Timoshenko (13), Den Uijl gave a description of the radial compressive pressure  $\sigma_{rr}$  in function of the radial strain  $\epsilon_{rr}$  of a deformed bar using a thick-walled cylinder model (2). This approach was also used by Oh et al. (4), Abdelatif et al. (6), and Fellingner (11) to model the behaviour of prestressing tendons with good agreement to experimental results. Furthermore, the thick-walled cylinder model takes into account the confinement of the reinforcement due to the surrounding concrete. The radial compressive stress is described for three stages (figure 4). The first stage describes the relation between  $\sigma_{rr}$  and  $\epsilon_{rr}$  for uncracked concrete. The constitutive behaviour of concrete is linear elastic and isotropic. Due to the radial compressive stresses, tangential tensile stresses will occur at the steel-concrete interface and when the tensile strength of the concrete is reached, the second stage in the thick-walled cylinder model is introduced. In this second stage, the concrete of the thick-walled cylinder starts to crack and the crackfront moves from the cylinders inner radius to its outer radius. The constitutive

behaviour is changed to accommodate for the partially cracked region of the cylinder. The cracked concrete is modelled with the use of the fictitious crack model where concrete softening is taken into account following a bilinear softening law. When the crackfront has reached the outer radius of the thick-walled cylinder model, the third stage is initiated. The constitutive behaviour is now in accordance with a fully cracked cylinder and it further follows the softening function while the fictitious crack width increases.

**Figure 4. Confinement model Den Uijl**

**Figure 5. Wedge effect of prestress strand**

The loss of confinement at the steel-concrete interface due to the formation and the widening of splitting cracks around the reinforcement is hereby taken into account. For a full description of the constitutive behaviour of the thick-walled cylinder model and the  $\sigma_{rr}(\epsilon_{rr})$  relation, reference is made to Den Uijl (2).

### 2.3 Bond-slip relation

The confinement model of Den Uijl describes the radial compressive stress at the interface between the prestress strand and concrete taking into account possible concrete splitting cracks around the strand. Inserting this relation into equation (1) denotes the bond stress in function of the radial strain at the steel-concrete interface.  $\tau_0$  is assumed to be zero due to the small impact of cohesion to the bond stress.

$$\tau = \mu \sigma_{rr}(\epsilon_{rr}) \quad (2)$$

In order to obtain the bond-slip relation, the relation between the radial strain and the slip ( $\delta$ ) has to be setup. As mentioned above, the Poisson effect, 'lack of fit' of the strand and the pitch effect exert an influence on the radial stress and thus have to be taken into account. The total radial strain can therefore be described as follows;

$$\epsilon_{rr,tot} = \epsilon_{rr,v} + \epsilon_{rr,lof} + \epsilon_{rr,pitch} \quad (3)$$

Where  $\epsilon_{rr,v}$ ,  $\epsilon_{rr,lof}$ , and  $\epsilon_{rr,pitch}$  respectively denote the impact of the Poisson effect, lack of fit, and the pitch effect to the total radial strain at the interface. Denoting the Poisson effect in function of the slip is relatively straightforward. The slip causes a decrease of the longitudinal strain which, in turn, can be linked with a radial increase through the Poisson rate.

$$\epsilon_{rr,v}(\delta) = C_v \nu \frac{\delta}{l_t} \quad (4)$$

Where  $C_v$  is a calibration constant,  $\nu$  is the steel Poisson ratio and  $l_t$  denotes the transfer length. The transfer length is taken into account because the change in diameter occurs along the transfer length (figure 5). The longitudinal strain due to the slip is therefore denoted as the ratio between the slip and the transfer length. However, the presence of the transfer length in the description of the bond-slip relation compels an iterative approach to the model due to the fact that a re-evaluation of the transfer length has to be performed during the analysis in order to make a proper assumption of the transfer length. An overview of the steps performed during the analysis can be seen in the flow chart of the on figure 6. Obtaining the radial strain in function of the slip due to the 'lack of fit' and pitch effect however is more difficult. A formula was developed by Den Uijl (8) which describes the influence to the bond stress resulting from the 'lack of fit' as a function of the slip but this formula is based on experimental results without a clear physical explanation. Furthermore, as mentioned above, the mechanical background to the pitch effect is not fully clear. Therefore, it was opted to describe the influence of the 'lack of fit' and pitch effect in a similar way as the Poisson effect. The radial strain can be denoted as the ratio between a radial displacement at the interface ( $u_r$ ) and the radius of the strand ( $r_s$ ).

$$\varepsilon_{rr} = \frac{u_r}{r_s} \quad (5)$$

Using a second calibration constant, the influence of the slip to the radial displacement resulting from the lack of fit and pitch effect can now be denoted.

$$u_{r,lof+pit} = C_{lof+pit} \delta \quad (6)$$

The radial strain due to lack of fit and pitch can be found by inserting equation (6) into equation (5).

$$\varepsilon_{rr,lof+pit} = C_{lof+pit} \frac{\delta}{r_s} \quad (7)$$

Equation (7), (4) and (3) can now be combined and filled in equation (2) to obtain the bond-slip relation at the strand-concrete interface.

Figure 6. Flowchart of bond-slip model

### 3. Calibration and validation of the bond model

#### 3.1 Experimental tests

The constants and the friction coefficient of the bond model will be calibrated based on the experimental research of Mitchell et al. and Oh et al. Both authors conducted experiments where the transfer length was measured for small pre-tensioned concrete beams with different geometrical and material properties and for different values of the prestress force. The geometrical properties which are varied are the concrete cover of the strands, strand diameters, and in case of Oh et al. the number of strands in the beam (mono or twin strands). The material parameter which is altered is the concrete strength ranging from 31 to 89 MPa for the experiments of Mitchell et al. and from 47.4 to 61.2 MPa for the experiments of Oh et al. Prestress transfer was performed when the concrete was not yet at full strength but the transfer length development was monitored for the period necessary to reach full strength. The values of the initial stress in the prestress strand at transfer ranged from 922 to 1442 MPa for Mitchell et al. and from 1357.4 to 1418.0 MPa for Oh et al. Details of the beams of both authors can be found in figure 7.

a) Beam details Mitchell et al. (3)

b) Beam details Oh et al. (4)

Figure 7. Beam details of experimental tests

The transfer length is measured with two different techniques for the two authors. Mitchell et al. apply the slope intercept method in which the transfer length is determined as the distance from the end of the element to the intersection of a line which is fitted upon the strain values in the transfer region with the line representing the strain value beyond this region (3). Oh et al. use the Average Maximum Strain (AMS) method. This method implies that the readings of the strain gauges are first smoothed out to avoid the influence of locally diverging readings. Then, the transfer length is determined as the length from the end

of the beam to the point where 95% of the maximum average strain is reached. A drawback of the slope intercept method is that the method heavily relies on the number of data points available. Furthermore, it is a graphical method so it can occur that separate researchers will obtain different transfer lengths for the same data. The AMS method does not have this drawback but it is stated that this method relies heavily on the accuracy of the two readings between which the 95% line intersects the strain curve.

### 3.2 FEM model

The numerical implementation of the bond model was performed with the commercial software package DIANA. The concrete beam is meshed with 8-noded quadrilateral elements, the prestress strands are modelled as one-dimensional truss elements which are embedded in the concrete continuum elements. The concrete was modelled with a linear elastic material model and not with a nonlinear cracking model because this is currently outside of the scope of the study. Note however, that the influence of possible cracking and softening of the concrete around the tendon on the confinement and the bond behaviour is already taken into account using the bond-slip relation. DIANA offers a material model to implement bond-slip behaviour for embedded reinforcement, this material model was used to implement the correct behaviour of the prestress strands. The bond-slip behaviour determined in paragraph 2.3 was entered in the material model using a multi-linear bond-slip relation. Because the prestress force was transferred before the concrete hardened up to full strength, the values for the concrete cubic compressive strength ( $f_{cc}$ ) at the time of release were inserted into the model. Furthermore, an evaluation of the tensile strength and Young's modulus based on  $f_{cc}$  was made using formulas from the CEB FIB Model Code 2010 (14).

Due to the small runtime of the analysis it was opted that the beams could be modelled as a whole so no symmetry assumptions were made. The four corner nodes of the beams are restricted in X- and Z-direction and the lower nodes in the middle of the beam are restricted in the Y-direction (figure 8). The prestress load is applied as a force load which acts only on the outer nodes of the reinforcement. Due to the fact that embedded reinforcement is applied, no load is exerted on the continuum elements representing the concrete and the force transfer from the prestress strand to the concrete elements is done entirely through the bond-slip behaviour. Concerning the analysis, a full Newton-Raphson solution algorithm was employed to solve the nonlinear bond-slip model.

Figure 8: FEM model M15-N-C4

### 3.3 Comparison FEM model with experimental data

Based on the experimental results, the average values of the constants  $C_v$ ,  $C_{lof+pit}$  and  $\mu$  are set to 0.667, 0.3 and 0.75 respectively. With these values, good agreement is found for the experimental results of Mitchell et al. and Oh et al. as can be seen in figure 9 and 10. An average relative deviation of 9.66% was found between the numerical model and the experimental results of Mitchell et al. For the comparison with the experiments of Oh et al., the mean relative error was found to be only 5.61%. This can be attributed to the fact that the slope intercept method, which was used by Mitchell et al., to obtain the transfer length is more biased as was previously mentioned. The 95% AMS method applied by Oh et al. offers a more objective method for evaluating the transfer length. Figure 11a, displays the evolution of the longitudinal strain in the M15-N-C4 beam and figure 11b displays the stress build-up in the prestress strand for the

same experiment. For this particular experiment, the initial value of the prestress in the strand equals 1392.5 MPa. The typical parabolic curves associated with pre-tensioned prestressed concrete can be observed.

#### 4. Discussion

The influence of the calibration constants on the transfer length can be found in figure 12. The change of the transfer length for  $C_v$  ranging from 0.4 to 0.93 is rather small and a linear relation can be denoted. When looking at equation 4, it can be seen that changing  $C_v$  has the same effect on the bond-slip relation as changing  $\nu$ . Therefore, the value of  $2/3$  for  $C_v$  can be physically attributed to adjusting the value of the Poisson ratio of steel to a value which is more representable for the strand-concrete interface. Altering  $C_{lof+pit}$  up to the value of about 0.5 appears to influence the transfer length according to a quadratic curve (figure 12b). However, when increased further this evolution changes to a more linear nature. It is noted that the convergence rate of the model for values of  $C_{lof+pit}$  higher than 0.5 decreases. This can be attributed to the fact that the confinement curve becomes more and more narrow as  $C_{lof+pit}$  increases and therefore, the area beneath the curve reduces and the total bond stress to be taken on by a certain amount of slip decreases. It is noted that the value of  $\mu$  is rather high. Common values of  $\mu$  range from 0.3

to 0.7, some authors (5,7) even adopt a value of 1 but often they also take into account some kind of measure for adapting  $\mu$  like for instance a plasticity model for  $\mu$  or a slip-dependent coefficient of friction (7). The influence on the transfer length of  $\mu$  ranging from 0.45 to 0.75 can be seen in figure 12c.

When observing the tensile stresses in the concrete, it is noted that in the top fibres of the beam the tensile strength of concrete is exceeded for some beams, though no report of whether or not cracks were formed at the top of the beams was made by Mitchell et al. or Oh et al. Nonetheless, the presence of these cracks would not have an influence on the bond behaviour.

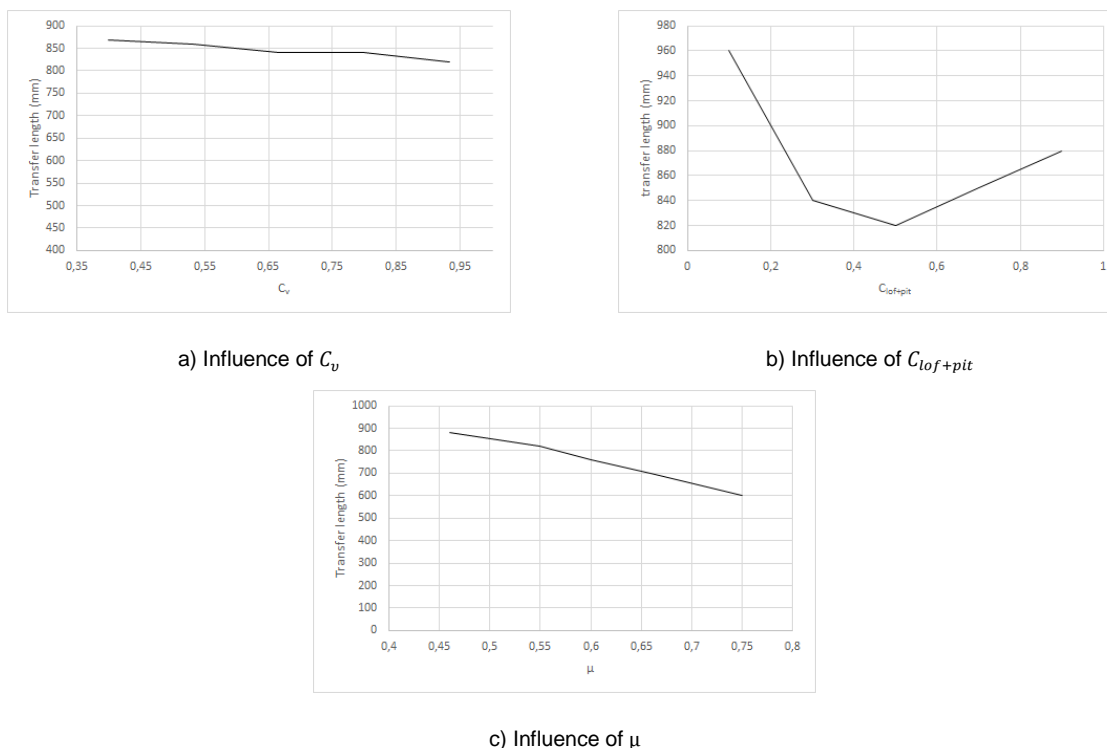

Figure 12. Influence of calibration constants

## 5. Conclusions

A bond-slip relation for the strand-concrete interface of pre-tensioned prestressed concrete was determined based on the confinement model of Den Uijl. The bond slip behaviour was implemented in a finite element model in order to evaluate the transfer length of pre-tensioned beams. Calibration constants were determined using experimental data from two independent researchers and good agreement with experimental results was achieved. Furthermore, the influence of the calibration constants of the bond-slip model on the transfer length was investigated and discussed.

# DESIGN FOR CONSTRUCTION COCKBURN GATEWAY STAGE 3

## CASE STUDY

Bassam Matty BSc MSc FIEAust, FAIM  
Director, Airey Taylor Consulting (ATC)

**Abstract:** This paper discusses the selection of a particular construction technique at the concept design stage to address site constraints and client operational requirements for designing a major extension to an operating Shopping Centre.

The selection of a non-common construction technique and the implication of that selection on the structural design parameters and construction tolerances are discussed. The advantages gained of adapting the structural design for the selected construction method and implementing it at the early structural design stage has delivered a 20% reduction in total investment cost.

The development comprises 19,200m<sup>2</sup> of underground parking, 21,200m<sup>2</sup> of ground floor retail and 19,700m<sup>2</sup> of part retail and part carpark upper floor. The significant cost reduction was achieved through the use of the top down construction technique. The design of special steel-encased pile shafts, for belled-end CFA piles to form the basement's columns and the use of short piles with micro fine cement grout to construct a unique reinforced retaining system are discussed. The top down construction technique combined with the use of hollow core planks resulted in a total reduction of formwork exceeding 80% when compared with conventional construction.

The use of post tensioning, significantly reduced the concrete used and a special fibre reinforced floating floor topping was used for facilitate the next stage of development. A lightweight floating floor for the retail area allows for the future replanning and service reticulation of the first floor without impacting the ground floor retail operation. The project was delivered on time and on budget.

**Keywords:** Construction, Sustainability, Innovation, Top down, Design, Economy.

### 1. Background

The Cockburn Gateway Shopping Centre is located in the City of Cockburn, Western Australia, approximately 21 kilometres south of the Perth city centre and 17 kilometres west of the City of Armadale. The development site is located on the south western side of the Kwinana Freeway and Beeliar Drive intersection. The existing Gateways Shopping Centre is located on a 7ha relatively flat site. With the completion of the stage three development of Gateways Precinct Shopping Centre, the shopping area were increased from 26,460m<sup>2</sup> Net Lettable Area (NLA) of shop/retail floor space to a total of 55,050m<sup>2</sup> (NLA) and the non-shop retail floor space was increased from 10,600m<sup>2</sup> (NLA) to 49,490m<sup>2</sup> (NLA)(1).

The ground sub surface profile consists of varying thicknesses of sandy fill overlying naturally occurring Bassendean sand with interbedded Coffee Rock bands. The historical groundwater level is approximately 10m below the existing ground level (2).

The stage-three development comprised 19,200m<sup>2</sup> of underground parking, 21,200m<sup>2</sup> of ground floor retail and 19,700m<sup>2</sup> of part retail part carpark upper floor. The top floor was designed to accommodate future utilisation of the entire upper floor deck as retail area.

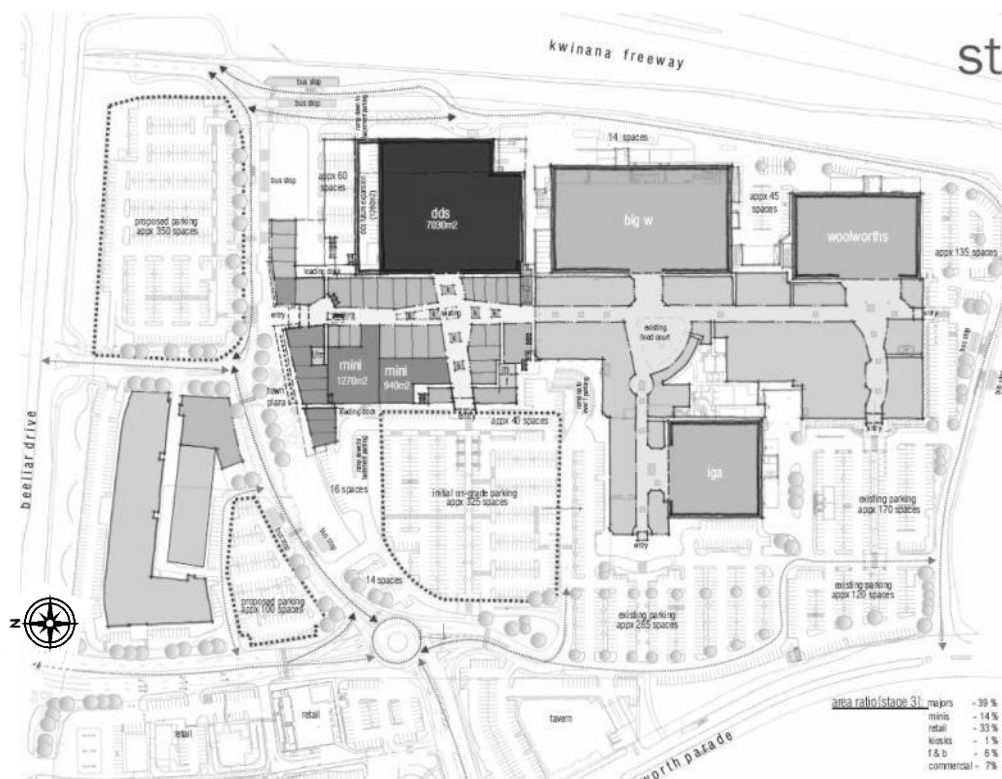

### 2. Construction Constraints

The close proximity of the existing building roads and services to the intended 19,200m<sup>2</sup> underground parking was assessed to add substantial capital cost of underpinning, re-routing of underground services and truck routes, and penalties to major tenants for service disruption and acquiring extra land for accommodate temporary car-parking to maintain normal trading. The cost of these extra requirements was assessed to be prohibitive and commercially unviable; however, without the basement carpark the expansion of the shopping centre was not possible.

To address the space and access constraints, ATC resolved that mining the dry Bassendean Sand in a confined space using small excavators was suitable. The amount of services and finishes are typically limited in a

basement and fall outside the critical path of the project planning, thus the extra time required to complete mining of the sand under the ground floor slab can be easily accommodated.

ATC proposed to the design team an alternative construction method to conventional open excavation; the alternative method employed a tailored top down construction technique that provided the prospect of addressing the operational restraints of the shopping centre whilst achieving substantial reduction in the construction cost and project delivery time without compromising the architectural intent. The alternative presented was based on ATC's past experience with a smaller sized building with comparable site geology, where we successfully developed and implemented similar techniques. The alternative construction method proposed allowed construction of the above ground structural elements to precede the basement excavation, thus facilitating overlapping construction activities and early site access to other trades to fit-out the retail areas while the mining of the basement progressed.

**Figure 1. The expansion to the existing Shopping Centre on Cockburn Gateways Site**

### 3. The Designed Solution

In top down construction, the walls are constructed first to support the excavation and these form the final external structural walls. Permanent piles or wall elements are installed internally between the soil retaining walls to reduce the span of the floor. Next the floor slab is constructed and tied into the walls. The building superstructure construction commences before or during the undercover excavation. The remainder of the excavation is completed under the protection of the top slab. Upon completion of the excavation, the base floor is completed and the services and finishes are installed within the completed structure.

The architect configured the basement using 8,550mm grid spacing in both directions with columns located at the grid intersection. This arrangement facilitates locating three spacious car-parking bays between the columns, with 2,700mm clear car bay width, leaving 450mm structural space for the columns. The same columns continue to support the first floor slab, with the exception of the elimination of 6 columns to form a column free 17,100mm span at the major retail.

A post tensioned floor plate was selected for the ground floor slab. The slab was designed to be cast directly onto the compacted sand. The post tensioning provided economy by reducing the slab thickness requirements

for punching shear and long term deflection as well as facilitating the driving of heavy construction equipment on the slab at an early age, prior to excavating the basement, as the pre-compression introduced increased the slab flexural capacity.

Assessment of the soil bearing capacity revealed the need for large diameter piles driven to a depth of 9.0~10.0m to achieve the geotechnical capacity required to support the column loads. The use of small shaft, enlarged base (belled-end) piles was investigated; 500mm diameter pile shaft with 900mm diameter belled-end base was selected. As the selected pile shaft was larger than the 450mm structural space considered by the Architect, a grouted pile was chosen to facilitate the installation of steel CHS caisson to form a smaller shaft for the exposed section of the pile shaft (407mm O/D).

Using Continuous Flight Auger piles (CFA) along the external perimeter of the basement and casting the Ground floor slab prior to excavating the soil offered the advantage of increased pile rigidity through the rotational restraint imposed on to the piles top end by the slab (Typical connection - Figure 2).

With the increased rigidity it was possible to reduce the diameter and depth of the reinforced piles and use micro fine cement injection to grout the soil block between well separated reinforced piles (Figure 3). The micro fine cemented block formed an infill between the reinforced pile while the reinforced piles provided the necessary wall strength and stiffness.

Figure 2, Slab / Retaining wall typical detail.

Figure 3, Reinforced cemented-block retaining wall.

#### 4. The Top down Challenge

Top down construction can impose a number of challenges and disadvantages including:

- Limited space and restricted access for excavation and construction of the floor below;
- A risk that the exterior walls (or centre columns) will exceed specified installation tolerances and impact the interior space;
- Potential water leakage through the soil retention system; and
- Inability to install external waterproofing outside the external walls.

Addressing these challenges is outlined below:

#### **4.1 Confined excavation**

Although the amount of services and finishes are limited in a basement and fall outside the critical path of the project planning, the use of small excavators to complete mining the sand under the ground floor slab was identified by the Builder as a risk factor that has the potential to impact the construction program. To reduce the risk, we looked at increasing the excavated depth between the internal piles to facilitate the use of large excavators. Agreement on the use of large excavators was made following evaluation and adjustment for the reduction in the shaft capacity of the piles due to the extra excavation depth. Mechanical ventilation and air quality monitoring were used at the start of the excavation to exhaust the fuel fumes. The need for the mechanical ventilation ceased once the excavation reached across to the first stair shaft, as natural ventilation provided adequate air flow.

#### **4.2 Installation tolerances**

Replacing the columns and footings with belled-end piles and achieving high positioning accuracy required careful design consideration. The Piling Code, AS 2159-2009 allows for 4% inclination to the vertical (3) in addition to out of position tolerance; if such tolerances were to be allowed, the out of plumb columns would be unsightly and would require architectural clad thus impacting the project cost and the car bay width.

To achieve high control in positioning the piles, the piling contractor elected to cast in-situ concrete guides cast around cylindrical polystyrene foams centred to surveyed pegs. Surveying the top level of the concrete guide prior to pile installation provided the necessary means to achieve high control on the cut-off level. The technique halved the out of position accuracy recommended in AS 2159-2009. Further adjustment was achieved by controlling the lowering of the caisson into the grout. Post construction survey of the projected UC sections of the piles confirmed the conformance of the installed piles/ columns with the tolerances for structures and members recommended in Clause 17.5, AS 3600-2009(4).

**Figure 4, Pile installation through the cast-in guide.**

#### **4.3 Waterproofing**

Although the water table is a few meters below the basement level, rain and surface water can enter the basement through the rather porous micro fine cement injected sand sections of the soil retention system. Waterproofing the external envelope was achieved through designing a free draining cavity wall around the external envelope. This was achieved by adding internal masonry leaf off the basement slab and maintaining the basement slab short of the piled wall to create a free-draining trench (Figure 5).

This formation was used to construct a plenum to circulate the air in the basement and exhaust the fumes. It was additionally beneficial in addressing the verticality issues and the micro fine cement injection protrusions.

**Figure 5. Detail of the free-draining cavity wall (left); Constructed air-shaft and soil retaining (right)**

## 5. The Structural System

### 5.1 Pile/Column Design

Conventional footings and columns were replaced with belled-end piles centrally located under the ground floor columns, at the grid intersections. Achieving high positioning accuracy was essential to control the load eccentricity imposed on the basement columns and that required careful design consideration.

To address the pile shaft size and verticality issues, the pile shafts were designed to have rigid composite columns rather than conventional steel cages. Steel CHS caissons with centrally located UC sections and interlaid reinforcing cage were used to form the pile within the basement's excavated zone. The composite columns were sized to provide the required ultimate load capacity. Careful detailing of the load transfer zones and the interface between the elements was essential. To address the load transfer between the ground floor reinforced concrete columns and the piles, the central UC sections were extended above the ground floor slab level to achieve the splice length, as shown in Figure 6. The extended UC section had the additional benefit of providing an above ground lever as a measure for checking and adjusting the caissons verticality during installation.

To achieve the fire rating of the basement columns without using fire proofing products, the interlaid reinforcing cages inside the CHS caissons were sized so that, for each pile, the central UC section and the reinforcing cage were capable of providing the fire design load capacity when acting compositely, while the CHS caisson was considered sacrificial in the fire load case. Upper and lower vent holes were provided in the caissons to relieve the hot gas pressure so that bursting of the CHS caissons in the event of fire is prevented(6)(7).

The pile reinforcement was detailed to have independently fabricated site lap spliced sections, a bottom reinforcing cage and an internally reinforced rigid caisson. This arrangement facilitated the lifting of the rigid caisson from a central hole located centrally to the UC section without damaging the rather flexible bottom reinforcing cage. The single point lifting allowed the caisson to act as a plumb bob enabling higher accuracy in achieving the column verticality. 75PFC sections were welded to the central UC section to control the pile cut-off level, guide the installation and enhance the punching shear resistance of the slab, as shown in Figure 7.

To accommodate for the thermal movement of the large floor area, the building was divided into five sections through full movement joints. Due to the use of belled-end piles, doubling the columns along the movement joints was not an option. Instead, all the ground floor movement joints in the post tensioned slab were located 1,650mm off their corresponding grid lines. The movement joints were articulated with high capacity stainless steel shear connectors; this arrangement eliminated the need for doubling the columns and achieved optimum structural design of the post tensioned floor slab through introducing negative bending movement to one end span and shortening the end span of the adjoining plate. (Figure 8 – detail; in Figure 9 – implementation)

Figure 6. Details of the rigid shaft and the belled-end pile reinforcement

Figure 7. Caisson lifting and cage splicing

**Figure 8. Use of shear connectors at movement and construction joints**

**Figure 9. Offsetting the movement joint from the column line**

### **5.1 Upper Deck**

The ability to drive heavy construction machinery on the ground floor slab prior to mining the soil provided the opportunity to maximise the use of precast pre-stressed hollowcore planks for constructing the first floor deck, thus eliminating the need for long reach cranes. Cast in-situ post tensioned band beams were designed to be monolithically cast with the hollowcore plank topping. This arrangement facilitated the use of linear formwork towers to support the tray for casting the beam base while supporting the installed precast planks. The band beam and precast propping arrangement significantly reduced formwork needs for the upper deck (Figure 10).

Delayed mining of the basement meant large linear loads. As a result of supporting the planks, topping and beams were directly transferred to the soil supported ground floor slab, completely eliminating the need for back propping.

**Figure 10. Linear formwork arrangement for supporting the planks and casting the P/T beam**

**Figure 11. Linear formwork arrangement and use of P/T slab as high-capacity working platform**

Casting the ground floor slab on compacted soil and the use of proprietary reinforced cemented soil block retaining achieved an 82% reduction in the formwork needs for the project when compared with conventional cast insitu construction.

## **6. Future proofing the deck**

To facilitate the planned future expansion of the retail area, which will incorporate the first floor car parking deck as future retail space, a floating floor was used. The space provided through the floating floor was selected to be sufficient to accommodate the future reticulation of the services above the structural floor. The future services shall be connected to pre-installed service risers. This configuration will facilitate the freedom of future service locations and will not affect the trading of the ground floor retail area.

The 290mm thick waffle floor was designed with 65mm topping (Figure 12 below) which allowed us to incorporate commercially available 1080mmx1080mmx225mm polystyrene void former pans, typically used for construction of raft floors for housing on clay soils. To construct the slab with reduced workmanship the use of steel fibre reinforced concrete at 15 kg/m<sup>3</sup> fibre dose rate, without supplementary reinforcing bars or mesh, was used. This configuration provided the required strength to resist the retail area design loads. The large void ratio of the waffle configuration assisted in reducing the design dead loads for the structure.

An independent plinth to falls was documented for the car parking area (Figure 12) for drainage. By removing the plinth and installing the implemented 290mm thick waffle, the full upper deck plan can be refurbished as retail area at the next phase of the development.

**Figure 12. Floating floor and car bay deck plinth**

## 7. Conclusion

The tendering process revealed the reality of the advantage offered by the tailored top down construction technique as opposed to conventional bottom-up construction for this particular project. Four contractors were invited to price the job. Three of the contractors provided their bid for constructing the building as documented with a variation of less than 5.5% between them, while the fourth bidder was fully against the use of the top down technique and offered an alternative bid to re-design and construct the development at a confirmed price of \$95.5 M. The project was awarded to the lowest bidder for a total construction cost of \$79.7 M, which is 16.5% lower than the alternative conventional construction bid. The construction was completed in 94 weeks, 16 weeks ahead of the alternative conventional construction bid.

The capital cost saving achieved was a direct result of the top down construction technique which delivered the following cost cutting advantages:

- Maintaining road access and securing uninterrupted trading operation to the existing shopping centre during construction of Stage Three;
- Elimination of the need to alter the main service supply route to the operating shopping centre;
- Significant reduction in the requirement to underpin the existing structure;
- Reduction in the excavation volume, backfilling requirements, total cement use and concrete volume and achieving 82% reduction in formwork usage;
- Significant saving in the cost of retaining the soil and eliminating the need for waterproofing the basement retaining walls;
- Maximisation of off-site production; and
- Shorter construction duration by effective overlapping of construction activities and providing an early start to critical path activities.

**Figure 13. Photo illustrating the achieved verticality and alignment of the pile installation**

Furthermore the approach developed achieved higher sustainability through the effective reduction in material usage, construction time and energy usage.

This design offered the owners the advantages of significant reduction in capital cost, lower holding cost and faster return to their investment.

## **8. Acknowledgement**

The writer would like to acknowledge the support provided by Mr Peter Airey and all Airey Taylor Consulting staff for their hard work and dedication in delivering this project. Mr Stuart Coutts and the Engineers of Bepile Australia Pty Ltd were critical in devising the installation technique for internal pile set- out and installation within very tight tolerances that made the construction technique viable.

# An Innovative Solution for Temporary Movement Joints in Concrete Floors

Lance Rogers<sup>1</sup>

<sup>1</sup>Product Development Manager, Refobar Australia

**Abstract:** Temporary movement joints are a complex and common joint used in post-tensioned concrete floors to relieve stresses from elastic pre-compression, shrinkage, creep and thermal effects. Common detail options available for temporary movement joints are pour strips, grouted dowel sleeves and stainless steel connectors. There are many issues associated with these options, including variation in material and site makeup as well as reliability of installation practice and standard site pressures of time and cost, leading to problems impacting joint quality and performance as a direct result. This paper presents the research and development of an innovative solution that has been engineered to eliminate the issues associated with the grouted dowel sleeve and stainless connector options. This latest product innovation is revolutionary as it fulfills all complex technical design criteria aspects as well as site installation reliability and efficiency requirements, whilst being economically advantageous through the use of low cost materials over all other options.

**Keywords:** Post-tensioned, Concrete, Grout, Dowels, Temporary Movement Joint,

## 1. Introduction

A paper written in 2011 titled “Temporary Movement Joints in Concrete Floors”, Sullivan et al (2011), presented the testing of the Grouted Dowel Sleeve System for various grout tube arrangements as well as the final locked tensile strength of various post-tensioned duct sleeve types. It is this prior paper along with its results and recommendations for further development of a proprietary product to resolve the issues, that motivated this paper and the research and development of an innovative solution. The final paragraph of the Sullivan et al (2011) paper quoted a recommendation as follows:

“There is also a possibility of developing proprietary sleeve that allows movement parallel and perpendicular to the joint with low resistance, then allows the sleeve to be grouted (for both load capacity and corrosion protection) including the bar length across the joint, without the necessity of filling the joint with grout.”

Temporary movement joints (TMJ) are a requirement within concrete floor structures to relieve initial restraint within floor plates due to fixed or stiff vertical elements, such as core walls. TMJs relieve this restraint effect to allow concrete to shorten ideally towards one fixed point of restraint, due to the actions of elastic shortening, shrinkage and creep. TMJs are more common in post tensioned floor structures due to the additional shortening actions associated with initial pre-compression elastic effects and long term creep effects.

TMJs are by far the most complex joint type as they are required to allow initial movement in two horizontal directions, the same as a permanent movement joint and then have a facility to lock the joining concrete elements together for permanent structural stability and integrity, similar to a common construction joint. The simpler and preferred design solution to achieve full initial movement and then final locking would be the pour strip. However, practical site installation aspects prove the pour strip system to be most undesirable due to typical site schedules and continuity pressures. As such the Grouted Dowel Sleeve option has proved to be the most popular and desirable option, mostly due to its initial low cost and lack of programme impact. It seems these initial up front time and cost attributes outweigh the immediate to long term issues associated with the Grouted Dowel Sleeve, despite being far less effective due to inherent system flaws and a heavy reliance on installation practices.

The problems associated with the Grouted Dowel Sleeve System, such as sealing and leaking grout, that lead to an ineffective joint, has been recognized for decades in the industry and is either largely ignored or remediated with band aid maintenance repairs such as re-sealing, re-grouting, crack injection and concrete patching. The reason the problem has remained unresolved for so long is down to the complex

nature of the joint itself. To be able to effectively seal and grout after movement has taken place calls upon structural engineers to think outside of standard structural engineering topics: To solve the problem, requires solutions from both mechanical and hydraulic engineering fields as well as material knowledge of plastics and rubbers. The added problem of the joint having an opening potential from a hairline crack up to 20mm or more poses the added problem of grout viscosity and pressure to fill the joint effectively.

Following the previous paper “Temporary Movement Joints in Concrete Floors” by Sullivan et al (2011) which tested and highlighted the issues of the Grouted Dowel Sleeve System, it is concluded that the key objective and desired outcome is to engineer and develop a product to provide a reliable, superior temporary movement joint system to raise the quality and safety of buildings while reducing cost of installation and maintenance. This paper outlines an innovative solution that answers these needs.

## 2. Previous Research

### 2.1 Paper by Sullivan et al (2011)

The Sullivan et al 2011 research paper had a primary purpose of understanding and developing an effective detail for grouted dowel sleeves, as there is limited information and an overall understanding in the post tensioned (PT) industry, both in Australia and the UK, that the current Grouted Dowel Sleeve System has many flaws and failings. The paper investigated four duct types and four grouting methods known within the industry to be common practice. The paper outlined a test procedure, presented observations and test results.

Despite test conditions being naturally more controlled and of higher quality than site conditions, the paper observations highlighted a number of issues relating to the ability to grout the sleeves and joint as follows:

1. **Blockages** – Grout flow from dowel sleeve into the joint is typically inconsistent due to concrete slurry or fines entering between the sleeve and pour 1 concrete face. The paper highlighted difficulty, even in a test environment, to ensure the sleeves were sealed against the first pour. This difficulty leads to concrete slurry entering the sleeve causing a blockage. Blockages were prevalent and random throughout the test sleeves.
2. **Grout Level in Joint and Sleeve** – General site practice demonstrates that grouting operations stop once grout flows out the top of the slab local to the sleeve. Naturally site personnel seek to avoid any cleaning up operations. As suggested by Sullivan et al (2011), the grout settles by flowing slowly along the joint and then settling below the level of the sleeve. This leads to the grout in the sleeve emptying into the joint and unless topped up multiple times as per the Sullivan et al (2011) test, the ducts will remain either empty or only partially filled.
3. **Gout leaking Underside** – The test demonstrated the underside seal to be insufficient causing grout to leak through the underside of the test slab.
4. **Initial movement restraint** – Jacking the test slabs apart to simulate initial free movement and attain a joint gap width of 10mm proved a considerable load of over 0.5T per sleeve in each direction, demonstrating the large amount of restraint in the Grouted Dowel Sleeve System.

The paper observations highlighted that the operation of grouting was a highly complex and sensitive task with many potential issues complicating the process resulting in an inconsistent performance outcome.

In addition there were some limitations to the test; the major limitation was the predetermined joint gap width of 10mm. The test method and setup ensured a 10mm joint opening was provided to enable the grout operator to visually determine if each sleeve had grout flow into the joint as part of the test observations. This process verified some sleeves were blocked from concrete fines, however, in reality the joint width can be as small as a hairline crack width due to the Grouted Dowel Sleeve System containing unreliable frictional restraint qualities. For this common situation a visual inspection would not suffice to witness flow of grout into the joint and places question on whether the joint is adequately filled to ensure fire and durability cover protection to the dowel bar across the joint itself.

## **2.2 Site Practices and Experience**

### **2.2.1 Grouted Dowel Sleeve**

Following the paper written by Sullivan et al (2011) and in conjunction with decades of knowledge and experience in the building industry, the many flaws associated with the Grouted Dowel Sleeve System have been identified below in relation to the two fundamental function requirements of a Grouted Dowel Sleeve TMJ system: Initial Movement and Permanent Lock.

Initial Movement is the first fundamental requirement of a TMJ. The criteria of free movement in both horizontal directions, x-direction for along the joint perpendicular to the dowel crossing the joint, and y-direction for moving away from the joint parallel to the dowel bar crossing.

Final Locking is the second fundamental requirement of a TMJ. The criteria for the joint to have the ability to lock two neighboring concrete elements together by grouting the dowel bar sleeves at a predetermined point in time, often 28 days after pour 2 concrete element has been cast.

The Grouted Dowel Sleeve System is simply a dowel bar (typically N grade 500 reinforcement) usually two meters long that has half its length installed and cast mid depth of the first concrete element pour. The second half of the dowel bar in the second concrete element pour is then sleeved with duct (either flat PT duct or round PT Duct). A grout tube arrangement is installed with the duct to facilitate the grouting and locking criteria at a later point in time.

Due to the many issues involved and interconnecting with the two function requirements, the issues will be explained per installation step.

### **2.2.2 Grouted Dowel Sleeve Issues**

**Stage 1 Pour 1 – Install Dowel Bar** –The first step is to drill an appropriate size hole in the edge form in order to pass half the length of the dowel bar through before chairing the end of the dowel bar to ensure the bar remains horizontal.

**Stage 2 Pour 2 – Install PT Duct** – The second step of the site installation process is to cut appropriate lengths of PT duct to sleeve the dowel bar protruding from pour 1.

Site manufacturing inconsistency is a major issue of this method as the dowel bars are all installed individually to slightly differing lengths protruding from the joint. In addition each sleeve is individually cut with a grinder or similar, which creates two problems, inconsistent lengths and inconsistent angle of the cut (i.e. not exactly 90 degrees). The combination of this site manual material preparation and installation leads to the following issues.

- **Sleeve Length not matching the Dowel Length** – When the sleeve is short a gap is left at the joint location. This gap allows concrete fines and often aggregates (with gaps of up to 30mm and more) surrounding the dowel bar at the joint face. This restricts the dowel bar and therefore the concrete elements moving in the x-direction along the joint generating a portion of restraint in the y-direction as well (depending on the gap width and amount of concrete slurry that has travelled up the duct).
- **Sleeve Cut Angle** – The cut is often roughly judged or measured, with each sleeve individually cut with a grinder or similar. This means each sleeve is slightly unique, close to 90 degrees though with a range of margin of error. As a result the duct often meets the joint face with a gap to one side allowing concrete fines and often small aggregates into the sleeve surrounding the dowel bar to block the duct sleeve. Again this restricts the dowel bar and therefore concrete element moving in the x-direction along the joint and generates a portion of restraint in the y-direction as well.
- **Sleeve Damage** – Often the typical flat PT duct is used which has an inside diameter of 19mm. In order to slide the duct over an N20 deformed reinforcement bar it is common for the duct to be manually manipulated out of shape. The result is a damaged piece of duct sleeve that is held to one or more sides of the dowel. In addition it is not uncommon for both flat and round duct to be trampled and so damaged in any case. All causing increased initial restraint.

- **Sleeve Horizontal** – Often the sleeve will not be installed horizontal. Transvers to the dowel bar (rotating about the dowel bar), it is not uncommon for the flat duct sleeve to be installed at a slight angle as there are limited means to ensure the light weight duct is not knocked or tied correctly from rotating. In addition, dowel bars, usually N20 (i.e. stiff bars) are not protruding horizontally from the face of the pour 1. These issue cause restraint and impact on the initial free movement requirement.
- **Sleeve Centralized Flat Duct** – It is extremely rare and uncommon for the dowel bar to be centralized within the flat duct as there is no real material system to achieve this. As such the dowel bar is often resting to one side and of course each dowel bar and adjacent sleeve will favour a random side. This deems any movement in the x-direction impossible and therefore causes restraint in the x-direction.
- **Sleeve Centralized Round Duct** – Evidence shows a similar issue as described above also occurs in the round duct, as the round duct is often damaged (squashed out of shape) making the requirement of initial free movement even clumsier. In addition, when the round duct is not damaged, the duct mostly hangs on the dowel bar so that the dowel bar is central at the top of the round sleeve. This means the concrete element the sleeve is encased in (pour 2) must move vertically upward in order to move in the x-direction. The forces due to self-weight are too great and so the system retains restraint in the x-direction.

**Stage 3 Pour 2 – Install Grout Tubes** – The third step of the site installation process is to cut and install appropriate lengths of PT grout tubing to the sleeves to facilitate the later grouting phase to lock the joint. Issues related to this phase are:

- **Grout Tube Arrangement** – There are a few different grout tube arrangements that Sullivan et al (2011) tested. Some arrangement can cause air void issues due to their arrangement design, however all arrangements have a potential of air voids due to blockages at the sleeve joint interface as described above.
- **Sealing Grout Tube & Duct** – Once the grout tube is installed, the end of the sleeve away from the joint must be sealed, again there are various ways and methods and likely left to what is available on site. A common method is duct tape, another is expanding foam. Both can be unreliable and completely open to the site operator installation practice per sleeve. I note the expanding foam is dangerous as it is quite difficult to judge the amount of expansion, which could potentially fill the sleeve.

**Stage 4 Pour 2 – Grouting** – The forth and final step of the site installation process is to grout the dowel bar sleeves and joint. This is by far the most crucial, however most complex stage.

- **Grout Joint and Sleeve Together** – The largest fundamental flaw of the Grouted Dowel Sleeve System is that it relies on the joint being grouted at the same time as the dowel sleeve. With the inconsistencies explained above coupled with the joint gap opening being inconsistent due to the systems inherent restraint issues explained above, then adding into the mix a reliance on the underside and edges being sealed sufficiently and effectively, make this process very unreliable and as shown in Sullivan et al (2011), often ineffective.
- **Sealing Underside** – There are no real set methods for sealing the joint on the underside and vertical edges to the joint and so each builder often try's their own solution. This makes the process unreliable and difficult to achieve. Typically a spotter has to be under the joint to spot any leaks and attempt to stop them as soon as possible. This can be quite messy, frustrating and sometimes impossible after grouting has begun.
- **Grout Pressure** – The pressure of the grout differs throughout the routable spaces. For example the size of the grout tube compared with size of the joint compared with the space in the sleeve and gaps through blockage zones. Ultimately this leads to the grout finding its way through the path of least resistance and so the path of most resistance is not filled of contains air voids. As per the testing results of Sullivan et al

(2011), which demonstrates all duct types and grout methods show the possibility of both air voids in the dowel bar sleeve and joint gap.

- **Blockages** – The above points regarding variance in dowel/sleeve length and sleeve cut angle and overall inability to seal the sleeve to the pour 1 concrete face, cause blockages that restrict the flow of grout into the joint and depending on the type of grout tube arrangement can result in the dowel sleeves being only partially full. This reduces the capacity of the tensile strength of the joint for the permanent locking.

### 2.2.3 Grouted Dowel Sleeve Consequences

Due to the above outlined issue there are a number of consequences to the Grouted Dowel Sleeve System:

- Corbels are required for all Grouted Dowel Sleeve System joints
- Labour inefficiency due to multiple sealing, grouting and cleanup activities
- Cracking (Initial) due to initial horizontal movement restriction (restraint)
- Cracking (Ongoing) due to insufficient grouting (locking) of the dowel sleeve
- Safety Risk Corrosion of dowel bar due to insufficient joint grout protection
- Safety Risk Fire to dowel bar due to insufficient joint grout protection
- Safety Risk structural stability of building reliant on joint transferring load

The above consequences outline that the Grouted Dowel Sleeve System has a number of manufacturing and installation inconsistencies that prove the system is an extremely low quality system and approach that is highly reliant on site manufacturing and installation practice, that even if perfectly installed such as the earlier test environment of Sullivan et al (2011), still contains all of the issues jeopardizing the quality and structural integrity of buildings long term. The system is definitely the most economical to initially install, however has the possibility of initial and long term maintenance issues associated that will often be ignored or missed years down the track.

### 2.2.4 Stainless Steel Option

There is a proprietary stainless steel product option available, however this option also relies on the joint being sealed and grouted effectively, which has similar sealing and joint gap width difficulties associated as the Grouted Dowel Sleeve System. In addition the product is extremely costly in comparison due to the stainless steel material used and therefore avoided and not preferred in the industry.

## 3. Product Development of an Innovative Solution for TMJs

### 3.1 Overview of the Innovative Solution for TMJs

The original innovative solution was initially conceived and designed for the “Slab to Slab” temporary movement joint connection type. Then as the product development stages unfolded the product range evolved to incorporate a “Slab to Wall” option, that allowed for both a compression situation, where the concrete slab element can move toward a wall structure (i.e. back of a core) and the standard tension situation pulling away from a wall. For ease of understanding, the full innovative solution range is best demonstrated in Figure 1 below.

Figure 1. Product Innovation – Applications

### 3.2 Prototype Design Development & In-House Testing

Prototype development occurred in conjunction with in-house testing over a period of 3 years from 2011 to 2014. There were a total of 8 prototypes manufactured each with their respective in-house testing regimes until the innovative solution had achieved all design criteria requirements set out in the beginning as follows:

#### Innovative Solution Design Criteria

1. Initial Horizontal Movement – 10mm transverse (parallel to joint) movement prior to grouting
2. Initial Horizontal Movement – 20mm pull out (perpendicular to joint) movement prior to grouting
3. ZERO vertical movement in the grouted permanent state
4. Vertical shear capacity in the un-grouted temporary state and grouted permanent state
5. Watertight leak resistant seal during and after all temporary movement has taken place
6. No reliance on joint being sealed or grouted to provide minimum cover for durability (corrosion) and fire protection to reinforcement dowel through the joint
7. Economic materials – Use plastics rubbers mild steel (i.e. avoid stainless steel or galvanizing)

There were various developmental features that were engineered into the innovative solution over this period to achieve either a design or practical functional requirement. The following briefly describe some of the primary features in line with Figures 2, 3 and 4 below for clarity:

**Figure 2. Product Innovation – Assembled**

**Figure 3. Slab to Slab – Exploded View**

**Figure 4. Slab to Wall – Additional Parts**

**Rubber boot seal** – The rubber boot seal is arguably the most intelligent part of the product innovation as it primarily functions as a seal between the two sides of a temporary movement joint. The seal has two sealing ends; the first is the rectangular end that is mechanically locked into Part A of the product during the manufacturing process. The second is the opposite end of the rubber boot, which is a circular pressure seal that grips Part A (Pour 2) of the innovative solution. The secondary function of the rubber boot seal is to have the ability to stretch and compress in order to remain fully sealed while allowing movement in both horizontal planes. The thin rubber web between the two sealing ends is flexible enough to move in both horizontal directions while being robust enough for site installation purposes.

**Joint Zone Cover** – The second major feature is the cylinder section of Part B (Pour 2). This cylinder represents the potential joint opening zone, where the joint and product has the ability to open up to at least 30mm and even further with the rubber boot inverted, however the inverted position has not been seal tested and is unlikely to be a requirement as a horizontal slab element would have to be greater than 120m between fixed elements such as core walls and shear walls. The reinforcement dowel bar remains central to the cylinder at all times throughout any movement as the dowel bar and Part B move together with pour 2. The result of this design is that the dowel bar retains the initial 20mm cover around the dowel bar in the joint zone prior to and after grouting. This negates the need to grout the joint to provide protection to the dowel bar in the joint zone.

**Grout Integrity** – A major design focus and therefore feature of the innovative solution is the reliability of the sealed product to be fully grouted. As such, the products distinguishing twin grout rails are a major physical feature of Part A, refer Figure 3 top of the sleeve main body. There are three design aspects to the twin grout rails that ensure the product performs both technically and practically.

- 1) The top height of the grout rails in Part A represents the filled level of grout in the product, which is also the same height as the top level of the cylinder in Part B. This ensures the dowel bar has grout filled to the full cylinder height providing grout cover for durability and fire protection through the joint. Similarly, the box section of Part A has been design to contain a small void zone for any air bubble turbulence while grouting and facilitate the rubber boot initial movement function.
- 2) Secondly, the grout inlet and outlet ports have been designed at a higher level than the top of the twin rails and cylinder to ensure the product is completely filled before grout exits the product.
- 3) Finally the inlet and outlet ports have been design to be on one side of the joint (pour 1). This eliminates any confusion with a looping arrangement that would otherwise be required when installing Part B in pour 2. The inlet and outlet ports on one side also facilitate the slab to wall product option and retain the same product pieces for both “slab to slab” and “slab to wall” options.

**Shear Capacity** – The purpose for the two grout rails (twin rails) is to provide an upside down pyramid zone above the dowel bar to achieve an un-grouted shear capacity. The pyramid zone contains concrete directly above the dowel bar and also works in a reverse shear capacity situation as well.

**Tension Capacity** – In order to achieve maximum dowel bar tension resistance many concepts were tested, with the resulting design consisting of two waved edges to increase the friction, however maintaining flat top and bottom surfaces to ensure both un-grouted shear capacity and no air voids other than the purposely design air void space.

**Other minors** – There were many other minor design features that provide design protection from the practical installation rigors. For example the two clips on Part B provide a mechanism for the installer to plug Part B into Part A, with a guide and robust clipping feel to assert the parts are successfully engaged. The corners of the flange to Part A have a primary and secondary tear away feature in case the product is screwed to the formwork as opposed to installation advice to nail. The primary perforations mimic the natural failure path demonstrated by in-house testing. Also the grout inlet and outlet ports are integral and part of the main body injection molding. This provides a robust port to resist the rigors of site installation practices.

### 3.3 Laboratory Testing

In addition to the 3 years of in-house prototype development and testing, it was decided to engage a 3<sup>rd</sup> party university laboratory to carry out a series of tests to confirm the products actual capacity in shear and tension strength. The testing method and project also formed a thesis topic for a student capstone project. Full details of the project and testing results are documented by Boland (2014), however the main tests and results will be briefly outlined below.

- 1) Un-grouted Shear Test
- 2) Grouted Shear Test
- 3) Tension Test

**Un-Grouted Shear Test** – This test stage had been designed to replicate the possibility of a worst case scenario on site when activities of stripping formwork and progressive back propping occur. Typically this transpires in a post tensioned structure after final stress, extensions approved and cut/seal of pockets has occurred. The final stressing requirement is for the slab concrete element strength to reach 22Mpa or 25Mpa depending on the post tension system used. The un-grouted test was therefore performed at 22Mpa.

**Grouted Shear Test** – This test stage had again been design to replicate the design requirement for the grout in the product to be 40Mpa. Due to limitations in laboratory time, this stage had to occur slightly earlier than desired when the grout had only reached 28Mpa, rendering the results slightly conservative.

**Tension Test** – Again this stage had been designed to conduct the test at 40Mpa, however had to occur at 28Mpa.

A situational calculation was carried out to determine a desired capacity for the product within a residential loading scenario, 200mm thick slab, 8m x 8m span and the product spaced at 600mm centres. This calculation determined the desired shear capacities were **10.4KN** for the Un-grouted case and **12.8KN** for the grouted case per product (service loads).

The test setup configuration of the two shear tests involved loading adjacent to the joint via LC3, refer Figure 5 below. A frame analysis programme was used to determine the theoretical load through the joint dowel, and then compared to actual load cell readings for data validation. Refer Figures 7 and 8 below which demonstrate the theoretical load through the joint dowel is 80% and 55% lower than LC3 for the un-grouted and grouted case respectively. It is noted the un-grouted case utilizes 4 points of reaction support due to the hinge nature and only 3 points of support for the grouted case due to the joint being locked via grouting.

Figure 5. Shear Test Set Up

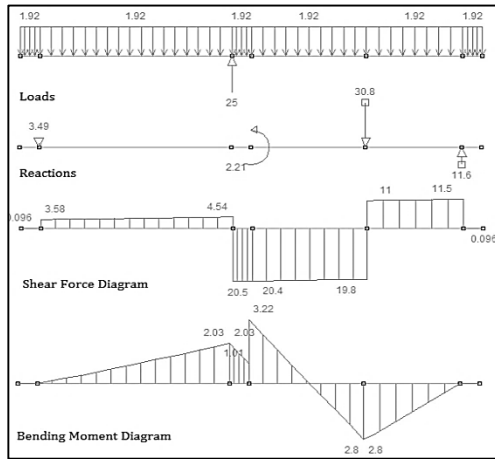

Figure 6. Pull out Test Schematic

**Figure 7. Theoretical Un-grouted Model**

**Figure 8. Theoretical Grouted Model**

Results in Tables 1 and 2 below show a comparison of the actual load through the dowel at the joint location compared to the theoretical models, for data validation.

The un-grouted test contained an anomaly in test 3 which could not be explained. By omitting test 3 results it is observed that test 1 and 2 are similar to the theoretical model calculation which validates the data and confirms an overall minimum factor of safety (**FOS**) of **1.96** has been achieved (20.4/10.4). It is noted the maximum FOS is unknown as the un-grouted case was not tested to destruction. It is noted that test 1 had errors for LC1 and LC2 as a result of the load cell rotating due to a lack of rollers under the pin, this was introduced for all following tests.

The grouted test results were very consistent and similar to the theoretical model calculations which validated all data. It is noted that the 3 tests reached different maximum shear results as the first test was to destruction, reaching **50.9kN** and the following 2 tests were restricted to preserve the specimens for the following tension tests. The following 2 grouted shear maximum loads were **39.2kN** and **27.9kN** respectively. Therefore, the **minimum FOS is 2.18** (27.9/12.8), with a **maximum FOS potential of 3.98** (50.9/12.8).

**Table 1: Comparison of Un-Grouted Results**

<b>Summary @ 20.4kN</b>	LC1 (kN)	LC2 (kN)	LC3 (kN)	LC4 (kN)	Self-Weight (kN)	Sum of Forces (kN)	Shear Force (kN)	Vert. Disp. (mm)	Horiz. Disp. (mm)
Theoretical	11.6	-30.8	25.0	-3.5	-2.3	0.0	20.4	-	-
Test 1	14.7	-34.1	25.0	-5.3	-2.3	-1.9	-	3.9	5.6
Test 2	13.8	-30.1	25.0	-5.9	-2.3	-0.5	-	5.2	5.6
Test 3	15.9	-31.0	25.0	-	-2.3	-	-	3.3	6.0
Average	14.8	-31.7	25.0	-5.6	-2.3	-1.2	-	4.1	5.7

**Table 2: Comparison of Grouted Test Results**

<b>Summary @ 27.9kN</b>	LC1 (kN)	LC2 (kN)	LC3 (kN)	LC4 (kN)	Self-Weight (kN)	Sum of Forces (kN)	Shear Force (kN)	Vert. Disp. (mm)	Horiz. Disp. (mm)
Theoretical	0.0	-26.7	50.0	-21.0	-2.3	0.0	27.9	-	-
Test 1	0.0	-26.7	50.0	-20.6	-2.3	0.4	-	0.2	0.6
Test 2	-0.3	-26.0	50.0	-21.2	-2.3	0.1	-	1.5	0.7
Test 3	0.0	-26.1	50.0	-21.0	-2.3	0.6	-	1.6	0.7
Average	-0.1	-26.3	50.0	-20.9	-2.3	0.5	-	1.1	0.7

There were 3 tension pull out tests, however 1 test had a bracket failure and was therefore omitted from the results. The remaining 2 tests achieved an average pull out tension capacity of 142.4kN with a grout strength of only 28Mpa.

### **3.4 Consumer Testing**

Following the success of laboratory testing the product was then trialed on one joint of a live project. The site testing plan was to investigate installation practicality and grouting practice. Observations from the installation lead to a minor modification to add a clip in chair to the product to speed up the installation process even further. Grouting was a success with no leaking.

## **4. Conclusions**

Overall, the 3 years of development and in house testing allowed multiple engineering modifications of the innovative product solution to occur to ensure the product evolved such that the full technical design criteria and practical site installation criteria were met. University laboratory testing has proved the product has a substantial shear and tension capacity, which can be utilized given a chosen factor of safety. The product application covers both a “Slab-to-Slab” connection and “Slab-to-Wall” connection, without the need for a corbel support. The product has been designed as a sealed unit that provides reliability of grouting and cover to the dowel bar across the joint, eliminating the need to seal and grout the joint. The innovative solution therefore meets the challenge posed by the previous paper Sullivan et al (2011), creating a high quality, professional TMJ product that will raise overall joint quality, performance and therefore building excellence.

## **5. Acknowledgement**

The author thanks all of the individuals involved from both SRG Limited and Refobar that contributed to the innovative product solution development as well as the cost involved.

The author thanks University of Technology Sydney for the use of their laboratory facilities, guidance with respect to the testing parameters and for their co-operation

The views expressed in this paper, and any errors, are those of the author.

# Officer South Sewage Pumping Station – A Diaphragm Walling Case Study

Marc Peril<sup>1</sup> and Jaya Weerasinghe<sup>2</sup>

<sup>1</sup>Network Quality Manager, South East Water

<sup>2</sup>Chief Engineer (Structural) Asia Pacific, MWH

**Abstract:** Officer South Sewage Pumping station is a critical component of the \$40 M Pakenham Narre Warren Sewerage scheme to transfer sewage flows from Officer and Pakenham to Melbourne. Designed and constructed by the 'US' Alliance on a fast-tracked program, it is South East Water's largest sewage pumping station. It includes two large in ground water retaining structures in close proximity: A 12 m diameter 13 m deep circular shaft, and a 30 m by 11 m, 6 meter deep rectangular tank. Both constructed using diaphragm walling, enabling incorporation of temporary ground support into the permanent structures, and minimisation of formwork and falsework. Consequently, creating substantial time and cost savings and enhancing safety. Diaphragm walling enabled safe and rapid construction below the ground water table whilst achieving the required degree of water tightness to facilitate subsequent epoxy coating. Design of the diaphragm walls was based on the approach outlined by the ICE Specification for Piling and Embedded Retaining Walls. This proved particularly useful for delineating responsibilities of: the permanent works structural designer; diaphragm wall designer; diaphragm walling contractor; and site manager. It also mandated development and use of a walling manual, critical for safety control. The walling manual documented constraints on construction sequencing and lateral wall movement limits to monitor safety of the structures in the temporary condition. Inclinator tubes cast into the tank diaphragm walls were used to monitor wall movements against limits set in the walling manual. This supported validation of the design and proved safety of ground support during construction.

**Keywords:** Diaphragm wall, risk management, liquid retaining, sewage pump station, shaft, tank.

## 1. Project Background

The Officer South Sewage Pumping Station (SPS) is South East Water's largest SPS facility. It is a key link in the Pakenham-Narre Warren transfer scheme from the Pakenham Sewage Treatment Plant to the Eastern Treatment Plant (Bangholme, Melbourne). The \$17 M SPS project was a fast-tracked design and construct project delivered by the 'US' Utility Services Alliance made up of South East Water, Thiess Services, Siemens and design partner MWH. Other key members of the project delivery team included the diaphragm walling specialists Piling Contractors and their structural design subcontractor MJ Civil. This paper focuses on the application and integration of the diaphragm walling method to the construction of the main structures:

- a 13 m diameter, 12 m deep wet well shaft (Hereinafter referred to as the shaft); and
- a 30 m long x 11 m wide x 6 m deep 1.2 ML flow control tank with provision for expansion to 3.6 ML in the form of two additional tank cells (Hereinafter referred to as the tank).

### 1.1 Intent of this paper

This paper aims to present a project case study and share lessons learned from our experience of applying diaphragm walling technology to the construction of liquid retaining structures in the Australian context. It is written from the perspective of a generalist civil engineer and diaphragm wall procurement client. It is aimed at those new to diaphragm walling considering its application, however a basic understanding of the technique is assumed.

### 1.2 Diaphragm walling construction methodology

Diaphragm walls are reinforced concrete walls constructed in ground as a series of panels. A diaphragm wall panel is a reinforced concrete cast in-situ or precast wall panel installed within a pre excavated trench supported by bentonite slurry. Diaphragm walls are typically excavated using specialist grabs or hydrocutters. Trenches are set out at surface or working platform level using temporary cast in-situ guide walls. Once the desired excavation depth is reached, a prefabricated reinforcing cage including tremie pipes is lowered into the trench. Concrete is then placed in the trench from bottom to top via the tremie pipes within the reinforcing cage. The tremie pipes are gradually withdrawn as the concrete is placed. The trench walls act as formwork for the diaphragm wall and the heavy bentonite fluid serves as trench support both during excavation and during the concrete pour until it is totally replaced by concrete.

Diaphragm wall panel joints are sealed with water stops. Stop ends or metal forms are used at the edges of panels to hold water stops and maintain their position during concrete placement. Stop ends also protect the cast panel from damage whilst the adjacent panel is being excavated. Once an adjacent panel has been excavated, the stop end is removed laterally. This exposes the remainder of the water stop prior to concrete placement.

### 1.3 Author involvement

At the time of the project, Marc Peril was employed by MWH as a senior civil engineer and was the Design Manager for the Officer South SPS project. He is currently employed by South East Water. Jaya Weerasinghe was the permanent works structural lead and project structural reviewer.

## 2 Design Phase

### 2.1 Wet well shaft

The wet well shaft has an internal diameter of 12 m and a depth of 12 m (internal). Originally conceived as a rectangular shaft, it was changed to a circular shape to take advantage of its inherent structural efficiency and for ease of construction. The shaft comprised of three chambers: an inlet drop chamber and two wet wells each housing submersible sewage pumps. The chambers are separated by an internal tee wall from the base slab to cover level. Flow between the inlet chamber and either wet well is through base slab level penetrations controlled by penstocks to enable isolation for maintenance access. Closing of the penstocks applies hydrostatic loading to the internal tee wall. The tee wall also supports the 14 precast concrete panel/beam system which makes up the pump station shaft roof. The floor of the pump station shaft also includes substantial secondary concrete benching intended to optimise pump station operation. Figure 1 shows the wet well shaft layout.

Figure 1. Officer South SPS wet well Shaft. From left: cover plan, benching plan, and section

### 2.2 Detention tank

The SPS facility also includes an in ground detention tank to attenuate peaks in flow and store flows in emergency scenarios. The detention tank is normally empty. The detention tank was planned to be developed progressively in stages. The first stage of development required an operational volume of 1.2 ML. At ultimate development, an operational volume of 3.6 ML is required. The first stage 1.2 ML detention tank is a single rectangular cell with internal dimensions of 30 m x 11 m and 6.25 m depth. The ultimate detention tank was originally conceived as comprising three rectangular cells with a common base slab and shared long walls.

Each detention tank cell includes four internal struts at roof level to prop long walls and support the roof system. The floor of each detention tank cell includes a secondary sloping concrete screed to facilitate cleaning and draining. Figure 2 shows the tank layout (Stage 1 only).

Figure 2. Officer South SPS detention plan and section

### 2.3 Ground conditions

The site geology encountered was predominantly clays with interbedded sands and silts. Of particular concern was a water bearing sand layer below the shaft at 14.5 m depth, 1.5 m below the shaft base. The water table was encountered at a depth of 3.5 m. Buttlings (1)

## 3 Diaphragm Wall Procurement and Design

### 3.1 Construction system selection

The 'US' Alliance design and delivery team faced the problem of building a 6 m deep tank structure and 13 m deep SPS shaft structure within mixed soft ground and below a high water table. It was evident that extensive temporary excavation would be required to enable construction. Design and construction planning commenced by investigating alternative temporary excavation support and construction solutions for the shaft. The tank was initially proposed to be constructed within an open battered excavation.

Options considered for shaft temporary excavation support included caisson construction (both cast in-situ and precast segmental ring types), sheet piling, cutter soil mixing and secant piling. Diaphragm walling was initially discounted due the relatively short length of wall in the shaft and the large mobilisation costs associated with this form of construction.

Tenders were called for the shaft temporary support. The tender documents included a performance based specification to encourage innovation and competition between the available technologies. The ability to incorporate the temporary works into the permanent works was explicitly encouraged.

The selected option was an alternative bid based on the use of diaphragm walling and inclusion of the detention tank in the scope of works. This alternative option was selected based on an estimated \$0.5 M construction cost saving.

By adding the detention tank into the scope of excavation support, the length of diaphragm wall increased sufficiently enabling it to become cost competitive with the other technology options. Diaphragm walls were able to perform the dual function of being temporary retaining structures during internal excavation and base slab construction. The 'temporary' excavation support walls were then incorporated into the permanent structures. The construction methodology eliminated the need for separate temporary structures and the requirement for extensive formwork and falsework.

## 4 Diaphragm Wall Specification and Design

Once diaphragm walling was selected as the preferred construction system, the temporary excavation support specification was re-written around the use of diaphragm walling. This specification [Peril and Weerasinghe (2)] was based on the example form provided by the ICE Specification for piling and embedded retaining walls 2<sup>nd</sup> edition (ICESPERW), ICE (3), which proved to be a valuable resource for this project. The revised specification paid particular attention to the following areas:

- detailed design criteria;
- the division of design and construction responsibilities;
- risk management in particular:
  - safety and stability of the diaphragm walls whilst in the temporary condition;
  - the use of a walling manual to construction sequencing and provide a reference for construction monitoring;
  - additional design criteria specific to diaphragm walling; and
- a high degree of water tightness (no damp patches etc. refer Section 4) to enable the subsequent application of internal coating to fulfil the requirements of the durability design.

### 4.1 Diaphragm wall design criteria

Both the wet well shaft and the detention tank were designed for the following criteria:

**Table 1. Design Criteria**

Design Life:	100 Years
Design Codes and References:	ICE Specification for piling and embedded retaining walls 2 <sup>nd</sup> ed
	BS EN 1538: Execution of Special Geotechnical works – Diaphragm Walls, BSI (4)
	AS3600 – Australian Standard for Concrete Structures, SA (5)
	AS3735 – Australian Standard for Concrete Structures for retaining liquids SA (6)
	AS4678 – Australian Standard for Earth Retaining Structures SA (7)
	AS2159 – Piling Design and Installation SA (8)
Internal Exposure Classification Ref AS3735 Table 4.1	D – Severe / Condensation/extremely corrosive environment due to sewage gases producing sulphuric acid due to bacterial activity.
Minimum Reinforcement Cover	75 mm + Epoxy coating (Note: Table 4.3 AS3735 requires only 55 mm cover for Grade 50 Concrete. Extra cover was specified to suit the construction method.)
Panel Maximum deviation from verticality	1 in 100
Concrete Mix (S50) Details	Minimum Characteristic Strength – 50 MPa Minimum cementitious content – 400 kg/m <sup>3</sup> Maximum cementitious content – 450 kg/m <sup>3</sup> Max w/c ratio - 0.40; Nominal 56 day shrinkage - 600 microns
Permissible lateral wall deflection	The maximum allowable lateral deflection of the diaphragm wall shall be compatible with the requirements of AS4678 and AS3735. The Subcontractor's design shall show the expected deflection of the wall giving due consideration to watertightness, crack widths and rebar stresses.
Ground water level	At surface for ultimate limit state 3.5 m below surface for serviceability limit state

## 4.2 Division of design and construction responsibilities

The 'US' Alliance design team was responsible for the design of the permanent works. The specialist diaphragm walling contractor carried responsibility for:

- interpretation of geotechnical data;
- diaphragm wall detailed design for the temporary and permanent cases;
- design of all temporary works required to ensure structural stability in the temporary condition;
- preparation of a walling manual; and
- conducting a seepage analysis providing estimated ground water inflow rates/quantities and identification of limits on ground water draw down including maximum head differential across the diaphragm walls.

The specialist diaphragm walling contractor was responsible for construction of the shaft and tank guide walls and diaphragm walls. The 'US' Alliance construction team carried responsibility for:

- wall trimming;
- carrying out excavation works in accordance with the walling manual;
- installation and removal of all temporary wallings and propping; and
- construction of all permanent structural elements other than the diaphragm walls.

## 4.3 Risk management

### 4.3.1 Safety and stability

The Singapore Mass Rapid Transit cut and cover diaphragm wall collapse, and subsequent Nicoll Highway incident, provides a vivid example of what can go wrong with the diaphragm walling technique. Both design and construction errors contributed to the diaphragm wall failure which resulted in four people losing their lives and three people being injured. Figure 4 shows the diaphragm wall collapse and associated impact on the Nicoll Highway.

**Figure 4. Singapore MRT Diaphragm wall collapse (Before and after), Singapore 2004 Photos reproduced from Chou (10)**

*“The key lessons from this event are:*

- *Trends of the temporary work during critical periods must be capable of being monitored.*
- *Those interpreting the analysis outputs must be competent to do so. The dangers of drawing conclusions from past behaviour, without careful consideration of the actual conditions, must be recognised.*
- *The management of uncertainty must be robust. There must be approved and tested contingency plans.*
- *The project must operate within a safety culture conducive to safe working. This means:*
  - *A ‘stop work’ procedure to be in place, clearly understood by all, and supported by management*
  - *Clarity in the chain of command and in responsibilities.”*

Reproduced from Chou (10)

#### **4.3.2 The walling manual**

The diaphragm walling specification included a requirement to prepare a walling manual [Buttling (11)] to encourage clear communication of key safety and technical information between all parties. In the case of this project, the walling manual was required to explicitly communicate:

- all design assumptions, in particular the intended construction sequence that the design was based on;
- the wall propping system;
- the maximum lateral deflections permitted and
- the monitoring requirements for the diaphragm walls whilst in the temporary condition.

#### **4.3.3 Monitoring lateral wall deflections using inclinometers**

As specified in the walling manual, both the shaft and tank structures were monitored using inclinometers. Inclinometer tubes were cast into the diaphragm walls at specified locations. During internal excavation of the shaft and tank, regular inclinometer readings were taken to monitor lateral deflections of the diaphragm walls whilst the structures were in the temporary condition. Actual lateral deflections were checked against predicted lateral deflections and specified deflection limits to ensure that the structures were stable and safe prior to construction of the base slabs.

#### **4.3.4 Geotechnical risk management**

Although it is not the focus of this paper, it is worth noting that substantial effort was made to manage geotechnical risk and uncertainty on this project. Following a traditional borehole and SPT (Standard Penetration Test) based investigation, a CPT (Cone Penetration Test) and dilatometer based investigation was undertaken at the request of the diaphragm walling contractor and geotechnical reviewer. Ground water sampling and testing was also undertaken to confirm the compatibility of the ground water with the proposed bentonite support fluid. The diaphragm walling contractor then prepared a geotechnical interpretive report [Buttling (1)] which was used by both the specialist diaphragm wall designer and the permanent works structural designer. The additional investment in geotechnical investigation increased the accuracy of the derived geotechnical design parameters and subsequent deflection predictions. This in turn enabled the diaphragm wall designer to be more aggressive when setting the depth of the tank diaphragm wall. The depth of the tank diaphragm wall was reduced from 15 m to 11 m based on improved geotechnical parameters. Essex (12) and ITIG (13) provide valuable guidance for the management of geotechnical risk and risks associated with construction of underground structures.

### **4.4 Water tightness specification**

To fulfil the requirement of a 100 year design life and to adequately protect the structures against the aggressive raw sewage internal environment (AS3735 Internal Exposure Classification D), the durability design called for coating all internal surfaces exposed to raw sewage gases within the shaft and tank. The ICESPERW water tightness specification adopted states:

- *“No weeping of water or greater rates of water ingress or flow is visible between the top of the wall and the WAL. Beading of water is permitted.*
- *Damp patches on the front face of the wall are permitted provided that the following criteria are met:*
  - *The total area of dampness does not exceed 10% of the visible area of the front face;*
  - *No individual patch of dampness has an area in excess of 4 m<sup>2</sup>.”*

Reproduced from ICE (3)

The ICE Specification for piling and embedded retaining walls defines damp patches, beading and weeping as:

- *“Damp patch; when touched, a damp patch may leave a slight film of moisture on the hand, but no droplets of water or greater degree of wetness are left on the hand. On a concrete surface a damp patch is discernible from a darkening of the colour of the concrete.*

- *Beading of water; beading of water is the state in which individual droplets of water (held by surface tension effects) form on the surface of the wall and adhere to the wall. The water beads do not coalesce with each other. The beads remain stationary on the surface and do not flow.*
- *Weeping of water; weeping of water is the state in which droplets of water form on the surface of the wall and coalesce with other droplets. The coalesced water does not remain stationary on the wall surface, but instead flows down the wall.”*

Reproduced from ICE (3)

## **4.5 Structural design**

The diaphragm wall/panel structural design and detailing and the temporary propping system was carried out by MJ Civil, the specialist diaphragm wall designer, and reviewed by MWH. MWH completed the remainder of the structural design and specified provisions for future extension of the detention tank including the capping beams, struts at roof level and base slab.

## **4.6 Diaphragm wall design outcomes**

### **4.6.1 Shaft**

The final shaft diaphragm wall layout is a dodecahedron in shape with six long sides and six short sides. The shaft perimeter wall is made up of six panels. Each panel has three sides. The panels are joined to each other along parallel edges with shear keyed joints. The shaft diaphragm wall panels were 17.5 m deep and 800 mm thick.

The shaft perimeter wall acts primarily in hoop compression, with each three sided panel acting horizontally as a pin jointed beam or arch to resist soil and ground water pressure. The major reinforcing of the shaft diaphragm walls included horizontal N32 bars and N24 vertical bars at 200 mm centres.

### **4.6.2 Tank**

The tank diaphragm wall is comprised of 14 panels. It includes two L-shaped corner panels and two T-shaped corner panels to enable construction of the second and third stages of the tank using diaphragm walling. The tank diaphragm wall panels were 11 m deep and 800 mm thick.

The tank structure also included four permanent struts, spanning between the capping beams, at roof level, to prop the long tank walls. The tank diaphragm walls act as vertical propped cantilevers resisting horizontal soil and water pressure. The major reinforcing in the tank diaphragm wall panels included: vertical N32 bars horizontal N20 and N24 bars at 200 mm centres.

Temporary steel struts (both transverse and diagonal) were installed at an intermediate level as the excavation progressed to control the wall panel deflection prior to the construction of the base slab.

## **4.7 Key details**

### **4.7.1 Vertical diaphragm wall panel joints**

All vertical diaphragm wall panel joints were formed using a temporary fabricated stop end. The use of the stopend also enabled a single rubber water bar to be installed in these joints.

### **4.7.2 Diaphragm wall - base slab joints and diaphragm wall internal wall joints**

Threaded female couplers were cast into the diaphragm walls to provide anchorage points for threaded starter bars for the base slabs and SPS internal wall reinforcing. The diaphragm wall base slab joints in both structures included hydrophilic water seals and a grout tube. The diaphragm wall internal wall joints in the SPS included a single hydrophilic water stop.

### **4.7.3 Diaphragm wall penetrations**

Penetrations through the diaphragm walls to enable installation of future piping were constructed using hexagonal timber box outs incorporated into the reinforcing cages at the relevant locations.

#### 4.7.4 Controlling ground water during base slab construction

The base slabs of both the tank and shaft were provided with temporary block outs/pipes and pumps to keep the excavation dry and relieve the build-up of ground water pressure whilst these slabs were in a plastic state. These penetrations were sealed once the base slab concrete had reached its' design strength.

## 5 Construction

### 5.1 Construction sequence

Table 2 outlines the construction sequence of the shaft and tank.

**Table 2. Shaft and tank construction sequence**

SHAFT	TANK
1. Preparation of working platform	1. Preparation of working platform
2. Construction of temporary guide walls	2. Construction of temporary guide walls
3. Construction of the diaphragm walls	3. Construction of the diaphragm walls
4. Removal of the temporary guide walls	4. Removal of the temporary guide walls
5. Wall trimming	5. Wall trimming
6. Construction of capping beam	6. Construction of capping beam and permanent struts
7. Excavation of SPS	7. Excavation (Stage 1 of 2)
8. Construction of SPS base slab	8. Installation of temporary bracing (wailers and raking struts)
9. Construction of pipe jacked SPS inlet sewer	9. Excavation (Stage 2 of 2)
10. Construction of internal tee wall from floor to roof	10. Construction of base slab
11. Construction of secondary benching concrete	11. Removal of DT temporary bracing
12. Construction of outlet pipe work	12. Construction of pipe jacked DT inlet sewer
13. Application of internal coating system	13. Construction of secondary floor screed
14. Installation of precast roof system	14. Installation of FRP roofing system
15. Mechanical and electrical fit out	15. Application of internal coating system

### 5.2 Quality control

#### 5.2.1 Diaphragm wall concrete mix testing

Extreme care was exercised in the concrete mix design with regard to the selection of good quality aggregates, proportioning of aggregates and selection and use of admixtures to arrive at a good quality flowing mix not prone to segregation with low drying shrinkage. This required good collaboration between the concrete supplier; Holcim and the design and construction teams. Extensive trials and testing of the as placed concrete was carried out to ensure good quality control.

#### 5.2.2 Verticality and deflection control

A steerable hydraulic grab was used to excavate the diaphragm wall trenches. This hydraulic grab was self-guided and self-levelling. A rig mounted inclinometer was used to validate the verticality of the diaphragm wall panels during excavation for each panel. Inclinometer tubes grouted into the Tank diaphragm wall panels at predetermined locations were used by the construction team to measure the actual lateral deflection of the diaphragm walls during excavation. The predicted lateral deflection of the diaphragm walls for each stage of construction was documented in the Walling Manual. The maximum lateral deflection predicted was 5 mm. Typical lateral deflections observed were in the order of 2-3 mm. Water tightness was achieved by adherence to verticality and deflection tolerances, and good workmanship which ensured the construction of sound homogeneous concrete wall panels with waterstops firmly embedded at all wall panel joints.

### **5.2.3 Diaphragm wall finish and internal coating application**

The diaphragm walls were cast against clayey soils. Upon exposure following excavation, they were found to be in reasonable condition however, relative to off-form concrete, substantial additional surface preparation was required to enable protective coating application: Additional cleaning was required due to the diaphragm wall surface being contaminated with bentonite. In some locations, the large concrete bar chairs dragged in clay as the reinforcement cages were lowered in to the excavations. Following excavation, these clay accumulations required removal and repair. The steel work and reinforcing left exposed at the temporary strut connection points required priming and covering. Polyurethane/water injection sealing was required in some areas of the panel – base slab joints, Wubben (14)

### **5.3 Beneficial outcomes**

The use of diaphragm walling technology for the shaft and tank structures enabled:

- Acceleration of the construction program and generation of an estimated \$0.5 M in savings due to:
  - Negating the need for temporary excavation support. The diaphragm walls provided temporary excavation support prior to being incorporated into the permanent structures;
  - Negating the need for 12 m of vertical internal and external formwork and falsework; and
  - Minimising the extent of works carried out at depth;
- Improved construction safety. Reinforcement cages for the wall panels were fabricated at ground level rather than in-situ, from scaffolding with difficult handling, using cranes etc.;
- Construction progressed in unfavourable wet weather - 2,000 mm of rain fell during the 18 month construction phase;
- Construction below the ground water table at 3.5 m depth and within close proximity to a water bearing strata – the sand layer at 14.5 – 16.0 m depth 1.5 m below the shaft base. The shaft diaphragm walls founded at 17.5 m in relatively impermeable clay provided ground water cut off for base slab construction.

### **5.4 Lessons learned**

With the benefit of hindsight performance aspects that could be improved include:

- Design management: Email based correspondence and paper based checking required very close collaboration and timely responses, sometimes requiring considerable extra work outside normal working hours as it was not time efficient. A project collaboration system such as a building information model, or file sharing platform, enabling a common CAD model able accessed by all parties involved would have made checking and change management far simpler;
- Water proofing: Additional measures could have been taken to enhance water tightness of the diaphragm wall panel joints at the level of the wall/base slab joint. Puller (15) provides useful insight to this problem. Some remedial polyurethane grouting was required at the wall base joint to enable coating work to proceed. Given its importance, greater treatment of water proofing in the walling manual would be warranted. Specifically work sequencing, timing of water proofing works, associated inspections and timing of secondary concrete placement;
- Walling manual: Along with additional treatment of water proofing suggested above, clarity of inclinometer reading interpretation responsibility, stop work procedures, chain of command, and contingency plans would be useful;
- Verticality: In the authors opinion, a tighter verticality tolerance is achievable in these ground conditions with the approach adopted. On this project typical panel verticality was in the order on 1 in 200+ for most panels. Depending on the ground conditions and construction methodology we understand a verticality tolerance of 1 in 400 is achievable;
- Wall trimming: Based on the project delays experienced, and the finish achieved using jack hammers, the use of high pressure water blasting for wall trimming in lieu of jack hammers for the majority of the panel surface may have been more efficient; and
- The use of diaphragm walling necessitates that greater allowance be made for substrate repair and preparation where protective coatings are to be applied.

## 6. Conclusions

On balance, the diaphragm walling based construction methodology had a substantially positive impact on the Officer South SPS project. However, the adoption of diaphragm walling as a construction system brings with it risk, complexity and differences to traditional cast in-situ construction. Particularly with respect to the division of design and construction responsibilities, risk management, water sealing, alignment of the design with the intended construction sequence and information hand over. Based on the good outcome and lessons learned on this project, for similar diaphragm walled based structures, we recommend utilising the specification framework provided by the ICE specification for piling and embedded retaining walls, following Pullers (15) water proofing recommendations. Developing an expansive walling manual and utilising a monitoring system to validate the safety and stability of the diaphragm walls during excavation is recommended.

For larger underground projects Essex (12) and ITIG (13) provide valuable guidance for the management of geotechnical risk and risks associated with construction of underground structures.

## 7. Acknowledgement

I would like to acknowledge the following people and organisations for their contributions to this project:

- Dr Julian Seidel of Foundation Specialists (Previously Foundation QA) The project geotechnical reviewer. Julian also introduced us to the ICE specification for piling and Embedded Retaining Walls;
- The MWH Sydney structural team involved in the design of the major shaft and tank structures including: Rafiqul Islam, Adam Chan-Sew, Maz Mahzari and Alan Gilbert;
- The Piling Contractors team including: Chris Simon (Project Manager), Dr Stephen Buttlng (Design Manager), and Branko Matkovic (Site manager);
- Mark Johns, MJ Civil, the specialist Diaphragm wall structural designer;
- The Thiess Services team: Craig Rogers (Project Manager), Ryan Bickerton (Project Engineer) and Alan Burns (Concrete Superintendent); and
- Rodney Wubben CorrCon the coating specifier and inspector.

# Expansion and Mechanical Properties of Reactive Concrete incorporating Fused Silica

Thamer Kubat<sup>1,2</sup>, Ahmad Shayan<sup>3,4</sup> and Riadh Al-Mahaidi<sup>5</sup>

<sup>1</sup>PhD candidate, Swinburne University of Technology, Melbourne, Australia

<sup>2</sup>Lecturer, Duhok Polytechnic University, Duhok, Iraq

<sup>3</sup>Chief Research Scientist, ARRB Group Ltd, Melbourne, Australia

<sup>4</sup>Adjunct Professor Dept. of Civil Eng., Swinburne University of Technology, Melbourne, Australia

<sup>5</sup>Professor of Structural Engineering, Swinburne University of Technology, Melbourne, Australia

**Abstract:** Fused silica was used to simulate reactive concrete in field structures. It was used as a replacement for fine aggregate at the dosage rate of 7.5% of total aggregate in the concrete. Expansion and mechanical properties of concrete mixes without and with fused silica were investigated. Incorporation of 7.5% fused silica in the concrete caused significant expansion and cracking of the specimens studied. Two high relative humidity (RH) values, 98% and 100%, were investigated to find the effect of this range of humidity on alkali aggregate reaction (AAR) and mass variation of concrete through two years of monitoring. Results showed that the RH conditions of 100% and 98% influenced the rate of expansion (being faster at 100% RH), but after two years, the magnitude of expansion was the same. The effect of reactivity of concrete on mechanical properties of concrete was also investigated after one year exposure at 98% RH. The mechanical properties of the concrete, especially compressive strength, flexural strength and modulus of elasticity, were adversely affected by AAR expansion. The decreases in the above properties at the age of one year were 74 %, 82 % and 93 %, respectively. These results indicate that the RH range of 98-100% is suitable for long term laboratory testing of concrete for AAR. More importantly, they highlight the significant damage that highly reactive aggregates can impart to the mechanical properties in concrete.

**Keyword:** AAR, fused silica, concrete expansion, mechanical properties

## 1. Introduction

Alkali aggregate reaction (AAR) is a chemical reaction between alkali hydroxides developed in the pore solution of concrete and certain silica-rich constituents within the aggregate in the presence of water to form an expansive gel. As the gel expands, an internal pressure develops, which may lead to cracking of the aggregate and the paste matrix. As a result of cracking, the rate of concrete deterioration will increase. The occurrence of AAR requires three main parameters to exist concurrently: reactive aggregate, sufficient alkali and humidity.

In the work reported in this paper, fused silica was used as the reactive aggregate, due to its uniformity compared to natural aggregates. Swamy and Al-Asali (1) also used fused silica as a reactive aggregate and found 15% of fused silica as a proportion of total aggregate caused large expansion in concrete. Abdullah (2) also used fused silica in an extensive laboratory investigation and found that 7.5% fused silica caused large expansion in concrete specimens. Alkali is usually derived from cement, but in laboratory expansion studies, alkali is added by dissolving sodium hydroxide to enhance the reaction and expansion.

Relative humidity (RH) is the expression of water content in concrete. The threshold of relative humidity to initiate and develop AAR has been investigated by several authors. Ludwig (3) concluded that 80-85% RH is sufficient to initiate AAR. Nilsson (4) stated that AAR degradation would not occur if the external RH is less than 80%. Most authors have found that higher external RH leads to more expansion and faster expansion rate.

The effects of AAR on concrete lead to loss in its mechanical properties, especially modulus of elasticity, tensile strength and, to a lesser extent, compressive strength (ISE (5)). Abdullah (2) investigated the effect of six percentages of fused silica (0, 3, 7.5, 10, 15 & 20%) as a replacement of fine aggregate to total aggregate used in concretes. The evolution of compressive strength of concrete with time up to 1 year was recorded and the results showed a decrease in the compressive strength of concrete which varied from 27 to 45%. The reduction in mechanical properties as the author explained is directly influenced by the amount of fused silica used and in general, the larger the percentage of fused silica, the lower the compressive strength of the concrete. Tensile strength is a sensitive parameter. The reduction in tensile strength due to AAR varied from 5% (Ahmed et al.(6)) to 85% (Siemes and Visser (7)). According to several authors, this variation depends upon the test method used.

For example, Han (8) explained that direct tensile strength testing showed the highest reduction in strength whereas the splitting tensile strength test (an indirect test) showed the least reduction in strength related to the AAR effect. Shayan et al. (9) stated that the flexural strength of concrete is significantly influenced by AAR expansion and is lower in specimens with greater AAR expansion. The flexural strength of concrete was reduced by as much as 40-50% when the expansion exceeded 0.12%. These authors also found that flexural strength is more sensitive to AAR than splitting tensile strength, especially at very low expansion. According to the expansion value, the authors classified the reduction in flexural strength into three groups:-

- Expansion value < 0.02% : no reduction
- $0.02 \leq$  Expansion value  $\leq 0.11$ : 30% reduction
- $0.12 <$  Expansion value : 40-50% reduction

The static modulus of elasticity is a sensitive parameter of concrete deterioration due to AAR (Ahmed et al. (6); Monette et al. (10); Mohammed et al. (11) and Giaccio et al.(12)). Marzouk and Langdon (13) found the modulus of elasticity of concrete containing rapidly reactive aggregate was decreased by 80%, whereas for concrete containing moderately reactive aggregate, the reduction was 20%. ISE (5) reported that the loss in elastic modulus varied between 20% and 50% at expansions ranging from 0.1 to 0.3% and could reach 80% at very high expansion levels.

As laboratory expansion tests are often conducted in the range of 98-100% RH, two RH values were investigated in this research to find the effect of humidity on AAR and the mass variation of concrete through two years of monitoring. The effect of the reactivity of concrete on the mechanical properties of concrete was also investigated for a period of one year after casting.

## 2. Concrete materials

Two types of concrete, reactive (RC) and normal (NC), were fabricated. The mix proportion was fixed according to the ASTM C1293 (14) requirements. One concrete mix of proportions 0.42: 1: 1.7: 2.54 (water cement ratio: cement: fine aggregate: coarse aggregate) was used throughout the research. General purpose cement was used for the mix. The percentage of alkalinity of this cement is 0.5% expressed as sodium oxide equivalent ( $\text{Na}_2\text{O}_{\text{equ}}$ ) according to the manufacturer's information. Crushed aggregate of 19 mm maximum size was used. Sodium hydroxide was added to water in the mix of RC and NC to increase the level of alkalinity in both concretes (RC & NC) to 1.25% expressed as  $\text{Na}_2\text{O}_{\text{equ}}$  according to the ASTM C1293 requirements. Fused silica of 0-1mm fraction grading from Sila Australia was used in the mix of RC. Table1 shows the chemical analysis of fused silica.

**Table 1. Percentages of chemical compounds of fused silica.**

Chemical Compounds	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	Na <sub>2</sub> O	K <sub>2</sub> O	TiO <sub>2</sub>
Percentage	99.8	0.05	0.015	0.007	0.003	0.01

The quantities of both types of concretes are shown in Table 2. Table 2 indicates that the unique difference between the two types of concretes is the use of fused silica in the mix of RC. Fused silica was used at a dosage rate of 7.5% by mass of total aggregate, replacing the fine aggregate component. According to Abdullah (2), this percentage leads to the highest expansion in concrete.

**Table 2. Reactive and normal concrete ingredients (kg/m<sup>3</sup>).**

Material		Reactive concrete (RC)	Normal concrete (NC)
Cement		420	420
Water		176	176
Fine aggregate	Sand	597	732
	Fused silica	135	-----
Coarse aggregate		1072	1072
Sodium hydroxide		4.07	4.07

### 3. Experimental work

Standard specimens were cast to determine the physical and mechanical properties of the concretes. Table 3 shows the distribution of specimens used throughout the research.

Samples for measuring the mechanical properties of concrete and those for assessing the expansion potential of concrete, using concrete prism test (CPT) method were stored in a chamber at 38 °C and 98% RH (Figure 1). To ensure that 100 % RH condition is achieved, a sealed stainless steel container, which could accommodate six prisms, was designed and used inside the larger chamber shown in Figure 1. This container was supplied with water at the bottom and wet cloth lining on the inside walls, without any contact with the prisms, which were placed vertically in the container.

**Table 3. Distribution of specimen sizes and numbers according to various tests.**

Test	Specimen size (mm)	Number of specimens
Accelerated mortar bar test (AMBT)	25*25*280	6
Concrete prism test (CPT)	75*75*280	12
Compressive strength, splitting tensile strength and modulus of elasticity	φ 100*200	60
Flexural strength	100*100*400	20

**Figure 1. Chamber where samples were stored at specified temperature and humidity.**

### 4. Results and discussion

#### 4.1 AMBT

Mortar bars measuring 25\*25\*280 mm were fabricated to test the reactivity of the fine and coarse aggregate phases. The coarse aggregate was crushed to appropriate size fractions in accordance with the ASTM C1260 (15) requirements, which are similar to those of the corresponding Australian Standard AS 1141-60-1(16). The average free expansion after 16 days of storage was 0.022% for fine aggregate and 0.045% for coarse aggregate, which are less than the 0.1% limit. In Australia for AS 1141.60.1, you need to compare the expansion at 21 days with the test limit of 0.10%. Therefore, you should also give the expansion values for the sand and coarse aggregates at 21 days. As a result, the fine and coarse aggregates are considered non-reactive according to both the ASTM C1260 and AS 1141.60.1 requirements.

## 4.2 CPT and humidity effect

Two high RHs, 98% and 100%, were applied to find the effect of humidity on AAR expansion and the mass variation of concrete over two years of monitoring. The results of two years of measurement (Figure 2) showed that the difference in RH conditions of 100% and 98% influenced the rate of expansion, which was initially faster at 100% RH, but the value of expansion after two years was the same. The expansion is still increasing for both RH conditions, but a much slower rate.

**Figure 2. Free expansion for RC & NC concretes at 98% and 100% RH.**

The weight of concrete prisms was also recorded at the time of expansion measurement in order to monitor mass variation. Figure 3 shows the mass variation for the two types of concrete (RC & NC) over the two years of measurement. The difference in the mass variation is clear between the two concretes. Reactive concrete increases in mass due to water uptake by the AAR gel. Figure 3 also shows that the small change in RH conditions (98% & 100%) affected the mass variation rate of RC at early ages up to 120 days, after which the values appear to be approximately the same.

**Figure 3. Mass variation % for RC & NC concretes at 98% and 100% RH.**

### 4.3 Mechanical properties of concrete

#### 4.3.1 Compressive strength, flexural strength and modulus of elasticity

Parallel strength testing is important to collect data about the relationship between expansion level and strength loss (Shayan et al. 2003 (9)). Table 4 represents the values of compressive strength, flexural strength and modulus of elasticity of RC and NC at the ages of 7, 28, 90, 180 and 360 days, which represent different expansion levels for RC (98% RH). More deterioration in the mechanical properties of RC was noticed as the expansion level increased. The reduction in compressive, flexural strength and modulus of elasticity at the age of one year reached 74 %, 81 % and 93 % respectively. Table 4 and Figure 4 show clearly that as the expansion level increased, the reduction in the property of RC also increased. The reduction in the modulus of elasticity of RC with respect to NC at the same age is higher than other properties, especially at early ages (i.e., at low levels of expansion), showing that the modulus of elasticity is more sensitive to expansion and microcrack development.

Figure 5 shows the stress-axial strain curves of compression tests on RC specimens at various levels of expansion: 0.01, 0.37, 0.76, 1.24 and 1.57%. As the expansion level increases, the stress-strain curve appears to be steeper and the slope of the curve (modulus) is less.

**Table 4. Summary of mechanical property results of RC and NC with different expansion levels at specified ages.**

Age (days)	Expansion level (%)	Compressive strength (MPa)		Flexural Strength (MPa)		Modulus of Elasticity (GPa)		Reduction in concrete property (%)		
		NC	RC	NC	RC	NC	RC	Compressive strength	Flexural strength	Modulus of elasticity
7	0.01	32.2	29.9	4.7	4.5	25.7	20.4	7	3	21
28	0.37	35.1	21.6	5.0	2.5	35.1	11.3	39	49	68
90	0.76	35.2	17.1	5.8	2.3	35.7	9.1	51	61	75
180	1.24	38.3	15.2	6.9	1.8	36	3.2	60	74	91
360	1.57	38.5	9.9	7	1.2	36	2.5	74	82	93

**Figure 4. Reduction in concrete properties with expansion level.**

Figure 5. Effect of expansion levels on stress-strain diagram

#### 4.3.2 Splitting tensile strength

To find the effect of AAR on the splitting tensile strength of concrete, twenty four out of thirty cylinders were tested at the ages of 7, 28, 90 and 180 days and the remaining cylinders were tested at 360 days. As shown in Figure 6, the reduction in splitting tensile strength of RC compared to NC at the same age reached 62% at the age of 180 days. The loss in strength capacity does not occur at the same rate as the expansion.

Figure 6. Results of splitting tensile strength against expansion levels.

## 5. Conclusions

The research focused on the effect of two high RH values, 98% and 100%, on the free expansion of reactive concrete, and the effect of various expansion levels (0.01%, 0.37%, 0.76%, 1.24% & 1.57%) on the mechanical properties of concrete. The results showed that the small difference in RH conditions of 100% and 98% influences the rate of expansion, but after two years of monitoring, the magnitude of expansion was the same. The mechanical properties of concrete, especially compressive strength, flexural strength and modulus of

elasticity, were adversely affected by AAR expansion. The reduction in the above properties at the age of one year was 74 %, 82 % and 93 % respectively, compared to normal concrete at the same age. In addition, the results showed the reduction in splitting tensile strength after six months age reached 62% compared to normal concrete at the same age.

## 6. Acknowledgement

The authors would like to thank all the staff of the Smart Laboratory at Swinburne University for their support.

**Abstract:** Additive manufacture or 3D printing is revolutionising manufacturing – from titanium aircraft parts to chocolate. 3D printing allows individually customised products to be produced without any of the tooling and set-up costs usually associated with manufacturing. The process of designing a 3D model and then fabricating it ‘layer-by-layer’ also allows complex shapes with optimised structural properties to be produced. There is no doubt that 3D printing will continue to grow as the technology matures, and will become one of the key manufacturing technologies of the 21st century.

Despite the clear benefits, the application of 3D printing in construction, and particularly concrete, has been relatively slow. This paper examines some of the key technologies in additive manufacture, their benefits and drawbacks, and explores how they will be applied in concrete construction.

**Keywords:** additive manufacture, 3d printing, concrete, construction.

## 1. Introduction

One of the most important trends in manufacturing over the past decade has been the rise of additive manufacture, or 3D printing. 3D printing allows direct manufacture of finished articles from computer models, unlike traditional mass production techniques, which require expensive tooling or moulds. 3D printing therefore allows ‘mass customisation’, where it is no more expensive to produce unique items than multiples.

3D printing techniques have been gaining traction in various industries as the technology has evolved. Some industries have embraced 3D printing much more rapidly than others. For example, direct manufacture of titanium parts through 3D printing has generated significant interest as it minimises waste of costly titanium metal, and allows highly complex shapes to be created. 3D printing has also generated interest in objects as diverse as bicycle frames, firearms and chocolates. [1] [2] [3]

This paper examines the drivers behind 3D printing, and explores how additive manufacture could revolutionise construction.

## 2. Background

3D Printing, or Additive Manufacture as it is also known, refers to a body of technologies that began to be developed in the 1980s. [4] Whilst these technologies are varied in both approach and material, they share the unique approach of constructing an object through layer by layer addition of material. This is fundamentally different from traditional approaches of manufacture such as casting in to a mould or die or removing material by machining.

All forms of additive manufacture follow the same basic process. First, a three-dimensional blueprint of an object is created and it is sliced into cross-sections using computer software. This is commonly referred to as Computer Aided Design (CAD) or Computer Aided Manufacturing (CAM). [5] Next, the design is converted to a set of manufacturing instructions which specify deposition of material at the required locations. Finally, material is deposited in successive laminations to build the object. Deposition of material can be achieved through a number of techniques that can mostly be divided into three key groups: Stereolithography (SLA), Fused Deposition Modelling (FDM) or Selective Laser Sintering (SLS).

In 1986, the first 3D printing related patent was issued to Charles (Chuck) Hull for the method Stereolithography (SLA). [6] He had invented a technique that could bypass the several week wait

normally expected when creating a plastic prototype and instead have it ready to be handled within a day. Hull's invention takes digital cross-sections which are then communicated to a Stereolithography machine consisting of a build platform suspended in a UV-sensitive liquid photopolymer resin filled basin and a guidable UV laser. This laser traces the path defined by the cross-section, applying energy to trigger solidification of the resin. Once a layer has been completed, the build platform drops slightly and the laser begins an adjacent cross-section, thus building the object one cross section at a time. For some applications stereolithography is the superior choice due to its ability to create highly detailed objects with thin walls and a clean surface finish. However there are also some challenges specific to this technique; as the object is being created in fluid, any objects with overhang require support structures. The necessity of support structures increases material wastage and labour time, as support materials are frequently difficult to remove. The phase-change of the material can sometimes cause shrinkage, warping or curling. Finally, due to the reliance on photosensitive liquids, materials are limited.

Concurrently, Carl Deckard was working on an entirely different method of Additive Manufacture at the University of Texas. By 1989 he was granted a US patent for the process of Selective Laser Sintering (SLS). [7] SLS enables three-dimensional models to be rendered in a similar fashion to SLA, however the basin is filled with a powdered material rather than a liquid. In this case a laser traces the cross section and applies thermal energy to sinter the material. The build platform within the basin is then lowered and a roller or scraper system deposits a fresh layer of powder so the process can be repeated; this time the laser simultaneously creates a new layer and fuses it to the layer below. Unlike stereolithography, the raw material provides support to the model as it is being created, meaning additional supports are rarely required. However selective laser sintering is also subject to limited suitable materials.

Perhaps the most similar technology to traditional two-dimensional printing is Fused Deposition Modelling or FDM. FDM was first patented in 1992 by Scott Crump [8] who partnered with his wife Lisa and founded a company called Stratasys. In early fused deposition modelling, a thermoplastic polymer or metal filament spool is fed to the print head in a similar way to thread on a sewing machine. The print head then melts the material and follows the path specified by the digital cross-section, depositing a layer of molten material. The successive layer is then deposited before the previous layer has fully solidified, enabling lamination. Depending on the machine being used, the build platform may be lowered as layers are printed or the print head may be raised. As FDM technology has advanced, the range of materials able to be "printed" in this way has broadened. Almost any substance that can start in a liquid state before solidifying can be used in this technique.

### **3. Applications in construction**

The construction industry is particularly well suited to take advantage of the benefits of 3D printing. 3D printing could bring improvements in safety, reductions in labour and time, and advances in customisation and form.

Perhaps the largest draw card for 3D printing in construction is the reduction in labour requirements, as this can translate to a saving in both cost and time. 3D printers would allow a house to be built by a skeleton crew, rather than a full team spanning multiple trades. [9] This reduction in labour would result in both decreased cost and an increased level of site safety, particularly in harsh or dangerous environments. Automated construction could also minimise costly errors and defects.

As well as the improved cost, timeline and safety, 3D printing also removes many design limitations. Rectilinear forms are known to be structurally weaker than curvilinear forms. [10] However, the creation of curvilinear forms in construction requires specialty formwork or engineering. This usually comes at a dramatic increase in expense and time. The use of 3D printing would enable curvilinear designs to be executed as easily as more traditional angular structures. This offers a structural advantage as well as an aesthetic one. Likewise, elements that are precast are limited to being solid whereas those which are printed are able to be created with cavities, saving on material and also creating channels for essential utilities. [11]

The construction industry is well positioned to capitalise on the benefits of 3D printing as the use of modelling is already commonplace. In fact, the majority of information needed to create a 3D blueprint is generated during the design of a building. In Building Information Modelling (BIM), which is rapidly

growing in popularity, it is standard procedure to create three dimensional CAD models of buildings. [12] It is a relatively small step to move from this type of model to instructions for a 3D printer.

#### 4. Current progress

At present, there are few examples of construction scale 3D printing. Early versions of concrete 3D printers operate by extruding very low slump concrete, designed to be self-supporting, from a deposition head mounted on a gantry. [13] This technique is analogous to Fused Deposition Modelling (FDM). Although FDM is not the only technique with potential application in the construction industry, it utilises the cheapest materials and is the favoured choice so far.

Since 2007, a team at Loughborough University in the United Kingdom, led by Dr Richard Buswell and Professor Simon Austin, have been focused on 3D printing applications within the construction industry. They are working to build and commercialize a 3D concrete printing robot, as well as helping to develop a supply chain for the required materials. [14] Construction company Skanska are collaborating with Loughborough University with the aim of facilitating the transition of 3D printing techniques to a commercially viable form of construction.

In 2014, Chinese company WinSun demonstrated how 3D printing could be used in practical terms by printing 10 basic dwellings in 24 hours. [15] The structures are claimed to have cost less than US\$5,000 each to manufacture and were created from mostly recycled materials. WinSun used a large FDM printer and high performance concrete to manufacture house components off-site. These completed parts were then transported and assembled in a similar fashion to traditional precast construction. Although the houses were produced rapidly and cheaply, the finish on the elements was poor compared to typical precast concrete. Furthermore, the true benefits of 3D printing were not realised, as the elements still required transport and assembly on site. This application may be better suited to providing affordable or emergency housing rather than typical residential construction.

WinSun are also pursuing production of taller structures, including a recently erected 5-storey apartment building, which currently holds the record as the tallest 3D printed structure. Next door, they also manufactured a 1,100 square metre concrete mansion, complete with interior fittings. This was printed at a cost of approximately US\$160,000 [6]. WinSun have since announced receiving an order for ten of these mansions from Taiwanese real estate company Tomson Group. [16]

US based Emerging Objects is employing entirely different technology to develop building components with a focus on the aesthetic advances that 3D printing has enabled. Using a proprietary cement-based material, the components produced are claimed to be lightweight and are toughened by the addition of fibre reinforcement. Emerging Objects offer a number of post-printing finishes, such as sand blasted, glossy or satin. Many of their products serve a dual purpose, which has been able to be incorporated due to the increased shape capabilities of 3D printing. These include interlocking seismically resistant blocks and acoustic dampening walls. [17]

Outside of engineering labs, Andrey Rudenko built and fine-tuned an FDM printer in his own backyard. By August 2014 Rudenko had successfully printed a castle in layers of concrete 10 millimetres high by 30 millimetres wide. [18] Due to limitations of the technique and material, the structure does not have a roof.

Another construction related application has been demonstrated by multinational engineering firm Arup, who have demonstrated steel components printed using selective laser sintering of powdered metal. The use of maraging steel has resulted in a low carbon, low weight, ultra-high-strength prototype. Arup are hoping further refining will result in a market ready product in the near future. Whilst these components are currently more expensive to create than their traditional counterparts, Arup believe this method of manufacturing will, in time, significantly reduce both cost and waste. [19]

A binder jetting method for 3D printing large structures with a stone-like finish called D-Shape uses sand mixed with a metal oxide catalyst as the powder bed onto which a low viscosity solution containing inorganic compounds, in particular chlorides, is printed. [20] Binder jetting is, in some ways, analogous to an inkjet printer wherein the printer head moves across the page depositing ink in predetermined locations. Once a layer has been printed a hopper deposits the next layer of sand which is then

compacted prior to printing. The binder for this system, a metal oxide combined with a solution of inorganic salts, is reminiscent of magnesium oxychloride (Sorel) cement which is made by mixing a solution of magnesium chloride with powdered magnesium oxide [21] and boasts strengths greater than those of traditional cement. A main advantage of this method in comparison with other examples of 3D printing in construction is that the whole structure is supported through the printing process by the excess sand surrounding the printed element. The D-Shape method also includes printing a wall around the structure as it is printed to hold the sand. Once the printing process is complete, this wall is broken and the excess sand removed to reveal the printed structure. Also, the printer itself is transportable and can be set up on site. Already, this method is currently being used in the construction of a four bedroom house in New York as well as military bunkers. [22] There is also talk of buildings in Perth being constructed from elements made using this technique. [23]

Contour Crafting (CC) [11] is a 3D printing system in which clay is extruded from a nozzle in a manner similar to that of the FDM technique. Attached to the nozzle is a pivoting trowel which smooths the sides of the structure as they are printed. The fact that the trowel can pivot means that curved structures such as cones or vases can also be produced with smooth surfaces. Individual printed layers are visible in the structures produced by both WinSun and Andrey Rudenko mentioned above and would need an extra finishing step to improve their aesthetic appeal. Given that the CC system is compatible with gantry systems which could be used on site, a combination of the CC technique with cementitious materials could result in a higher quality 3D printing system for construction.

## 5. Key challenges

Although some clear benefits of 3D printing are apparent in the construction industry, there are numerous challenges to be overcome before the technique is genuinely useful. Unfortunately concrete, as a material, is susceptible to the effects of weather, ambient temperature and deficiencies in mix design. These factors can make concrete unpredictable, even when utilising current technology. With the additional complications of extruding concrete through a finely tuned print head there is a lot of opportunity for errors to occur. [11] The setting time and rheology of concrete are also not ideal for layer-by-layer construction; however, these properties can be controlled to a certain extent through the use of admixtures. The problems associated with using hydraulic binders as 3D printing materials have, in part, begun to be addressed through the advances in large scale 3D printing discussed above. Whilst concrete itself is not amenable to extrusion due to the size of the aggregates it contains, a cement paste is and has been successfully utilised by WinSun in the construction of their buildings. Alternative binders, such as that used in the D-Shape system, are also another option to explore.

Another consideration is the finish produced when concrete is 3D printed. The clearly ridged texture is apparent; this may be irrelevant in applications where speed or large cost savings are the driving forces, such as emergency housing. However, structures like WinSun's mansion beg the question of how this finish will be received by consumers considering higher-end printed dwellings. [13] If the completed surface is deemed to require further finishing, the cost and effort may outweigh the initial savings. A simple answer to this problem has already been reported by Behrokh Khoshnevis, inventor of Contour Crafting. Through addition of a trowel to the system which smooths each layer as it is printed Khoshnevis is able to produce structures in a variety of geometries, including both curves and right angles, with a smooth outer wall. [11] Combination of such a system with a printer that extrudes cement paste may go some way in improving the appearance of objects printed in this manner.

A further challenge is in incorporation of reinforcement. Extrusion in layers makes conventional reinforcing difficult to achieve. Fibre reinforcement does not solve the issue, as fibres will be aligned with the direction of printing and therefore provide no inter-laminar bonding. Reinforcement is a key issue to overcome if structural concrete is to be 3D printed. Incorporation of reinforcement appears to be conversant with the CC methodology with printing able to take place over the top of an embedded metal coil due to the pressure with which the clay paste is extruded. It is not clear how the metal coil is incorporated into the system, however, nor have other materials such as cement pastes been tested. Another interesting enhancement to the CC system is the ability to produce hollow layers. It was suggested that a similar method could be used to extrude two materials simultaneously with the aim of having a reinforcing

material surrounded by clay. [11] The D-Shape system claims to be able to create structures so strong that traditional iron reinforcement is unnecessary. However, reinforcing fibres such as fibres or metal shavings are being investigated for incorporation into the house to be built in New York to ensure it can support a roof. [24]

Large scale printers face additional challenges created by transportation. Generally a printer remains in situ and can be expected to produce the same results with each task. 3D printers capable of constructing buildings must be sufficiently durable to withstand the rigours of transport and operation at construction sites. Ideally, a gantry system could be employed which would allow a building to be printed as a whole, saving time and money as the need for assembling individual parts would be eliminated.

Industry pushback could delay the rise of 3D printing applications in the industry. Mechanisation is almost always met with scepticism and any new technology that has the potential to automate industry jobs will encounter resistance. [25] Phillips & James Construction Consulting Firm estimates that construction of a typical family home can employ up to 63 construction workers over a four-month period. [26] 3D printing techniques could see this number drastically slashed; a prospect that may see sectors of the construction industry meet the new technology with some resistance. Retraining of current workers could provide a solution to this resistance whilst also addressing the lack of workers skilled in the use of this technology.

The types of materials that have already proven themselves useful for use with current 3D printing technology mostly consist of special preparations which are expensive to purchase, In addition, such materials are not fit for use in the construction of buildings. For 3D printing to prove itself as a viable construction method there needs to be a cheap, failsafe and readily available system that can be prepared easily on site. WinSun used recycled building materials along with glass fibres, steel and cement in their projects, while Rudenko used only cement made to a strict recipe. Whilst it is likely that cement is the main material from which 3D printed buildings would be constructed, there are still a lot of variables that need to be considered when designing a system to be used in a 3D printer such as the setting time of the cement. Once cement has started to set it will be harder to pump or extrude making printing impossible so a long setting time is, in this case, desired. However, once a layer of an object has been printed it would be advantageous to be able to complete the next layer in a short amount of time so the printed cement needs to set quickly so it can support the weight of subsequent layers. Alternatively, the D-Shape system utilises a quick setting 2 part cement which can be incorporated into the sand from which the structure is made. [20] Research and testing of potential cement mixtures for use in a 3D printing system would need to take place, along with long term stability testing to ensure the final structure is satisfactory.

Another unknown is if 3D printed structures will comply with building codes. This is a new method of construction which doesn't necessarily use standard materials and so no regulations exist to aid those designing and constructing buildings using 3D printing techniques. The first residential structures built using 3D printing have been built only in the past year so there is no information regarding long term performance. For 3D printing to become an acceptable method of construction it will need to be further investigated by regulatory bodies so that guidelines and standards can be written. Given the current difficulties in including traditional reinforcement in 3D printed structures and the fact that non-standard materials will likely be used, it is conceivable that elements produced using 3D printing may not be as durable or last as long as traditionally produced elements. Such elements may also have different requirements for maintenance.

Depending on the material or equipment used to make an object, some level of post-processing may also be required. For example, removal of rough edges or an additional treatment to improve the strength of the finished article may be required. Whilst the houses constructed by WinSun [9] did not require further treatment after printing to improve strength since they were made of cement, the overall finish was lacking. On the other hand, Contour Crafting [11] produces articles where the individual layers are considerably less pronounced but currently uses clay as the building material which requires firing to reach its final strength.

## 6. Limitations of 3D printing

3D printing has the potential to make a significant and positive contribution to the construction industry but in order to make the best use of this technology, not only should what it can do be investigated but the limits of 3D printing should also be recognised. Arguably, the most important limitation of current 3D printing technology is the range of compatible building materials. The structures made by WinSun and Rodenko, outlined above, use a cement paste which, in the case of WinSun, also contained building waste materials as reinforcement. It is unlikely that these methods could be altered in such a way so as to allow traditional concrete to be used in place of cement paste. D-Shape uses sand to form its structures which gives the system flexibility in that it can use sand from any source which can reduce the cost of materials.

There currently isn't a "one size fits all" 3D printer for fabrication of structural elements. Whilst there are similarities between the reported examples of 3D printing in construction, each is different and specific to an individual situation or set-up. It is envisioned that over time as the popularity of 3D printing increases and the price of the technology decreases further exploration into the use of 3D printing in construction will yield modifications to the current technology that will allow for increased flexibility and ease of set up.

Printing elements with overhanging areas is a challenge for 3D printing as support structures are needed to hold up overhanging areas until they have developed enough strength to support their own weight. Selective Layered Sintering (SLS) [7] and other powder bed methods, in which the unfinished object is supported by a bed of powder during fabrication, present a solution to this problem but require extra time and effort to remove the powder after production is complete. As far as examples such as the WinSun and Rudenko structures are concerned, this may mean that printing an entire building, including the roof, all at once is beyond the capabilities of current 3D printing technology. The D-Shape system, being a powder bed method, allows the object being printed to be entirely supported throughout printing but the current size of the printer means that the size of the object is limited to what can be printed in a 6 x 6 m space. This size is likely not going to accommodate an entire house.

## 7. Cost-benefit analysis of 3D printing in construction

At this particular moment in time, it is hard to evaluate exactly what impact 3D printing will have on construction. What is known, however, is that there is a potential for savings using 3D printing. In its current state, the largest immediate impact that 3D printing can have is in producing models from technical drawings and designs. Often, a three dimensional model can more easily communicate an idea or concern than technical drawings or computer models. In addition, a 3D printed model can cost less than a model made in a traditional manner. A recent study suggested that a sensible estimate of the cost of such a model is approximately 0.1% of the total project cost, not including costs relating to purchase of equipment, materials and software, or labour associated with building the model. Depending on the level of complexity of the model, it can be made in a short space of time ranging from hours to a number of days which compares favourably with current methods. [27]

A major cost associated with concreting is formwork. Cost estimates for construction in the Sydney CBD show that when the cost of building a concrete wall in a multistorey building is broken down, formwork contributed approximately 80% of the total costs (Table 1). By eliminating the need for traditional formwork during construction, there is the potential for considerable savings to be made (Table 2). The cost of the printer is currently unknown, and this is not included in Table 2. Given the magnitude of the gap, there is significant scope for printer costs to be absorbed and still provide a cost effective solution. Without the need for installation and removal of formwork, a saving of approximately 1 day per floor could also be achieved. The WinSun or Rudenko examples do not require the use of formwork to construct their elements but are unable to cope with overhanging sections without the incorporation of supports. Even so, buildings can be made piecewise without the need for formwork. As discussed above, powder bed methods (such as D-Shape) allow a great deal of flexibility in the types of shapes which can be produced

as the unreacted powder provides support to an object as it is being printed eliminating the need for formwork altogether.

**Table 1. Cost estimates for constructing a wall from 40 MPa concrete in a multistorey building in the Sydney CBD using formwork.**

	<b>Cost</b>	<b>Amount</b>	<b>Price</b>
<b>Supply of concrete</b>	\$200/m <sup>3</sup>	150 m <sup>3</sup>	\$30 000
<b>Pumping</b>	\$20/m <sup>3</sup>	150 m <sup>3</sup>	\$3 000
<b>Labour</b>	\$20/m <sup>3</sup>	150 m <sup>3</sup>	\$3 000
<b>Formwork</b>	\$100/m <sup>2</sup>	1500 m <sup>2</sup>	\$150 000
<b>Total</b>			\$186 000

**Table 2. Estimate of cost for constructing a wall from 40 MPa concrete using 3D printing.**

	<b>Cost</b>	<b>Amount</b>	<b>Price</b>
<b>Supply of concrete</b>	\$250/m <sup>3</sup>	150 m <sup>3</sup>	\$37 500
<b>Pumping</b>	\$20/m <sup>3</sup>	150 m <sup>3</sup>	\$3 000
<b>Labour</b>	\$20/m <sup>3</sup>	-	-
<b>Formwork</b>	\$100/m <sup>2</sup>	-	-
<b>Total</b>			\$40 500

Overall, the cost of labour would also be expected to fall as the number of workers required to construct a building would be decreased. Only those people required to oversee the printing activities, assembly and installation of utilities would be on site resulting in a reduction of labour costs. With less people working on site, the potential for injury is also decreased. With the reduction in traditional roles, an increase in new roles would also be seen. Staff with expertise in design and the ability to create commands for a printer, technicians conversant with the technology, as well as those skilled in the assembling and dismantling of the printer will all be required. There will also be costs associated with training and development of staff as new skills are acquired.

It is likely that the cost of building materials consumed during a project could be less for a 3D printing project. More exact placing of material means less waste is generated. There is also the possibility of incorporating construction waste materials into the printing media, such as was done by WinSun. [8] The inventors of D-Shape can use sand from any source, such as the building site itself, reducing the costs of raw materials and impact on the environment caused by production and transportation of these materials.

Another way in which an automated system can reduce waste is through lessening the impact of human error on the building process.

There are also cost savings to be realised through the speed with which building can take place with 3D printing versus traditional building methods. 3D printing boasts speed and efficiency and also greater transportability with systems that are able to be taken apart and rebuilt at the construction site. The completed elements can then immediately be placed without the need for transportation from a factory or warehouse to the site.

Another cost associated with the implementation of 3D printing is the cost of research and development. The current methods, whilst providing an exciting glimpse into the future, can be improved upon and scaled up to more effectively service the needs of the industry. There are also issues surrounding the incorporation of reinforcement; currently there are no systems which are compatible with traditional steel reinforcement and there is a reliance on fibres and metal shavings for additional strength. New binder systems may also improve the quality and strength of 3D printed systems. In addition, efforts into making more user friendly programs for creating digital models for use with 3D printers could increase the popularity of 3D printing techniques and make them a more cost effective option.

The nature of 3D printing is such that it costs no more in equipment to print a once off design than it does to mass produce that same design. Also, curved and irregularly shaped structures will likely cost no more to build with a 3D printer than a structure with a regular shape giving architects and designers a wider degree of freedom in choosing the shape of a building without inflating costs. However, this could result in buildings for which there exist no standards to use to evaluate structural integrity. Therefore a cost to governments and authorities will likely result as they introduce new standards specific for 3D printed structures. Intellectual properties issues must also be investigated to avoid plagiarism of technology and designs.

## 8. Conclusion

Recent activity indicates that there is growing interest in construction scale 3D printing. There are clear apparent benefits in safety, speed, design flexibility and cost, but also significant practical hurdles to overcome. The key benefits of 3D printing align well with the continual drivers of the construction industry: improve safety, reduce cost and increase design freedom. Although in its infancy, 3D printing may become an important part of construction in the relatively near future.

### Abstract

The coarse aggregate volume fraction in conventional plastic concrete is controlled relatively low to ensure a required workability, but its low aggregate content play negative roll on the service properties of the concrete. In this paper, we revealed the mechanism of a coarse aggregate interlocking concrete prepared by Scattering- Filling Stone Concrete (SFSC), it can keep the fresh concrete its workability but increase its service performance by scattering coarse aggregate during the concrete casting, the experimental and engineering application of SFSC indicated that: the strength of concrete prepared with this method increases obviously whereas the shrinkage decreases significantly when 20% cement dosage is saved, the adding aggregates absorbs water from cement paste so tighter and narrower ITZ is formed in the SFSC. The SFS process was utilized in a highway pavement, the core of the concrete is very dense and no obvious defect could be found when 8% pavement concrete was replaced by coarse aggregate. The SFSC is a type of low carbon concrete.

**Keywords:** Coarse aggregates; scattering-filling stone process; aggregate interlocking concrete; strength; shrinkage; interfacial transition zone

### Introduction

Concrete is arguably the most widely used manufactured materials in the world, the production processes of concrete result in tremendous environmental impact, cement is the most remarkable ingredient in the concrete which has the largest resource consumption, energy intensity, green house gases and acid rain gases emission [1,2,3], the manufacture of Portland cement (PC) is responsible for up to 10% of anthropogenic CO<sub>2</sub> emissions worldwide, to prepare qualified concrete with low cement content is a very effective approach to reduce the total environment impact of the concrete even the human activity CO<sub>2</sub> emission. The concrete is a three phased material: aggregate particles, interfacial transitional zone (ITZ) and cement paste matrix [4], the coarse aggregate is the strength framework of the plain concrete and it is the structure unit with highest strength, volume stability, durability and lowest cost in the most concrete [5,6]. As a composition material, the concrete's hydration heat, shrinkage, permeability and creep will decrease, whereas the strength, elasticity modulus and anti-cracking will increase with the increase of coarse aggregate content [7,8,9]. The conventional plastic or fluidal concrete is prepared by mixing the binders (cement and mineral admixture), fine aggregate, coarse aggregate and water together then placing and vibrating the mixture to fabricate a consolidated matrix. In order to keep the fresh mixture a reasonable flowability and avoid gravity segregation, the aggregate content in the conventional concrete (especially those high strength high performance concrete) keeps relatively low [10], the total aggregate volume

**Fig.1. Schematic diagram of the scattering-filling stone concrete placing process**

fraction in high performance concrete is around 65% [11], and the coarse aggregate volume ratio is around 40%, so the aggregates can't act fully as the matrix structure of the concrete, the high volume fraction of cement paste increases the permeability, creep and drying shrinkage of the concrete [11]. The first author invented a new concrete placing process named scattering-filling stone method: adding 10~30% (by the volume of the finished concrete) of coarse aggregate while the concrete is being poured, paved or placed, then vibrating the matrix to form a consolidated concrete [12,13,14] (illustrated in Figure 1). This concrete content 10~30% less cement than the conventional concrete so it is a typical low carbon concrete, in this paper, the mechanism of concrete is revealed, the experiment and engineering utilization of this technology is reported.

### The mechanism of the coarse aggregate interlocking concrete

As illustrated in figure 2, with the increase coarse aggregate in the concrete, the workability will become worse, to keep a reasonable workability, the w/c ratio need to increase therefor its strength of the concrete deduced. Whereas the increase of the coarse aggregate make the strength, modules of concrete increase but the permeability, shrinkage, creep, hydration heat reduce. Simplified it, the increase of coarse aggregate make worse the workability but make better the service performance.

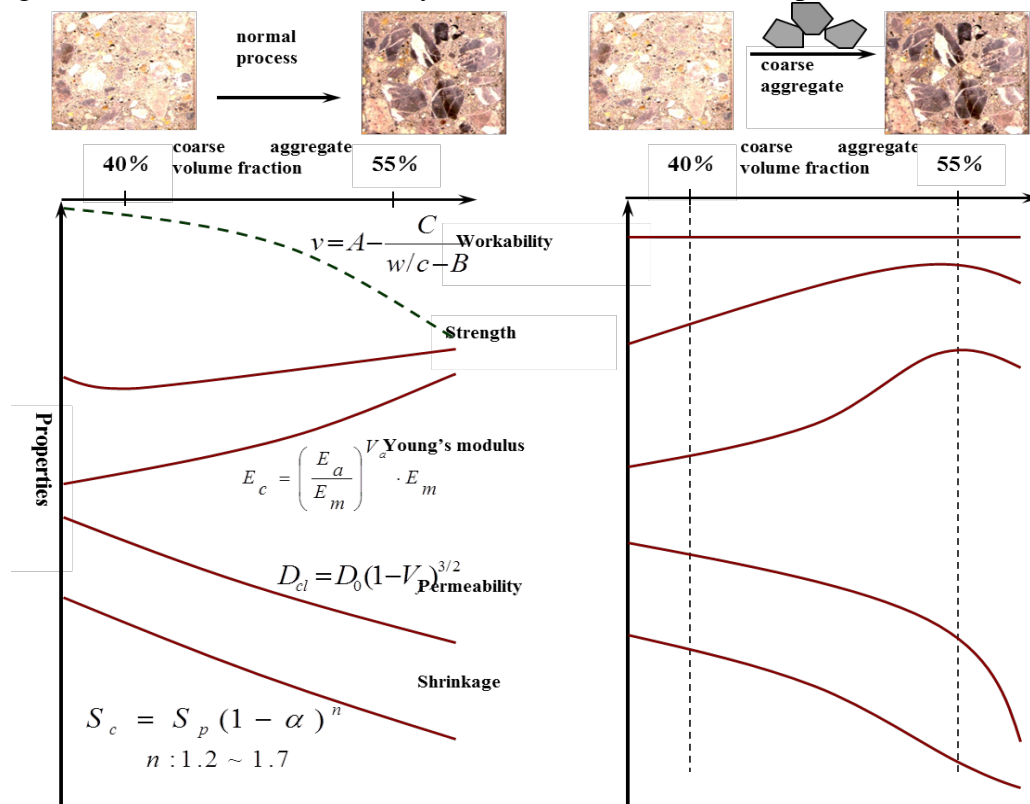

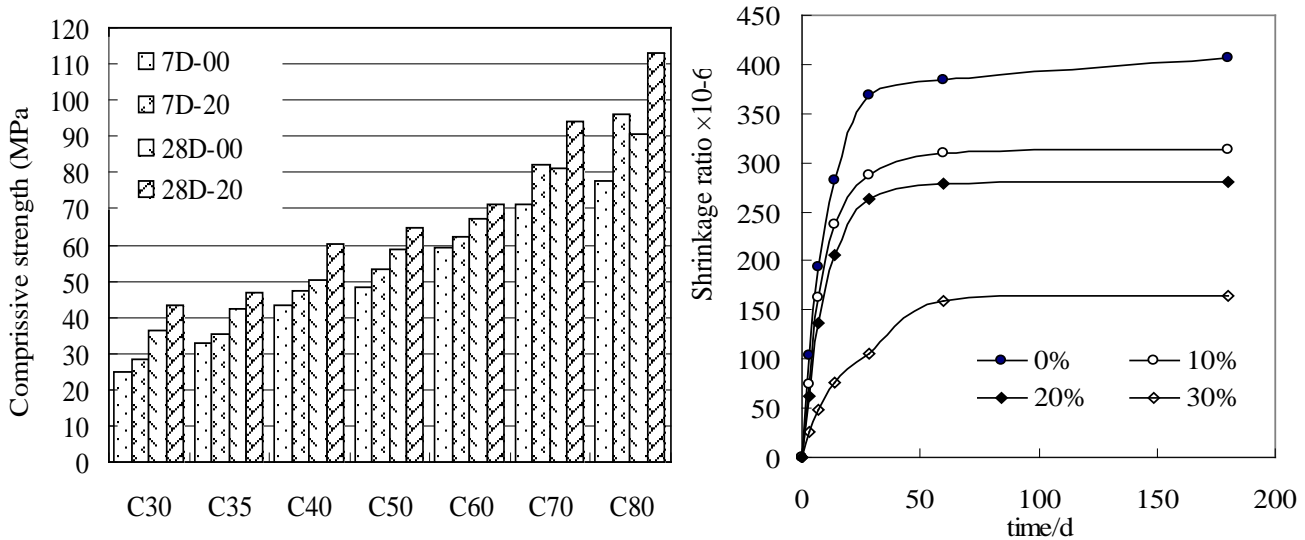

Figure 2 The mechanism of Scatering-Filling Stone Concrete

This new SFS process is a solution to this dilemma, the concrete is designed, mixed and ship with traditional method, so the fresh concrete keep the workability of itself, when the concrete is cast, the coarse aggregate (stone, it can be coarser than the original coarse aggregate in the concrete) is scattered in, the finished concrete has high coarse aggregate content, so the service performance increased. First of all, the coarse aggregate volume fraction increases dramatically in this type of concrete when more than 20% of coarse aggregate is scattered in the mixture, the coarse aggregates can interlock with each other, the friction forces among the aggregate contribute to the strength enhance in a certain extent. The second,

the coarse aggregate distributes more evenly in this kind of concrete than the concrete prepared with conventional process. With the vibration, the segregation of the coarse aggregate toward the bottom of the form and the of the cement paste toward the top may result in the conventional concrete [17], the surface of the concrete will be very weak, but when scattering-filling process is applied, the coarse aggregate will fill evenly at the top of the form. The third, the addition of extra amount of air dry coarse aggregates acts as somewhat water reducer, not only reduces the W/C of the paste close to the aggregate and make the paste stronger so the ITZ of the concrete is enhanced. With the volume fraction of the aggregate increasing, as a composite material, the concrete will become stronger and stiffer.

### Experimental study

The conventional concretes with strength grade varying from C30-C80 are prepared with various kinds of aggregates, cement, mineral admixture and mixing proportions, the aggregate interlocking concretes are prepared with scattering-filling stone process by adding 20% volume ratio of coarse aggregates to substitute the conventional concretes mixtures, the 7 day and 28 day strengths of those concretes with different content of adding coarse aggregate contents are illustrated in Figure 2 (a).

**Fig.3. The strength and shrinkage of original concrete or concrete prepared with SFS**

It can be found that the strengths of all those concretes with different mix proportions increase obviously with the 20% (the volume ratio of scattering concrete in the finished concrete) adding aggregate ratio only different in the extent. The increasing ratio can be as high as 25%. It is easy to find that concretes with 50-100 MPa have been prepared with only 362~440 Kg/m<sup>3</sup> of cement or binder when 20% coarse aggregate is scattered to substitute the original concrete mixtures through some simple calculation, this can be never achieved with the conventional concrete placing process. The scattering-filling stone can prepare concrete with very high coarse aggregate, although the “pre-placed aggregate” concrete process [16] can prepare concrete with as low cement dosage as this process, but it can only prepare low or middle strength concrete. The scattering-filling stone method can produce consolidated concrete with less cement but higher strength and performances at the same time, the decrease on cement dosage not only give the concrete good cost competitive but also good environmental harmonization.

The shrinkage crack of concrete sometime results in damage of concrete structures, increasing of the aggregate can reduce the crack of concrete [17], the shrinkage curves of the concretes with different

scattering-filling stone replacement volume fractions are illustrated in Figure 3 (b), which indicates that with the increase of the replacement volume fraction of the scattering-filling stone, the shrinkage of the concrete decreases significantly. With increasing of the volume fraction of the extra coarse aggregate is added to the concrete, the shrinkage of the concrete decreases markedly. The aggregate scattering-filling process is a very effective approach to reduce the shrinkage of the high strength concrete, which is highly desired by engineers [17].

#### 4.3 The micro-hardness distribution of the aggregate paste ITZ

Figure 4 illustrated the micro-hardness distribution of the ITZ in ordinary concrete and scattering-filling concrete, the rigid origin of X axis is the edge of the aggregate can be found in the microscopy. It is easy to see that the micro-hardness of the scattering-filling aggregate is much higher than that of the ordinary concrete. Generally, the ITZ has the lower hardness than aggregate and cement paste [18]. If the edge of ITZ is where the micro-hardness begin to increase, the width of the ITZ in the ordinary concrete is around 110  $\mu\text{m}$  but the ITZ in the scattering-filling aggregate concrete is 90 $\mu\text{m}$ . This test result also can be explained with the water absorption of the air dry coarse adding aggregate which enhance the microstructure of the ITZ.

Fig.4. The micro-hardness of the ITZ

#### The utilization of Scattering-Filling Stone Concrete

The scattering-filling stone concrete was used in the pavement concrete in the Provencal highway project 305 in Xiangyang, Hubei (Figure 4), the mix proportion of the original concrete and Scattering-Filling Stone Aggregate Concrete is listed in Table 1.

**Table 1 The mixing proportion of original and Scattering-Filling Stone Concrete**

Concrete type	cement (kg/m <sup>3</sup> )	Crushed stone (kg/m <sup>3</sup> )	Water (kg/m <sup>3</sup> )	Sand (kg/m <sup>3</sup> )	Sand ratio	W/C
Ordinary	380	1211	167	652	0.35	0.44
SFSC	350	1323	154	600	0.31	0.44

The Scattering-Filling Stone Concrete is construction with a process nearly the same as the ordinary concrete, the only difference is this process need to scatter 8% of coarse aggregate by volume under at the surface of the base course of the pavement before the pavement concrete is cast. The pavement cores specimens were drilled 29 days after the ordinary and SFSC pavement were cast, the strength of those cores are listed at table 2, the cores of SFSC pavement have higher mean strength than that of the ordinary pavement.

**Table 2. The strength of core of the pavement at 29 day**

Core Site	Distance to middle (m)	Hight of core (mm)	Spilting strenght (MPa)	Flexual strenght (MPa)	Mean flexual (MPa)
K101+791	0.2	205	3.41	5.14	5.11 (Scattering-Filling Stone Pavement)
K101+780	1.5	214	3.39	5.12	
K101+752	0.2	207	3.34	5.06	
K101+740	0.2	220	3.33	5.05	4.97(Ordinary Concrete Pavement)
K101+732	0.2	224	3.25	4.97	
K101+721	0.9	217	3.18	4.90	

$$f_{sp} = \frac{2F}{\pi d_m \times l_m};$$

Note: the spilting strength is calculated by:

The flexual strength is writon:  $f_c = 1.607 + 1.035 f_{sp}$

**Figure 4. The building site of SFSC pavement**

8% to 10% of cement can be saved when SFSC is used in the pavement, the pavement has higher crack resistance than the ordinary concrete, the segregation of the mortar and aggregate is not so obvious, there are nearly no water bleeding above the surface of the pavement as usually. It is well known that the pavement concrete has very low slump, and not so high strength, there are nearly no the mortar more than needed in pavement concrete, whereas, this SFSC process can be used and get good technical and economic benefit. If we can invent an equipment to fulfil the scattering- filling stone process in the flowing especially the pump concrete, much more aggregate can be scattered and filled in the concrete, and much more cement can be saved, the performance of concrete can be improved more remarkably. Nearly all concrete except the roll compact and no fine concrete can use this process, if this concrete have the opportunity to be applied in all the possible concrete project, more than 15% of cement can be saved, around 1% of the anthropogenic CO<sub>2</sub> can be saved. It is promising to be a low carbon solution to the concrete industry.

## Conclusions

This article relates to a new type of SFSC process developed by the first author, the mechanism, experimental study and engineering application of this process is reported. The following conclusions can be drawn:

1. The increase coarse aggregate volume fraction increase the service performances but reduce the workability of fresh concrete, the SFSC keep the workability of fresh concrete but increase the service performance of the concrete at the same time.

2. C30~C80 concrete with higher strength is prepared but lower cement dosage is prepared with scattering-filling stone method, the dry shrinkage of the aggregate interlocking concrete decrease with the increase of volume ratio of the extra adding aggregate.

3. The application of SFSC in highway pavement indicate this process can be successfully used and increase the strength of the pavement 8-10% cement can be saved.

# Preparation and Application of 3D Printing Materials In Construction

Xiqiang LIN, Tao ZHANG, Liang HUO, Guoyou LI, Nan ZHANG, Baohua Wang  
China State Construction Co., Ltd. Technology Center, Beijing, China

**Abstract:** The main 3D printing material is cement and sand tailings, in addition to add coagulant admixtures, retarding admixtures, thixotropic agents and volume stabilizer. The material can be directly pumped to 3D building printers and applied in construction. The 3D printing materials have high early strength, its 2h compressive strength is 10 - 20MPa and 28days compressive strength is 50 - 60MPa. The setting time can be adjusted among 20-60min. It is low-cost, rapid coagulation, high early strength, good adhesion, stability and could meet the requirements of construction 3D printing.

**Keywords:** 3D printing material, R-SAC, coagulation, application

## 1. Development of 3D printing in construction

3D printing technology is widely used in the jewelry, footwear, industrial design, automotive, aerospace, dental and medical industry, civil engineering and firearms fields<sup>1-4</sup>. It is also popular in the field of construction. Compared with traditional architecture, its speed is faster. Without use of templates, it can save substantial costs. It doesn't need a huge number of construction workers which greatly improved the efficiency of production. It can easily print out otherwise difficult building construction curve with advances of low-carbon, green and environmentally friendly 3D printing technology. It could change the direction of building construction industry and obvious change the environmental, construction and ready-mixed concrete industry.<sup>5-7</sup>

In January 2012, the US space agency (NASA) fund collaboration with the University of Southern California and researched the 'outline the process' 3D printing technology.<sup>8</sup>

In January 2013, the Dutch designer Janjaap Ruijsenaars planned to use 3D printing to build houses. The imitation Mobius ring 3D printing houses. At the same time, the European Space Agency proceeded with the construction company of Forster to develop a space station on the moon used print projects which planned to use the lunar soil and other materials readily available to complete the construction of space station through 3D printing materials.<sup>9</sup>

In February 2013, the British designer Soft kill Design worked on the use of 3D printing to build large quantities of civilian houses with nylon fiber.

In March 2013, the Dutch company DAS' architects built the printer which was known as the construction of first 3D printing canal house. In January 2014, it achieved three-dimensional actual canal house component by 3D printing and expected to be completed in three years.<sup>10</sup>

In January 2014, Shanghai surplus company of china used high-grade cement and glass fiber to manufacture its first 3D printing building, causing much attention at home and abroad.

In February 2015, it showed 3D printed Villas with area of 1,100square meters and 6-storey residential buildings in the Suzhou Industrial Park<sup>11</sup>.

## 2. Research status of 3D printing materials

Currently, 3D printing materials mainly include four types which are plastics, metals, ceramics, waxes and like. The cost and the demand of 3D printing materials is difference. For example, plastic material is mainly used in printing and manufacturing industry, metal material used in aerospace and defense, automotive, medical and dental, and ceramics used in home decoration purposes<sup>12-15</sup>.

Among the four types of materials, the most likely used in 3D printing of construction is plastic material. However, the organic materials are prone to oxide, decompose and react under molten state at high temperature for 3D printing. It emits unpleasant toxic gases to the environment and is harm to humans. Besides, the requirement and cost of organic material is high and its mechanical properties are poor. So its use in 3D printing of construction is limit<sup>16-17</sup>.

For present, 3D printing materials used in the building are not yet ripe. Shanghai surplus company used waste of building materials in 3D printing. The material were crushed, ground and cement, fiber, organic binder was added to make toothpaste-like 'ink' to print. Experts from Netherlands made use of resin and plastic materials and US researchers studied resin, mortar, clay and concrete for 3D printing <sup>18</sup>.

3D printing material needs to settable quickly in construction. But the condense time of common concrete is too long, for example, the initial setting time is 6-10h and the final setting time is about 24 hours. Besides, common concrete generally showed to be mobility which could not meet requirements of 3D printing.

The paper researched kind of cement-based composite material suitable for 3D printing. It not only solved the problem of organic material, but also solved the setting time and mobility of cement-based materials.

## 3. Research of technical and mechanical properties of 3D printing material in construction

### 3.1 Cement-based building materials used in 3D printing

(1) Cement: Tangshan Polar Bear 42.5Rapid sulphoalumillte cement (R-SAC) made in China, the performance parameters are shown in Table 3.1 and Table 3.2.

**Table3.1 Chemical composition of cement**

Name	Al <sub>2</sub> O <sub>3</sub>	CaO	SO <sub>3</sub>	SiO <sub>2</sub>	Fe <sub>2</sub> O <sub>3</sub>	MgO	Loss
42.5R-SAC	35.17	42.54	10.79	6.13	1.53	1.24	2.10

**Table3.2 Physical-mechanics performance of cement**

cement	Setting time/min		compressivestrength/MPa		bending strength/MPa	
	Initial	Final	3d	28d	3d	28d
42.5R-SAC	45	73	47.6	55.7	7.70	8.60

(2) Superplasticizer: polycarboxylate superplasticizer (PC).

- (3) Fine aggregate: 20-40 mesh and mechanism tailings of 40-70 mesh.
- (4) Early strength agent: Lithium carbonate (J1), lithium hydroxide (J2), sulfates (J3).  
Retarder: boric acid (H1), sodium gluconate (H2), tartaric acid (H3), citric acid (H4), sodium tetraborate (H5), tripolyphosphate (H6)
- (6) Homemade composite volume stabilizer (VS):Complex admixture includes: thixotropic agents, cellulose ethers and fiber.

### 3.2 Key technology to control setting time of cement-based 3D printing material

#### 3.2.1 Selection of cement admixtures for rapid coagulation

R-SAC has faster condensation speed and higher early strength than ordinary Portland cement. But it also could not meet the requirement of 3D printing materials. In the hydration process of cement, coagulant could act as catalyst to promote hydration of  $C_3A$  and anhydrous sulfur calcium aluminate for formation large amount of ettringite which rapidly shorten the setting time of cement<sup>19</sup>. So the paper selected J1, J2 and J3 coagulant to research the effect on R-SAC and the results are shown in Figure 3.1.

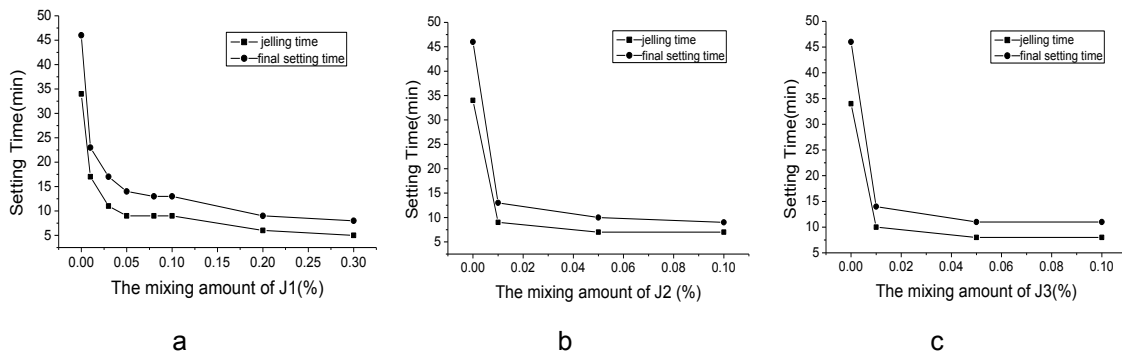

Figure 3.1 Effect of Coagulant J1, J2, J3 on setting time of R-SAC

Figure 3.1 shows that J1 has obvious effect on the setting time of R-SAC. With the ratio of 0.01%, the coagulation time is halved. With ratio of 0.05%, the initial setting time is shortened to nine minutes and when the ratio is 0.3%, the initial setting time is 5 minutes. J2 is a kind of strong base, the effect on the setting time of R-SAC is more than J1 and J3. When ratio of J2 is 0.01%, the setting time could be shortened to 9 minutes, which is the same with ratio of J1 is 0.05%. I. Jawed and J. Skalny et al said that with the presence of base, it promotes generation of ettringite (Aft)<sup>20</sup>. It could be explained that as J2 is a kind of strong base, it promoted the hydration of cement. J3 is ordinary Portland cement which is commonly used as coagulant is not good for the procoagulant effect of R-SAC. Therefore, the coagulant effect of J1 and J2 on R-SAC is more than J3.

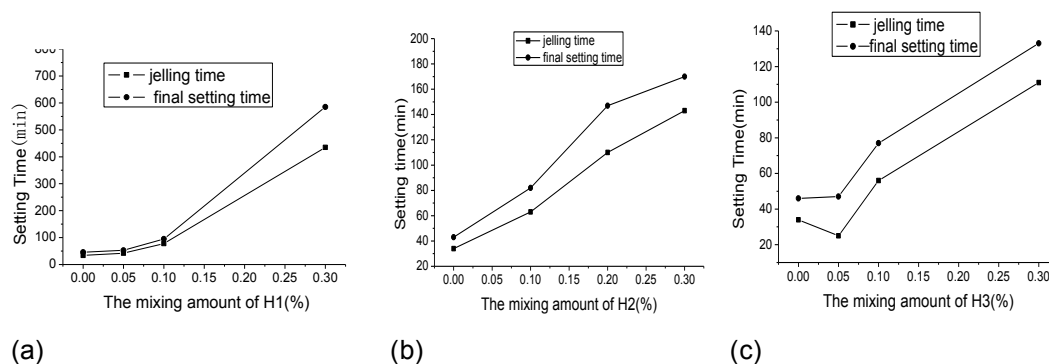

**Figure 3.2 Effect of coagulant on the strength of cement mixed with J1, J2 and J3**

Figure 3.2 shows results of strength of cement mixed with J1, J2 and J3. It could be seen that compared with the cement without coagulant, the 28-day strength of cement mixed with J1, J2 and J3 decreases. Among them, cement mixed with J1 declines the smallest which is 3.3%. But, the 2-hour strength of cement mixed with J1 and J2 is significantly improved which are 26.5% and 32.7% of 28-day strength respectively. It also shows that the 2-hour strength of cement mixed with J3 is low. It could suggest that J1 and J2 could be mixed with R-SAC. Due to the effect of J2 on late strength of cement, J1 is selected as coagulant of R-SAC. Its setting time is short and the early strength is improved at the same time.

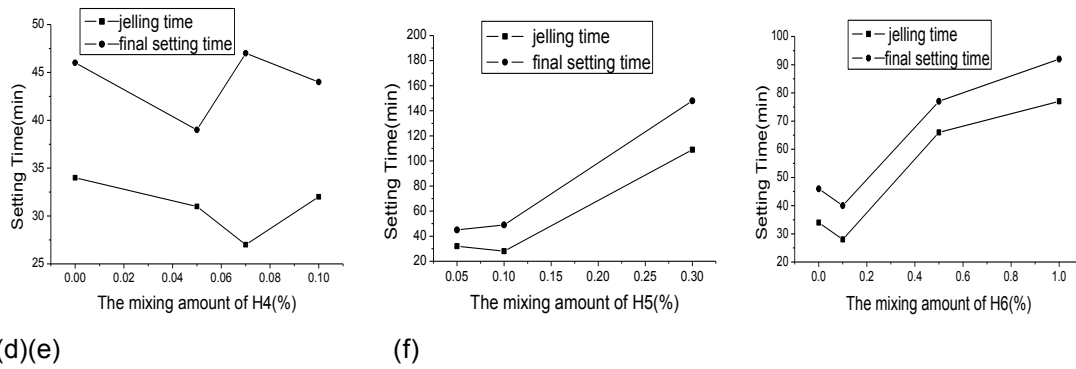

### 3.2.2 Selection of retarding admixtures of cement

Although the early strength of R-SAC is high and it is micro-expansion, the process of hydration is fast. In actual use, it often requires some working time. Especially in summer high temperature environment, it needs to be mixed with appropriate retarder to control the time of construction. Retarder could be adsorbed on the surface of cement particles and formed insoluble layer to delay the hydration of cement. It enables the setting time of 3D printing material to be more stable and easier controlled.

The research selected six common retarder H1, H2, H3, H4, H5 and H6 and tested the effect on the setting time and strength of R-SAC to find a suitable retarder to be mixed with R-SAC, the results are shown in Figure 3.3 and 3.4.

**Figure 3.3 Effect of coagulant on the setting time of R-SAC mixed with H1, H2 and H3**

**Figure 3.4 Effect of coagulant on the setting time of R-SAC mixed with H4, H5 and H6**

Figure 3.3 and 3.4 show the impact of different retarder on setting time of R-SAC, it has the trend of H1>H2> H3> H5> H6 and H4 could cause the setting time abnormal. With the increase of H1, the retarding effect and the setting time increases much. It is not conducive to control and resulted in a certain risk to actual use. H2 is commonly mixed with Portland cement as retarder and it also plays well effect to R-SAC. When ratio is 0.05%, H3 plays little procoagulant effect. With the ratio increase to 0.1- 0.3%, the retarding effect is similar to the trend of H2. It is also suitable to be mixed with R-SAC. H4 is also commonly mixed with Portland cement and to be mixed with R-SAC, the setting time is not stable. With the ratio of H5 increase, the procoagulant effect increases too. With ratio of H5 increase from 0.1% to 0.3%, the setting time increases from 28 to 109 minutes and final setting time increase from 49 to 148 minutes. Its procoagulant effect is more stable than H1 and available to R-SAC. As to H6, it would pay the opposite effect and is not suitable to be mixed as retarder.

**3.2.3 Complex retarder admixtures of 3D printing material**

In production and engineering applications, the setting time of R-SAC is commonly used accelerators and complex retarder to be adjusted. According to experiment, the complex of lithium carbonate as coagulant, anhydrous borax as retarder, lithium, sodium gluconate and tartaric acid could effectively regulate the setting time of R-SAC.

In the study, a lot of tests at different temperature were experiment, and the results were analyzed. Ratio of coagulant and retarder to R-SAC at different temperature is as shown in Table 3.3. Table 3.3 shows the ratio of coagulant and retarder to R-SAC which could effectively control the setting time of R-SAC from 10min to 1h at different temperature.

**Table 3.3 Ratio of coagulant and retarder to SAC at different temperature**

Temperature	Ratio of coagulant		Ratio of retarder	
	J1	H5	H2	H3
0°C~15°C	1.5‰~1.6‰	1.0‰~2.0‰	0~2.0‰	\
15°C~30°C	1.0‰	2.0‰~3.0‰	2.0‰	0~0.6‰
≥30°C	0.5‰~0.6‰	3.0‰~4.0‰	2.0‰~2.5‰	1.0‰

In the material both of coagulants and retarders are mixed in, because they have different role in hydration of cement and effect on different periods<sup>21</sup>. Retarder mainly play role in the induction period before hydration of cement, delaying the initial setting time. And the main role of coagulant is to shorten the induction period, which make both of the initial and final setting are setting time be shortened. So both of coagulants and retarders mixed in the 3D printing

materials could make the materials have particular setting time. It could meet the requirement of construction and the 2-h strength is high enough.

### 3.3 Preparation and study of mechanical properties of 3D printing materials

In the study, R-SAC and water quenched slag powder composite binder was used as the base of 3D printing materials. Industrial tailings sand, water reducer, complex of setting time modifiers and composite volume stabilizer was added to improve the performance of 3D printing material to meet its requirements. Table 3.4 shows the basic ratio of admixtures 3D printing material which were used to make 3D printing materials in the experiment.

The paper mainly studied the technology of controlling setting time and the effect on the mechanical properties of 3D printing materials. Therefore, it took 3 kind of coagulant complex to study the change of setting time and compressive strength of 3D printing materials with different ratio of three kinds of coagulant complex, the complex ratio is shown as in Table 3.5. The results of setting time and compressive strength change with different ratio are shown in Table 3.6.

**Table 3.4 Basic ratio of admixtures to 3D printing material**

W/B	Cement	Ore	Tailings 20-40m	Tailings 40-70m	PC	Coagulant	Other admixtures
0.35	400	100	300	200	1.0‰	JH	VS

**Table 3.5 Complex ratio of coagulant and retarder to 3D printing material**

	Coagulant		Retarder	
	J1	H5	H2	H3
HJ-1	1.5‰	2.0‰	/	/
HJ-2	1.0‰	3.0‰	2.0‰	/
HJ-3	0.6‰	3.0‰	2.0‰	1.0‰

**Table 3.6 Setting time and Strength of 3D printing material with different ratio at different temperature**

Temperature		Coagulant complex of JH	Setting time (min)		Strength (MPa)			
			Initial	Final	2h	1d	3d	28d
5-10°C	A-1	JH-1	33	50	16.1	37.2	48.6	60.5
	A-2	JH-2	58	122	7.6	36.5	40.4	58.3
	A-3	JH-3	140	175	/	35.9	45.8	61.6
15-20°C	B-1	JH-1	15	26	24.4	41.2	54.6	59.5
	B-2	JH-2	35	46	15.8	40.3	50.5	64.7
	B-3	JH-3	75	90	5.3	38.7	52.3	62.3
30°C	C-1	JH-1	8	15	28.9	47.1	56.1	64.1
	C-2	JH-2	26	38	23.1	43.2	54.5	60.8
	C-3	JH-3	47	59	19.2	46.8	55.7	67.5

Table 3.6 shows the setting time of 3D printing material could be flexibly controlled within 10-60min under three different temperatures by adjusting the ratio of coagulant and retarder in

the composition for the requirement of different seasons and environments.

The 3D printing material has high early strength and rapid coagulation. The 2h strength could be achieved to 10 - 20MPa, 3-day strength was 40 - 50MPa and 28-day strength was about 60MPa which could meet the requirements load-bearing walls and columns strength of 3D printing architectural. It could also make the printing members have good mechanical properties. The printing process used 3D printing materials is shown in Figure 3.5 and Figure 3.6 shows small 3D printing members.

**Figure 3.5 Printing process used 3D printing materials**

**Figure 3.6 3D printing construction members**

The raw materials of 3D printing materials are low-cost and friendly to the environment and humans. It also has the advantages that the adhesive of material is good, the stability is strong, the pump retention shape and bonding properties is good, and the 3D printing buildings has good printed form and volume stability. The 3D printing building and members could be mobile and assembled in short time, it has wide applications and could greatly promote the application and popularization of 3D printing technology.

#### **4. Conclusions**

(1) It used R-SAC in the 3D printing building materials to overcome the long setting time and low early strength of ordinary Portland cement-based materials. It have high early strength, its 2-h compressive strength could be 10 -20MPa and 28-day compressive strength is 50 -60MPa.

(2) At different application temperature, it could adjust the ratio of coagulant and retarder J1 H2, H3 and H5 to be suitable for the 3D printing material, and it could make the setting time of the material flexibility and easily controlled among 20-60min.

(3) It could change different kind of admixtures which have different functions to be mixed with R-SAC to adjust its performance. The shape is stability and the compressive strength is high enough for the continuity and security of 3D printing.

(4) The raw materials of 3D printing materials used in the study is low-cost and are friendly to the environment and humans which could promote the use of 3D printing technology in building construction.

# Repair and Retrofitting

# The restoration and repairs of the Sir William Goodman Bridge designed by Sir John Monash, Adelaide

John Woodside<sup>1</sup> and Leo Noicos<sup>2</sup>  
Principal, J Woodside Consulting Pty Ltd,  
<sup>2</sup> Principal, LN Engineering

**Abstract:** This paper examines the engineering design and project management of the restoration and repairs to a heritage listed tram bridge in Adelaide.

The bridge built in 1908 is the second oldest reinforced concrete girder bridge in South Australia. The bridge has performed remarkably well for over 100 years and is a tribute to the original designer, (Sir) John Monash, one of the early pioneers of reinforced concrete in Australia. The bridge was originally designed as a tramway bridge; it then became a one-way car bridge in the 1950s and now is a pedestrian/cyclist bridge. During an audit of the bridge in 2010, because of the extent of reinforcement corrosion and cracking of the concrete, the bridge was immediately closed causing concern to residents and the public who used the bridge.

From the repairs and reconstruction and other sources, it became evident that reinforcement corrosion was initiated by stray electrical currents from the trams, commencing early last century, although this was not initially understood.

The bridge was subject to many investigations and reports, and because two Councils owned the bridge, there was difficulty in agreeing on what should be done with the bridge. One Council wanted to restore the bridge, and one wanted to demolish it and build a new bridge. This political situation was overcome by one Council giving their half of the bridge to the other Council together with a monetary reimbursement. The restored and repaired bridge was reopened to the public in September 2014 as a cyclist/pedestrian bridge.

This paper reviews in particular the structural engineering and project management of the concrete repairs and restoration of a heritage concrete bridge, including the investigations, preliminary design, trial repairs, final design and documentation, construction and the lessons to be learnt from this project.

**Keywords:** Restoration, bridges, heritage, Sir John Monash, SARCC.

## 1. Introduction

To understand heritage restoration of concrete structures, it is important to understand the early history of reinforced concrete and the role of Joseph Monier (1). Miles Lewis in *"200 Years of Concrete in Australia"* (2) provides background to the early days of reinforced concrete in Australia. Many early reinforced concrete structures in Australia, including this bridge, used the proprietary Monier System of reinforcement (3).

The Sir William Goodman Bridge, as it is now known, is a SA heritage listed structure and is the second oldest reinforced concrete girder bridge in South Australia, built in 1908 originally as a tramway bridge spanning the River Torrens as shown in Figure 1. In recent times, the bridge has provided a direct route for pedestrians and cyclists across the Torrens River and connects with the River Torrens Linear Park and Path on the north side of the river which is a very important pedestrian and cyclist route in Adelaide.

Richard Venus has provided a marvelous historical record of the area, the bridge, Adelaide's tramways and the engineers involved originally in the bridge in the nomination of the bridge for engineering heritage recognition by Engineers Australia (4).

The design of the bridge was by (Sir) John Monash and the Reinforced Concrete & Monier Pipe Construction Co (RCMPC) with construction by the South Australian Reinforced Concrete Co (SARCC) (5,6,7).

In 1953 following the closure of the tram system, the Municipal Tramway Trust (MTT) offered the bridge to the SA Highways Department but they refused to take over as it unsuitable for vehicular use. In 1954, two councils had joint ownership of the bridge. In 1961, the Highways Department (now DPTI) became responsible for the bridge, and it was reopened in 1962 with a 5 ton limit and one-way traffic. Some upgrading work was carried out (but no concrete repairs) which included filling in the set down for the tram tracks with bitumen and the provision of guardrails on either side, inboard from the cast iron handrails.

**Figure 1 The bridge under construction 1908**

(Photograph courtesy University of Melbourne Archives BWP/24366 Reinforced Concrete & Monier Pipe Construction Co.)

The bridge was SA heritage listed in 1986 due its historical significance and could not be demolished but could be retained as a managed ruin. With the merger of councils, the Holland Street Bridge, as it was then known, became jointly owned by the City of Charles Sturt and the City of West Torrens. The load limit of the bridge was lowered to 2 tons and closed to road traffic in 1990 and then became a pedestrian and cyclist shared use bridge. It was closed in 2010 because of safety concerns, following a bridge audit.

**Figure 2 The bridge prior to restoration**

**Figure 3 Typical Deck Section**

(Figure courtesy flightpath)

As shown in Figures 2 and 3, the bridge is a three-span continuous reinforced concrete deck slab and beams. Both ends of the bridge and the two middle A Frame-Bent-supports are integral with the bridge superstructure. The deck slab is supported by two interior and two exterior beams.

## 2. Sir John Monash

Much has been written about Sir John Monash, as he was brilliantly successful in three different careers during his life (8, 9, 10, and 11). Holgate and Taplin have provided an excellent background on the contribution of Sir John Monash to 20th-century engineering in Australia (12).

Monash established the *South Australian Reinforced Concrete Company (SARCC)*, which built this bridge, and he was one of the 4 directors of the SARCC. However, it was not as successful as its Victorian counterpart; the *Reinforced Concrete & Monier Pipe Construction Co* was. Holgate states (7) that after Monash established SARCC in 1906, its primary work seems to have been in the field of city buildings and elevated water tanks from 1909 in South Australia.

### 3. Investigations

The bridge was subject to a number of investigations over about two years with the final recommendation that the bridge be abandoned, and new pedestrian bridge be constructed. The City of Charles Sturt decided to explore the possible restoration of the bridge and engaged John Woodside of J Woodside Consulting (JWC) in 2011 to provide an independent second professional opinion on the structural deterioration and the possibility of restoring the bridge, suitable for a walking and cycling bridge.

**Figure 4 A view of the worst external beams 2011, which was the trial beam, repaired in 2013.**

The key question was could the bridge be successfully repaired, and its life extended and Figure 4 shows some of the damage observed in 2011. From a series of inspections, research and a long involvement with concrete and repairs, JWC believed that the bridge could be successfully repaired, with an estimated serviceable life of at least another 30 years. JWC also concurred with the Council's decision to close the bridge to all traffic. JWC findings were set out in their initial report to the Councils (13).

### 4. Preliminary and final design

The City of Charles Sturt then engaged the project team to carry out the preliminary design and design development of the restoration and repairs of the bridge to give a better understanding of the repairs and the likely costs. This stage also included trial repairs of one of the beams of the northern span of the bridge recommended by JWC, which was extremely successful. A further report in 2013 was prepared by JWC (14) confirmed that repairing the bridge was a significantly cheaper option than constructing a new bridge and maintaining the old one, by an order of 50%. The report concluded the bridge could be successfully repaired, based on the trial repairs and other design work, for a total budget cost of \$2.6m.

From the various investigations and reports, it was obvious that the structural deterioration of the bridge with reinforcement corrosion and cracking of the concrete had been occurring for many years. Together with other information and the trial repairs, it also became apparent that the corrosion of the reinforcement had been initiated by stray electrical currents from the trams rather than from carbonation as firstly supposed, as shown in Figure 5. When the trams ceased in 1953, the rate of corrosion slowed significantly.

The top reinforcement of the trial beam over the North “A” frame was also exposed, and it was found to be in good condition with no evidence of any corrosion.

***Figure 5 Corrosion of the original round reinforcement and the density of the uncracked concrete***

The trial repairs showed that where there was no corrosion and spalling, the existing concrete was in sound condition and of a satisfactory strength and those areas which were damaged could be successfully repaired to meet the requirements of the current Australian Standard AS 5100.

The architectural work included documenting the restoration of the existing cast iron balustrades on the outside of the bridge. As the existing balustrades did not comply with the requirements of the current Bridge Standard, new galvanised steel balustrades inboard complying with current requirements were provided. The new balustrades were designed using contemporary materials and included LED lighting in the posts and overhead lighting. Also to new lighting to the top bridge, there was up lighting under the bridge. The architectural design also included landscaping and urban design at either end of the bridge together with entrance statement and seating at the northern end of the bridge.

Discussions were held with Heritage SA on the colours for the coatings of the repaired concrete surfaces and other heritage matters during the design and construction stages. Heritage SA also required a simulated tram track to be cast into the new concrete surface, and the architect chose two lines of pavers in the concrete that were also lit, to represent the previous tram rails.

The electrical engineer was responsible for the lighting on top and lighting under the bridge to provide a visually exciting view of the bridge at night and to meet the P3 level required for safety reasons on top of the bridge as shown in Figure 9. The civil engineer designed the scour control around the two concrete A-frame bents in the river and one of the abutments, to protect the existing pile caps and piles and footing under flood in the River Torrens.

The structural engineer was responsible for the design and documentation of the concrete repairs including additional bar reinforcement to all the beams and carbon fibre reinforcement to all the beams to provide sufficient shear reinforcement. The existing reinforcement in the bottom of the external beams was only used in part, and additional bottom reinforcement added to take the design loads. Additional top reinforcement was included in the infill slab poured in the set down area on the top of the bridge, for the live load condition for the two inner beams. The structural design was based on carrying out a number of site inspections to confirm dimensions of the structure as taken from sketches and drawings included in previous reports and the identification of obvious major deterioration to the key structural elements of the existing bridge structure. The documentation of the structural work was also based on all visually accessible components of the bridge at the time of the inspections and the various reports. The data, which was collected was then used to carry out the structural analysis of the existing bridge structure. This data provided the basis for identifying the structural capacity of each element and the extent of the required upgrading and repair.

The structural analysis of the existing bridge was undertaken to check the existing capacities of the critical components for the most adverse combination of loadings that could act on the structure and to determine the strengthening procedure to restore the safe working condition of the bridge in accordance with the requirements of the current Australian Standards.

The assumed concrete compressive strength was 15 MPa for the structural analysis and design, consistent with the adopted strength in reports and analysis by others. The concrete strength was based on the average results of the laboratory testing carried out on the two sets of concrete cores taken from the existing bridge elements.

In the absence of original information on the properties of the existing reinforcement, 200 MPa yield strength of the existing reinforcement was adopted. This yield strength was in general agreement with the reported yield strength of 230 MPa (1914) of plain reinforcement bars which has compiled information on steel reinforcement as early as 1914 to the present time (15). Subsequent testing of a main reinforcing bar from the southern span confirmed yield strengths of 260 MPa, which was reassuring (16).

The design loads adopted for the structural analysis of the bridge structure were based on AS 5100 and included self-weight, imposed dead load, pedestrian live load, water flow drag force, debris load, wind load and earthquake load. In accordance with AS 5100 and AS 1170.0, these loads were combined to produce the most adverse case of loadings acting on the respective structural components of the bridge and to assess their structural capacities.

A 3-D computer model was created using the above information then to determine the local and global structural behavioural responses of the key elements of the bridge as shown in Figure 6. The converted three-dimensional frame model used section properties based on cracked concrete to account for the expected conditions of the concrete elements. The structural models assumed continuous beams over internal supports given the monolithic construction of the superstructures with the 'A Frame' and pinned supports at the abutments.

The sizes, dimensions, and arrangements of structural members were based on the reviewed sketches and drawings included in the previous reports and check dimensions obtained during site inspections.

The design loads were combined in accordance with the provisions of AS 3600 and AS 5100 for concrete structures. The gravity loads applied to both the exterior and interior beams at the deck level were determined from the dead load, superimposed dead load, and pedestrian live load imposed between the new handrails. Furthermore, the bridge was analysed for transverse wind loads of 1.80 kPa and 3.0 kPa applied to the superstructure and 'A Frame' supports, respectively.

The earthquake load  $E_U$  was estimated to be  $0.04G_g$ , where  $G_g$  is the seismic weight in the order of 2580kN and was determined in accordance with the provisions of both AS 5100.2 and AS 1170.4. The bridge 'A Frame-Bent' was also analysed using 1.74 kN/m drag force and debris load of 50kN for each 'A Frame' from flood loads. These flood loads were determined in accordance with AS 5100.2 based on a river velocity of 2 m/s and water depth of 6.0 metres.

Based on the analysis, both the exterior and interior beams of the existing bridge were found to have insufficient capacities under vertical actions without strengthening to sustain the worst combination of the proposed loadings. The 'A Frame' internal supports were structurally sufficient to carry the proposed loadings; however the detailing of reinforcement particularly fitments did not meet the requirements of AS 3600 and AS 5100.

The sagging moment capacity of the outer beams were not adequate to provide resistance to the demand bending moment due to the reduced area of bottom reinforcement damaged by severe corrosion. The existing bottom reinforcement of the beams was 8 No  $1\frac{1}{4}$  inch diameter bars in two layers. However, the area of the reinforcement was estimated to be approximately 30% of the original area due to corrosion in certain places. Also, the beam had insufficient shear capacity near the supports due to the absence of required fitments required by the current relevant Australian Standards.

**Figure 6 Rendered 3-D Model of Bridge**  
(Figure courtesy URS)

The interior beams, which carry the majority of the applied pedestrian live load between the new handrails, were overstressed for both hogging moment and shear. Fortunately, the bottom reinforcement was largely undamaged, and additional top reinforcement could be added to the new slab on top of the bridge. The bending moment and shear force diagrams for the interior beams for both serviceability and ultimate limit states are shown below Figure 7.

**Figure 7 bending moments and shear force diagrams for inner beams**  
(Figure courtesy URS)

4 no. N24 additional bars were added to the bottom of the outer beams to increase the sagging moment capacity. All beams were also provided with U-wrap carbon fibre to increase their shear capacity and to comply with the minimum shear requirements of AS 3600.

The rectangular columns of the two 'A Frame-Bents' internal supports were found to be satisfactory to carry the proposed loadings but to ensure compliance with the minimum confinement requirements of AS 3600 and AS 5100, carbon fibre was wrapped around them also.

The footings were considered to be adequate with no sign of differential settlement observed based on the reviewed survey deck levels and a previous footings assessment report. Each column of the 'A Frame' internal supports was supported by 4 no 300mm x 300mm by 7610mm long concrete piles as shown on the existing original drawing and as recorded in a newspaper report at the time of the construction.

Following various political considerations and consultations, the City of West Torrens gave their half of the bridge to the City of Charles Sturt together with a contribution to the cost of future works and accepted no further responsibility. Together with a grant from the SA government and money from the City of Charles Sturt, this provided the funds to allow the final design work to be completed and the repairs and restoration to proceed under one owner.

The City of Charles Sturt then appointed the project team to finalise the design and documentation and to manage the restoration and repair work. The final design was undertaken in late 2013 and tendered by the Council by open tender, with tenders closing just before Christmas 2013. Five bids were received, and after careful evaluation, Synergy Remedial was awarded the contract. An updated cost plan by the QS also confirmed that the project could still be delivered for an overall budget cost of \$2.6 million.

## 5. Construction

Work on the repairs, restoration, and upgrading started in mid-January 2014 and was completed in mid-September 2014, a period of nine months.

The outermost beams were the most severely corroded together with local corrosion to the internal beams, the underside of the slab and the column A-frames. The beams and the underside of the slab were repaired using appropriate concrete repair techniques. Scaffolding and propping to repair the underside of the bridge was supported either on the banks of the river or hung from the centre span of the bridge.

The depth of the external beams was increased by approximately 75 mm to accommodate the additional bottom reinforcement as shown in Figure 8. This increase in depth is not obvious and had the approval of Heritage SA. The beams were repaired and strengthened, and all cracked concrete was removed, to provide space around the existing reinforcement to allow the new concrete to encase them. All existing reinforcement was grit blasted to bare metal, all existing and new reinforcement was coated with a zinc rich paint, and additional steel reinforcement was added to the bottom of the external beams as discussed previously.

**Figure 8 The existing & new reinforcement together with new concrete to half of an external beam**

The new concrete to the beams used 10 mm aggregate with a super plasticiser and was 20 MPa in strength to match the existing concrete strengths. Concrete was placed into formwork with bird mouths.

The new concrete enclosed the existing and additional reinforcement and restored the bottom of the beam previously cracked. It was also significantly cheaper than proprietary patch repair material. Carbon fibre reinforcement in discrete vertical strips was then applied to the sides and bottom of the beams as shear reinforcement. In a similar manner, the two A-frame bents were also repaired and strengthened. A thin render was then applied to the concrete surfaces under the bridge to provide a suitable surface for the application of the coating system with the colour to approval by Heritage SA.

The existing cast iron handrails were repaired and restored together with 12 new matching cast-iron posts but did not comply with current regulations. New handrails were installed inboard together with lighting.

The repair and restoration work were reasonably consistent with the expected extent of repairs and in accordance with the documentation and the trial repairs. However, there were a few hidden surprises with the concrete repairs; principally because there were no slabs at either end of the bridge; and there were also changes required to the new concrete slab on top of the bridge. This was in part due to the increased depth of set down which was not anticipated, resulting in an additional amount of bitumen to be removed.

Also, the extent of concrete repairs was more than was documented, which was not unexpected, and this additional work was allowed in the construction contingency.

The final construction cost including all fees, trial repairs and contingency was \$2.3 million, \$0.3 million under the \$2.6 million budget, which pleased everyone involved in the project, and in particular the client.

The reconstruction and restoration work included not only the repairs to the existing concrete with the coatings but also included a new concrete slab to fill the set down for the tram tracks to the top of the bridge, new lighting and scour protection at the base of the pier foundations as well as landscaping and signage and entrance statement at the northern end of the bridge. From the repair work carried out, it is obvious that the bridge will easily meet the brief requirements of 30 years additional life and should have at least another 50-100 years of life before possible further repairs and restoration are required.

Although load testing was not required since the design complied with the Australian Standards, testing was allowed for in the contract. The reason for the inclusion of load testing in the contract was to alleviate any concerns by other parties as to the structural adequacy of the bridge. Traditionally where a structure cannot be proved to be structurally adequate by structural mechanics, load testing of the structure is carried out. The proof load was 9kPa (900kg/m<sup>2</sup>), and the southernmost span was tested over the full width, with strains and deflections measured on two beams and corrected for temperature effects. The maximum deflection was of the order of 2 mm after correction, and the calculated internal stress was 9.2 MPa showing that the bridge was essentially uncracked, and the concrete had not reached its tensile strength. The test results were almost embarrassing, and the bridge may be suitable for future trams!

## **6. Existing tram tracks**

Initially, it was hoped that the existing tram tracks could be used in the project but they were badly corroded and after careful consideration, it was concluded that they could not be incorporated in any of the new works. As a result, they were given to the Tram Museum at St Kilda in Adelaide at no cost.

## **7. Lessons learnt**

With all concrete repair work, it is vital to determine the reasons for the deterioration of the concrete, consider the feasibility of repairs and reconstruction and then to proceed with the work if practicable.

It is important to select the right consultants and contractor to suit the project, with experience in heritage and concrete repair work. Use the same consultant team throughout, provided they are competent and work as a team, so design knowledge is not lost. Make the consultants responsible for preparing the as-built drawings of the final work. In a similar manner, it is important to have an architect experienced in heritage matters, and they may have a better overview than engineers of the final result. As lead consultant, they should manage the design team with input from the project manager.

Consult widely with those who are knowledgeable on all such projects to get their valuable input.

Do not use the currently fashionable method of documentation using partly finished and vague documents for tender or a design and construct tender and let the contractor sort out the details afterwards, it just does not work on these types of projects. Do not have liquidated damages and have a flexible construction period to allow for the unknown. Use an experienced project manager, as owners of such assets, do not have the experience for managing this type of project at a technical level. Heritage projects require a different mindset by all involved and the urgency for completion must be tempered with patience.

One of the major difficulties with concrete repairs is specifying the extent of repair work based on visual inspections as not all repair work can be identified. There are two approaches to this problem; one is to allow the contractor to take all the risk, but that can result in a loaded price but with no risk to the owner. The second approach based on previous experience by JWC on such projects is to use a cost plus approach for additional concrete repair work over above those repairs identified on the tender drawings. It is considered that this latter approach provides the best outcome for both the client and the contractor, and they share the risk between them. As a result, the contract price was not loaded at the time of tender,

a competent contractor will do all the necessary repairs required even if not documented without delaying the project and the final repair works can be readily measured, and variations agreed with rates established at the time of tender.

In heritage type projects such as this, unknown problems will always appear, and a construction contingency of 10% of the construction cost was included in the project budget. This allowance was found to be not be entirely sufficient, and should have been closer to 15%.

Cost management is also crucial in such works, and it is necessary for the QS to prepare cost plans at each stage of the design process to ensure that the works can be carried out within the approved budget and to maintain an accurate cost of the work and variations during the course of the construction.

A repair and maintenance regime must be established on completion of the project with a sufficient allocation of funds so that proper operational works can be undertaken on an annual basis with a major condition audit every 10 years. The bridge will require recoating of the top coat in 20 to 25 years' time.

## 8. Conclusions

The restored and reconstructed bridge was officially opened to the public and cyclists on the 13 September 2014 after more than 100 years of lack of care and uncertainty and 4 years of closure. The bridge has been recognised along with other bridges of that era in Victoria as having been designed by Sir John Monash and were celebrated as part of the 100<sup>th</sup> anniversary of the ANZAC landing at Gallipoli.

The whole team including the designers and the contractor worked together well on this project and with these projects, prompt information transfer is vital so that work on the site is not delayed over minor issues. Also, because the contractor was on a cost plus basis for the concrete repairs and other work, this meant that they were not delayed sorting out who is responsible for what and the contractor was able to proceed with the works without financial penalty and loss of time, knowing they would be fairly paid for the additional work.

***Figure 9 Photograph of the top of the bridge at night***

The restored and repaired bridge shown in Figure 9 was delivered at a significantly lesser cost than a new footbridge, justifying the decision taken to restore the bridge and in reusing the existing structure. The restored, and repaired bridge is a great sustainable result for a significant heritage bridge. It is also an outstanding example of perseverance by those involved to question the original advice, to take the time to understand the problems and to make the right decision to restore and repair the bridge. The restored and repaired bridge, beautifully lit at night, is a wonderful outcome for this heritage bridge, the environment and which the owner, the public, the users, the contractor and the design team are justly proud of.

## 9. Acknowledgement

Dr Alan Holgate and Dr Geoff Taplin for their wonderful recording of Sir John Monash's engineering work including this bridge.

The City of West Torrens and their consultants in carrying out the initial investigations and reviews of the bridge.

Councillors, Mayor Kirsten Alexander and Philip Hewitt, Manager Engineering Strategy & Assets, and the staff of the City of Charles Sturt for their support for the repairs and restoration of the Sir William Goodman Bridge. In particular, Phil Hewitt for allowing JWC to project manage this project on their behalf without undue intervention.

The design team and the contractor including J Woodside Consulting as project managers, flightpath as architects, URS as the engineers, Rider Levitt Bucknell as the cost planners and Synergy Remedial as the contractor for their work on this project but in particularly Leo Noicos for his contribution to the structural engineering for this project and Steve Freeman for his assistance during construction.

The University of Melbourne for permission to use the photograph of the construction of the bridge.

The South Australian Government for their funds for this project through their Open Space Grant system.

Richard Venus for his marvellous historical work in the submission of the bridge to Engineers Australia for engineering heritage, which has been approved.

Ian Maitland from Maitland Heritage Engineers in WA and Dr David Morris from David Morris Consulting in VIC for their invaluable advice and encouragement to the authors and the project.

Figures and photographs are by John Woodside unless otherwise credited

To others whom we have missed and who should be acknowledged.

# Condition Assessment and Structural Repair Solutions for the Renovation of the Sheraton Hotel at Doha, Qatar

Satyajit Datar<sup>1</sup> and Sajeev Kumar Krishnan<sup>2</sup>

<sup>1</sup> Principal Structural Engineer, GHD, B.E. (Hons), F.I.E. Aust., RPEQ

<sup>2</sup> Sr Structural Engineer, GHD, M.Tech (Structural), G Member IStructE (UK), PMP (USA), M.I.E. (India)

**Abstract:** Constructed in 1978, the iconic Doha Sheraton Hotel and resort complex of buildings having an area of 70,000m<sup>2</sup> with up to 20 storeys was completely renovated in 2014. This paper discusses the risk assessment and repair methodologies employed in the project for the various structural elements. The repair works were classified into repairs of damaged elements, strengthening of partly deteriorated elements and demolition and reconstruction of highly damaged elements. The repair strategy consisted of structural condition assessment by visual survey followed by non-destructive and destructive testing of concrete elements. A discussion of the results of testing and causes of identified defects was provided to the client. Based on a number of design life criteria contemplated by the client and building owner, various repair solutions were derived. Structural defects in concrete were primarily due to carbonation, chloride and sulphate attack, and corrosion of reinforcement. The types of structures affected included a sea water intake chamber, plant rooms, kitchen floors, underground water tanks, façade elements, roofs, walls, beams, columns and slabs at many locations. Solutions presented included protection against ingress, moisture control, salt extraction, concrete restoration, strengthening, cathodic protection and complete replacement of reinforced concrete. The paper discusses the challenges of addressing the time, cost, quality and risk constraints and outcomes inherent in a design and construct contract environment, and the practical problems faced in carrying out the repair works.

**Keywords:** structural defects, concrete, structural repair, strengthening.

## 1. Overview

The Sheraton Hotel at Doha was commissioned in 1982, designed by an American Architect Mr. William Pereira. Constructed over a plot area of 180,000 m<sup>2</sup>, the facility has a separate convention center, health and recreation center, swimming pool and many halls in addition to the main hotel building.

The ultimate client (the current Emir of Qatar) required a major renovation to restore the buildings back to their original condition. The project duration was only 9 months. The cost of the project was approximately 2 billion QAR (approx. AUD 700 Million). The scope of work included renovation of the rooms, public areas, lobbies, reception, ablutions, kitchens, back-of-house areas, MEP facilities, external landscaped areas, pools, sports facilities and external façades. The works constituted areas to be left unchanged, areas to be repaired, areas to be completely re-designed maintaining functionality and areas to be re-designed with a different functionality. GHD was the lead consultant for the architectural and structural works. This paper describes the structural assessment and subsequent repair solutions carried out on the buildings.

## 2. Structural systems

The structural system of the main hotel can be divided into two. The main building is a steel- concrete composite structure triangular in shape converging at the 16<sup>th</sup> floor. The shape appears as a truncated pyramid with a cantilever projection above the top floors. It consists of inclined steel frames supported at the top by concrete cores. Cantilevered floors project outwards from the steel frames. The remainder of the building consists of reinforced concrete (RC) columns, orthogonal slabs and beams of various spans and depths, with a podium roof, mezzanine, ground floor lobby and one basement floor. The steel structure is separated from the RC structure by means of expansion joints. Separate reinforced concrete structures served as liquid retaining underground water tanks and pump rooms. Chilled water for the air conditioning system, was drawn from the sea through an 8 meter deep intake chamber under the main pyramid building. All the main structures were supported on bored piles founded on bedrock up to 25 m below ground level.

### 3. Visual Assessment

A visual survey conducted by structural engineers in March and April 2014 consisted of inspections of representative and accessible areas of floors, soffits, walls, beams, columns, roofs, trusses, lintels, stairs and external pavements - identifying the general extent and location of visible deterioration. A photographic record was taken and visible defects logged.

Confined spaces such as tanks and concealed spaces such as behind ceilings, partitions and finishes, were partially inspected. The major defects noted were spalling of concrete at various locations, visible cracks in the beams and slabs, corrosion of exposed reinforcement and a number of non-structural defects such as damage to water proofing membranes and fire proofing coatings. The degree of corrosion of exposed steel reinforcement varied depending upon the location and proximity to moisture. The attempts of previous repair works were also visible at a number of areas. Generally the RC elements had the most deterioration but a few structural defects were noted on the major steel structure. Refer photos 1, 2, 3 & 4 for a representation of damage at various locations.

Photo 2 – Sea water intake column: Extensive damage to the concrete and exposed reinforcement

Photo 3: Slab above the service corridor: reinforcement exposed after removing the damaged concrete.

Photo 4 : Pump room slab: spalling of concrete and exposed reinforcement

#### **4. Investigation and Testing**

Further investigation and testing was undertaken by an appointed local laboratory. Destructive and non-destructive tests were carried out that included:

- Initially 12 and eventually 18 no. 75 mm diameter cores, in the slabs across the site, for compressive strength, carbonation, sulphates and chloride ion tests
- Cover meter tests at 21 locations
- Rebound hammer tests at 21 locations
- Ultrasonic pulse velocity (UPV) tests at 21 locations
- Reinforcing bar tensile strength and chemical composition tests at 2 locations

The results indicated that carbonation at the surface level (less than 20mm depth) was extensive, where surfaces are exposed to water, moist air or both. Carbonation is deeper than the 20mm cover concrete for slabs, in a number of the cores taken; indicating that carbonation had been ongoing for several years and reinforcement corrosion had been accelerating. Two of the cores had a carbonation depth of 80mm.

Chloride levels in the tested cores were very high. The Qatar Construction Specification (QCS) limit for chloride % by mass of cementitious material is 0.10%. The actual values in all of the 18 measured samples were in excess of 0.10%, with a maximum of 1.26% and an average of approximately 0.45%. The chlorides were mostly at-or-above the corrosion activation threshold, considered to be between 0.4 to 0.5%.

Sulphates were very high with up to 20% by mass of cement in the cores tested. There is no prescribed QCS limit; however normal levels are usually expected to be less than 3 to 5 %. Though there was no sign of the concrete matrix having broken down in the cores tested, there was evidence of severe degradation of concrete in some areas, notably external suspended slabs on the sea side of the building.

It is likely that the chlorides and sulphates were a combination of external ingress and internal contamination present in the original sand and aggregate of 35 years ago.

#### **5. Causes of failure**

The causes of structural failure of the various structural elements can be broadly divided under the following topics:

##### ***5.1 Reinforcement corrosion and concrete spalling***

The two primary initiators of corrosion are carbonation (which reduces the inherent alkalinity of concrete) and chloride attack (which is the effect of chloride ions in contact with the reinforcement). The presence of moisture and oxygen in combination with carbonation and/or chloride ions, causes corrosion. When steel corrodes, it expands and exerts a force on the concrete. The cover concrete cannot resist this force and spalls.

##### ***5.2 Carbonation***

Carbonation is dependent on the carbon dioxide concentration in the atmosphere, the concrete porosity (including cracking) and moisture content, and the relative humidity and temperature. Each of these conditions was prevalent at the site.

The depth of carbonation is approximately proportional to the square root of time. The Sheraton concrete core samples showed carbonation depths of up to 80mm, indicating that carbonation was initiated many years ago.

### **5.3 Chloride attack**

Chloride attack arises most commonly, by external ingress from seawater and spray or internally cast-in the concrete constituents such as sea-dredged aggregates or calcium chloride admixtures.

Chloride ion concentrations increase, when in combination with carbonation, which appears to have occurred in the Sheraton structure.

### **5.4 Sulphate attack**

Sulphate attack also arises by external ingress or internally cast-in, and causes the concrete matrix to disintegrate into loose friable material, such as sand, gypsum and stones. Water/moisture presence is a must for expansive (deleterious) sulphate attack to occur.

The Sheraton structure was exhibiting extensive carbonation, chloride attack and some sulphate contamination of the concrete, and corrosion of the reinforcement, which had progressively worsened over the period since construction 35 years ago, principally in the reinforced concrete elements as described above. The main outcome was spalling of the concrete, in slabs, walls, columns and some beams. Where sulphate attack was advanced, the concrete matrix had deteriorated completely and required demolition.

Water ingress was a significant problem, from a variety of external sources (groundwater, irrigation, storm water) and internal sources (water supply and drainage pipes). Waterproof membranes and joint sealants to horizontal, vertical and sloping surfaces were in the majority of cases aged, degraded, ineffectual or absent.

## **6. Risk Assessment**

The full extent of concrete contamination, reinforcement corrosion and concrete degradation or spalling in the Sheraton structure was not known. The visual survey, investigation and testing was limited by constraints of time and access. There remained significant areas of structure not inspected nor tested due to concealment by services, ceilings, partitions and finishes. However, a majority of the reinforced concrete elements at the basement, ground, mezzanine, first floor and podium roof levels, exposed to humid atmosphere were able to be inspected.

An approach to risk mitigation, durability and protection of reinforced concrete structures was broadly taken from the BS EN 1504 Part 9, General Principles of:

1. Protection against ingress
2. Moisture control
3. Concrete restoration
4. Structural strengthening
5. Physical resistance
6. Resistance to chemicals
7. Preserving or restoring passivity
8. Increasing resistivity
9. Cathodic control
10. Cathodic protection
11. Control of anodic areas

Principles 1 to 6 are “must haves” for sound concrete, and are generally achievable by adhering to relevant British or other design standards, during the original design and construction, or retrospectively as applicable. Principles 7 to 11 are desirable or necessary for durable reinforcing steel, usually only under conditions where some or all of Principles 1 to 6 cannot be achieved.

Where carbonation and chloride depths in concrete cover are minimal, (such as, if carbonation depth is less than the reinforcement cover, or the chloride level is not high enough at the reinforcement level), it is

common to treat the symptoms only, by applying appropriate protective coatings to prevent or minimize future ingress of water, chlorides, carbon dioxide and sulphates. Removal and reinstatement of isolated damaged concrete may be required.

However, in the Sheraton hotel structure, the depth of carbonation and chloride contamination in many areas was likely to be well in excess of the depth of reinforcement. Under such conditions, treatment of the symptom alone was considered ineffective and may serve to move the corrosion cells to adjacent areas.

A specialist materials engineer was engaged to review the test results and recommend repair solutions. A number of meetings were convened with the contractor, project manager and owner's representative to convey the levels of risk to be accepted commensurate with the likely design life of each solution.

**Electrochemical repair solutions presented were:**

- Realkalisation
- Chloride extraction
- Cathodic protection (CP) – galvanic anodes or impressed current
- Penetrative/migratory corrosion inhibition
- Removal of contaminated concrete

**Realkalisation and chloride extraction** under the application of an electric current are temporary measures that would have taken several weeks to undertake and were not considered to be suitable at the Sheraton structure due to the high chloride levels present at the reinforcement level.

**Cathodic protection** of two types was considered: a permanent impressed current (ICCP) or with sacrificial galvanic anodes to accommodate future carbonation or chloride attack. Galvanic anodes were expected to provide a service life of up to 10 years, under the right conditions. ICCP would provide up to 25 years' service life if full electrical continuity (and monitoring) was able to be guaranteed.

**Penetrative corrosion inhibitors (PCIs)** were relatively new to the market having been introduced from 1996, and only one product in the Middle East, Sika Ferrogard 903, appeared to be proven in Europe in reducing corrosion and chlorides. Its success in the field had been mixed, with success rates for corrosion inhibition and penetration depths, ranging from 30% up to 80%. In our opinion, it would have a 50% chance of success in the Sheraton structure to extend the service life by up to 10 years. This was conveyed to the contractor and client and ultimately accepted, mainly due to time and cost constraints of the other solutions.

## **7. Proposed Solutions**

Solutions were developed based on the requirements of Principles 1 to 3 being implemented as far as practically possible:

1. Protection against ingress
2. Moisture control
3. Concrete restoration

This applied extensively for roofs, floors, walls and columns particularly throughout the back-of-house (BoH) areas of the complex and all areas (external and internal) exposed to humid air.

Conventional methods of concrete and reinforcement restoration were proposed wherever spalling or delamination was evident – by removal and cleaning of all deleterious material, replacement or addition of reinforcement as required, treatment of surfaces, followed by restoration with approved concrete mortars with protective coatings.

For the majority of the slabs and beams, cracking and spalling was not yet present, but the concrete was contaminated. A combination of protective coatings and galvanic anodes were recommended to achieve a design life greater than 10 years. Alternatively, impressed current cathodic protection (ICCP) was recommended in lieu of the coatings and anodes. Restoration alone was not recommended, as corrosion would likely accelerate in the un-restored areas. However, due to the lack of experience in ICCP or galvanic anodes of the contractor and the short duration of the project, only conventional methods of

repair works plus the application of PCIs were adopted, after careful examination of the various options and their design lives, by the owner's representative and contractor.

The general procedure adopted for repair work in slabs was as follows:

**1) Back Propping:**

Back prop the slabs and beams. The props were placed at the beams and at 1/3 span in each panel. During the repair operation, the max live load allowed on the slab was not to exceed 1.5 KN/m<sup>2</sup>.

**2) Repair first the top of the slabs.**

- a. Remove all material collected on top of the repair area
- b. Remove minimum 3 cm or the depth of concrete affected by carbonation.
- c. Clean the reinforced concrete. If reinforcement is corroded, remove the layer of corrosion using a mechanical brush.
- d. Apply a corrosion protecting, epoxy coating to the reinforcement.
- e. Fix anchoring steel to the top of slab. Use T12 @ 250 both ways. Anchor the rebar using a high performance anchoring adhesive. (This step was an option depending upon the location)
- f. To enhance further the long term durability of the concrete and embedded rebar, a corrosion inhibitor barrier to air and humidity was applied on the old concrete.
- g. Apply a PCI to the old concrete surfaces – both the residual surface after removal and the surfaces where concrete was not removed
- h. Apply a pre-packed concrete or mortar either by normal placement methods or by spraying.
- i. Apply an anti-carbonation coating to the finished surface.
- j. Apply a silane coating where exposed to external elements or a waterproof membrane.

**3) Repair the bottom of the slabs.**

- a. Remove the concrete cover around the corroded reinforcement; the area to be removed was defined by rebound hammer testing for delamination, but not less than 2m away from the visually corroded steel. The concrete was removed to a uniform depth not less than 40 mm or as determined from the carbonation tests.
- b. The surface of all exposed reinforcing rebar surfaces was be cleaned by means of wire brushing.
- c. Visible cracks, honeycombs or voids within the slab were injected with an epoxy mortar.
- d. All exposed rebar was coated with an epoxy resin for corrosion protection and as a bonding agent.
- e. Concrete surfaces were coated with a bonding agent.
- f. Remaining steps were as per the top of slabs including the PCI and anti-carbonation coating but excluding the silane or waterproof membrane.

A similar procedure was adopted for repair of beams and other elements with minor modifications based on element type, size of repair and location. For example, columns were repaired by following the above procedure with additional reinforcement and extra concrete at the base over a height of 1m.

Based on the initial repair methodology, a number of chemical products from various manufacturers were identified and the contractor was allowed to select the suitable material based on availability and support from the supplier.

In some cases where the corrosion and structural deterioration was prominent, a structural analysis was carried out to confirm the reinforcement and member sizes were satisfactory for the current structural code requirements and loadings. Where it was not satisfactory, CFRP (carbon fiber reinforced polymer) strips were adopted as a strengthening solution.

Where extensive damage wreaked the element beyond repair or strengthening, a full demolition and reconstruction of the element was undertaken.

## 8. Construction

Based on the nature and extent of the damage to the structural elements, repair and restoration, repair and strengthening of the elements or complete demolition and reconstruction of the elements were undertaken. The construction work for different areas based on the problem and repair methodology adopted are described below:

### 8.1 Seawater Intake Chamber & MER -1

The sea water intake and Mechanical & Electrical Room-1 (MER-1) were considered as one of the major areas where repair work and logistics caused critical impact on time and cost. The seawater intake chamber is 8m deep, 20m long and 10m wide, taking sea water to the mechanical room through two 2m diameter pipes connecting between them. The initial issue was to curtail the water inflow to the chamber. This was critical as the water was drawn directly from the sea without any control valves. The other issue was arrangement of alternate temporary cooling facilities once the plant closes. After many rounds of discussions and various proposals, a cost effective and efficient solution was established to contain the water inflow. The contractor used the excavated soil from the site to construct an earthen bund across the intake and continuously pumped out water that may leak in. The heavily damaged beams and slab were removed completely. The columns were found to be in good condition below the tidal water level and hence demolished only where damaged and re-constructed with additional rebar.

Photo 5 : The shuttering work for columns and slab of seawater intake structure

Photo 6: The beam and column of seawater intake structure after repair work

### 8.2 Underground Water tanks and Main Pump Rooms

The underground water tank and main pump rooms are separate structures situated around 100m away from the main building. The underground structure is rectangular in shape with a plan dimension of 22m x 84m. There are two expansion joints provided at 18m and 49m making 3 separate structures. The 250mm thick top slab is supported on 9m span secondary beams (400x750mm) provided longitudinally at every 2.75m. These are supported on main beams of size 750mmx1000mm spanning 11m laterally. The foundation is piles of various numbers under the walls with pile caps of various sizes. The top slab supports a dual carriageway and hence the slabs were analysed for bridge loads. Elements such as slabs and beams were checked to determine their structural compliance. The analysis and design was carried out employing current structural software applications, and the results were compared with the existing sizes and reinforcement. This approach helped to identify the mode of repair or strengthening required, or a combination of both to be carried out at damaged locations.

The design review showed that strengthening was required for some of the beams due to non-compliance with the structural design standards BS 5400, BD 21/01 and BD 37/01. In addition, repair work was required for a number of members, due to concrete contamination and reinforcement corrosion. In addition to standard procedures for repairing concrete work, approved hydrophobic impregnation (pure silane) to the entire surface was applied.

### **8.3 The Main Entrance Lobby**

The main entrance lobby was a reinforced concrete structure with a basement. It was found that the slab was extensively damaged due to ingress of water from the water fountain in the main entrance. A few bays were removed completely and reconstructed with fresh reinforcement and concrete. The rest of the area was repaired following the standard procedure.

### **8.4 Back of House areas**

All of the BoH areas (bulk store, service corridor, loading docks, five large plant rooms, several kitchens, engineer's offices, wet areas) were eventually repaired or reconstructed. This greatly increased the scope of works for the contractor, without increasing the project duration.

The bulk store was located near to the main entrance and was a reinforced concrete structure. It was found that the slab was deteriorated due to water ingress from kitchen floors above. A few areas of retaining wall also had cracks and corrosion of reinforcement. Standard procedure was adopted for repair work.

The service corridor also was a huge area away from the main building where damage to slabs and beams were noted extensively. A separate analysis was carried out for this area and as a result CFRP strips were provided to strengthen the beams in addition to the repair works for slabs and beams.

A lot of other areas such as large plant rooms and halls had extensive spalling and corrosion, and were repaired using the above repair methods and procedures and several areas were demolished and reconstructed.

A major non-structural item of the repair was replacing the existing water proofing membrane in almost all the podium roof slabs.

## **9. Key Lessons Learned and Conclusions**

The successful completion of the project within the prescribed time was hailed as a victory for the meticulous planning and nonstop implementation of the planned activities by the team behind the project. During its peak time an average of 16,000 labourers and more than 1,200 engineers and drafters worked on the site. Proper cooperation and coordination among various departments was paramount to the progress and success of the project.

One big lesson learned was that the anticipated repair work at the beginning of the project was multiplied many times as the project progressed as new areas were uncovered and the identified areas were extended during final inspections. Sufficient time and budget is needed for major repair works to be satisfactorily carried out for such large buildings in close proximity to the sea.

Another key lesson, working for a design and build (D&B) contractor; a consultant needs to always consider the multiple and often conflicting needs of many parties – the ultimate client and their representative, the contractor client, the local authorities, the subcontractor supply chain capabilities – in addition to the technical and ethical requirements inherent in professional engineering. Clear articulation of cause and effect, risks and consequences, design life, methodologies and cost estimates for each situation was required. Such articulation was difficult but achievable in a multi-lingual, multi-cultural project environment.

Managing expectations was another lesson - for example, the original aspirational design life of 50 years for all structural elements desired by the ultimate client, was not achievable given the time, cost and quality constraints for the location of the building and the climate. The typical design life warranted by subcontractors was 10 years. This required careful and persistent articulation by GHD of the design and repair options available – for acceptance by the contractor and the ultimate client's representative.

Professional lessons learned by the engineers and inspectors covered a wide range of technical aspects including:

- Concrete repair methodologies for numerous structural elements and conditions
- Climatic considerations in applications
- Variances in subcontractor/tradesmen skill levels
- Making informed judgements on the basis of incomplete investigations and small sample sizes of non-destructive and destructive testing

In summary, the project was exemplary in demonstrating the key challenges for engineers – to deliver practical design solutions that balance the competing drivers of time, cost, quality, risks and opportunities within a finite duration.

# Adelaide Railway Station Façade Conservation Works Structural Engineering Aspects

David Kennedy<sup>1</sup>

<sup>1</sup>Senior Structural Engineer, Aurecon Australasia Pty Ltd  
Adelaide, South Australia

**Abstract:** Aurecon was engaged by the South Australian State Government to review the condition of the façade of the Adelaide Railway Station, a 5 storey rectangular building constructed from a concrete encased steel frame with ribbed one way concrete suspended. The façade walls are predominantly clay brick masonry with decorative features made from precast concrete all rendered with a thin sand/cement finish to unify the external appearance.

Our diagnosis identified that deterioration of the concrete and reinforcing in precast elements was caused by carbonation and Aurecon recommended that concrete repair and the application of elastomeric coatings was required. Degradation was concentrated at horizontal surfaces where deteriorated screed coats allowed to pool for long periods and be absorbed into the concrete where it was able to initiate the damaging process of reinforcement corrosion.

The north façade was assessed to be the most heavily damaged and so conservation works were undertaken on the north façade throughout 2013.

The colour, texture and location of elastomeric coatings were negotiated in consultation with the heritage architect, and government authorities so that a balance could be struck between the need to satisfy the aesthetic and heritage requirements, and the need to provide lasting protection to the structure.

**Keywords:** Facade, Concrete, Repair, Heritage, Conservation.

## 1. Introduction

Aurecon was engaged by the Department of Planning Transport and Infrastructure (DPTI) to prepare an Asset Management Plan for the Adelaide Railway Station, which included consideration of the condition and maintenance of the façade of this historic building. The façade has been the subject of condition inspections by specialist façade contractors Synergy Remedial who issued reports in 2006 and 2009. Selective repairs of the more obvious defects, such as delaminating decorative features, have been carried out over the last 4 years. As part of the Asset Management Plan, Aurecon undertook a reassessment of the condition of the façades in conjunction with an appraisal of the 2009 Synergy report.

**Figure 1. North Façade.**

The following summarises the background information on the building, the investigation findings and subsequent conservation works undertaken:

## 2. General Façade Description

The railway station is a 5 storey rectangular building constructed from a concrete encased steel frame with ribbed one way concrete suspended slabs formed using cast-in sinter blocks laid in rows on formwork. The façade walls are predominantly clay brick masonry with decorative features made from precast concrete all rendered with a thin sand/cement finish to unify the external appearance.

The façades feature a range of decorative elements in addition to the solid walls:

- a) 2 storey fluted columns with Corinthian column capitals
- b) Cantilevering cornices around the full perimeter of the building incorporating two rows of major and minor dentil mouldings
- c) Fluted string course tiles at the mid-height position
- d) Scroll mouldings over archways

## 3. Inspection Findings

Inspections were carried out using zoom lens photography, close up inspections of accessible locations followed by inspections using abseil ropes and articulated boom towers.

**Figure 2. Precast columns undergoing carbonation North Façade.**

The following recommendations were made:

- e) Address the deterioration of the concrete and reinforcing, with particular reference to the external columns and the cornice mouldings (carbonation).
- f) Paint and treat corrosion to the steel windows (particular attention to the exterior) and steel tension rods for the external canopies.

Improve the stormwater disposal from the concrete slab roofs of the east, south, southeast and north external porticos

**Figure 3. Removal of loose items.**

It was determined that intervention was required to prevent the irretrievable loss of decorative components and a further acceleration in the rate of deterioration. Concrete cancer leads to structural failures with falling components threatening life safety, increases in water ingress and a reduction in heritage value. With the understanding that the costs of rectification of these types of façades increases exponentially with time, it was decided that repairs and installation of coatings would be undertaken in a progressive manner over several years.

Although general deterioration was observed in all locations, the north façade was assessed to be the most heavily damaged and so conservation works commenced on the north façade throughout 2013.

**Figure 4. First of 3 stages of scaffolding for the Northern Façade conservation works.**

## **2. Conservation Works**

A major contributing factor to the degradation of the façade was the lack of suitable vertical pathways for rainwater travelling down the face of the façade. Degradation was concentrated at horizontal surfaces where deteriorated screed coats were unable to provide adequate drainage. Water was then allowed to pool for longer periods and be absorbed into the concrete where it was able to initiate the damaging process of reinforcement corrosion.

The problem was compounded by the lack of “drip initiators” (vertical grooves on inverted surfaces used to break the surface tension which otherwise allows water to stick to the surface). Water flowed over the

edges of cornices and parapets and down the vertical faces of decorative features (such as dentils) in an uncontrolled manner leading to the growth of mould, which in turn trapped more moisture and exacerbated the effect.

Of equal concern was the integrity of the waterproofing membranes on the concrete portico decks and northern terrace.

**Figure 5 – Removal of defective concrete along the edge of the top ledge**

The works involved the following:

- a) Repair of leaking perimeter gutters and hip flashings of the roof turrets,
- b) Replacement of defective concrete, reinforcement and render
- c) Application of elastomeric membranes to all horizontal surfaces with modern membrane coatings to adequately shed rainwater and insulate the concrete from air and moisture,
- d) Localised repair of cracking external fluted columns.
- e) Use of elastomeric membrane coating of all external fluted columns to compensate for the low cover to reinforcing steel and disguise previous patch repairs,
- f) Localised repair to corbels, scrolls, dentils, beam soffits
- g) Repair and protection of corroded steel window frames and steel tension rods

The colour and texture of coatings and suitable locations for application were negotiated in consultation with the heritage architect, DPTI and the Heritage Division residing in the Department of Environment Water and Natural Resources. A negotiation was required so that a balance could be struck between the need to satisfy the aesthetic and heritage requirements, and the need to provide lasting protection to the structural elements.

**Figure 6 – Fluted column following removal of defective concrete with corroded reinforcement cage visible**

### **3. Conclusions**

All of the above measures were aimed at removing the hazard posed by loose material, managing rainwater flow paths and arresting the progress of corrosion by using modern coatings with the ultimate goal of reducing the requirement for expensive future maintenance to heritage fabric.

# A Variety of Remediation, Maintenance and Serviceability in its 15 Year Life

Peter Kastrup<sup>1</sup> and Andrew Turnbull<sup>2</sup>

<sup>1</sup>Queensland Maritime Leader and Senior Engineer, Arup

<sup>2</sup>Engineer, Arup

**Abstract:** The Redcliffe Jetty is a reinforced concrete structure and was constructed in its current form in 1999. Soon after construction was completed (1999-2000) significant immediate rectifications works were required to keep the structure in service. Following further assessment, further significant remediation works and subsequent load testing was carried out in 2003.

An engineering inspection was carried out in 2007 with minimal budget available for maintenance.

In 2013 a level 3 inspection including testing was carried out. Based on the findings of this inspection and the results of the testing, condition of each element of the structure was assessed and the remaining residual life estimated. A number of repair options for each element were used to investigate four different maintenance strategies: “Do Minimum”, “Reactive Maintenance”, “Preventative Maintenance” and “Replacement”. The specific repair applied to each element was varied depending on the overall strategy. The “Preventative Maintenance” strategy was selected for the main jetty and detailed repair design and tender documentation was prepared. This repair work was completed in mid 2014.

The lower level finger piers were deemed as in need of short term replacement. However, a further detailed tailored assessment was proposed to further investigate the life span. This assessment challenged the failure mechanism of the structure and revealed that the damage was not at a level warranting replacement, subject to a number of identified risks. In parallel, the replacement detailed design and tender documentation was prepared so the Council is ready to proceed when required.

**Keywords:** Concrete, Jetty, Steelwork, Maintenance, Durability, Repair, Structural

## 1. Introduction and Background

Redcliffe has had a number of jetties constructed since the late 1800s. In 1999, the current Redcliffe Jetty was constructed. Redcliffe is located within Moreton Bay Regional Council (MBRC) in Queensland, north of Brisbane. The coastal location is naturally sheltered from major offshore waves by Moreton Island, however local waves can occur and therefore a breakwater is located east of the jetty, refer **Figure 1**.

The jetty is approximately 250 m long in total and the water depth is up to 5 m at high tide at the seaward end. The different sections of the jetty are:

1. The Main Jetty is the longest part with the highest deck level comprising:
  - Jetty Stem landwards
  - Halfway House
  - Jetty Stem between halfway house and head
  - Jetty Head
2. The Jetty Fingers are the easternmost structures with low deck level and pontoon to facilitate vessel access:
  - Finger North (including pontoon and gangway)
  - Finger South (including pontoon and gangway)

Refer to **Figure 1** for plan showing the above description.

Figure 1. Top: Photo of Jetty from Land. Middle Aerial of Jetty and Breakwater. Bottom: Description of Jetty Structure. @MBRC/Arup

The jetty superstructure is predominantly a concrete structure consisting of precast hollow spun piles, in-situ pile caps, precast prestressed beams and precast deck panels. Refer **Figure 2** for typical sections and note the difference in deck levels.

**Figure 2. Left: Main Jetty Typical Section. Right: Jetty Fingers Typical Section. @MBRC**

## 2. 1999-2000 Immediate Remedial Works

Immediately after construction, issues were identified with the jetty superstructure, primarily relating to the beam supports. Arup was not the original designer, but was engaged to provide independent advice. Concerns were raised over the integrity of the half joints, refer **Figure 3**, as movement was observed and cracks were appearing. This led to the immediate localised installation of temporary steel supports, designed for the full joint loads. Shortly after installation, some of the concrete beams had deflected such that full support was provided by the steelwork.

**Figure 3. Half Joint Detail. Left: Main Jetty @Arup. Middle: Jetty Finger @Arup. Right: Reinforcement Detail. @MBRC**

The half joints (**Figure 3**) were found to have issues with limited capacity for the specific articulation and associated movements plus uneven bearing, which resulted in vertical capacity being compromised in the joints subject to the largest movements.

Another concern identified (not only for the half joints) was that design issues including inadequate allowance for tolerances had led to dowels for lateral capacity not being installed in a number of locations. Piling tolerance and precast installed directly on precast were key factors.

The purpose of the fingers is to facilitate vessel berthing and mooring, however due to the concern of insufficient lateral capacity of the timber fender piles, new independent berthing piles for the northern finger were designed and installed to accommodate a commercial tour operator vessel. The southern finger was not upgraded as there were no plans for accommodating more than one commercial vessel.

The observed issues and concerns for latent conditions and construction defects led to design of a number of permanent remedial works for the jetty.

### 3. 2003 Remedial Works

#### 8.1 Fingers

The decision was made to largely adopt a 'Do Nothing' strategy for the two fingers. It was assessed that it would not be financially viable to repair the fingers due to the nature of the relatively low level structures in combination with the fact that the remaining half joint defects were not severe enough to warrant strengthening at the time.

#### 8.1 Main Jetty

The previously identified half joint issues were further assessed and led to the detailed design of permanent remedial works. The most feasible and practical remediation option was determined to be structural steelwork supports. This was provided in all half joint locations, and where dowels were suspected missing brackets to address lateral restraint were installed. Some half joints were also located such that the loading provided a torsional load in the relevant beams. These beams were found to have insufficient torsion capacity and to counteract these loads, steel struts were designed to connect to the underside of the relevant beams opposite the half joints.

Due to the geometry of the jetty, a combination of vertical, torsional and lateral supports were specified where required, refer **Figure 4**.

**Figure 4. Examples of Installed Steelwork Supports. Left: Vertical and Torsional Support. Middle: Torsional Support. Right: Lateral Support. @Arup**

Although well above the tidal zone, the steelwork is subject to salt water splash and spray and a maintenance manual was provided to advise Council of expected and recommended inspection and maintenance regime for the jetty including all remedial works.

The round in-situ pile caps was another element where remediation was required. The majority of the beams are supported on the pile caps and in a number of instances there was found to be insufficient bearing area and cover to reinforcement mainly due to inadequate allowance for piling and other tolerances.

The remedial solution adopted was the construction of a larger pile cap, which encapsulated the original element. The main objectives were to increase the bearing area for the beams, increase structural capacity and improve durability. To address these objectives, stainless steel reinforcement was used

throughout and the bars were dowelled into the existing pile cap and pile for load transfer, refer **Figure 5**. The dimensions of the remediation pile caps were tailored to suit the particular geometry at each location.

**Figure 5. Pile Cap. Left: Finger Pile Cap (original). Middle: Jetty Pile Cap (strengthened). Right: Remediation Design Detail. @MBRC/Arup**

Concerns over the quality and durability of the concrete lead to a decision to adopt a preventative intervention for the prestressed beams and deck panels. As prestressed strands has an inherent risk of sudden failure when subject to corrosion, it was decided to apply a protective coating to the highest loaded central span zone of the beams. Silane coating was applied to the remaining surfaces in the splash zone (soffits, beam edges).

To confirm the capacity of the structure a load test was carried out in increments up to a uniformly distributed load (UDL) of 6 kPa, which is 1 kPa higher than the characteristic design UDL.

#### 4. 2007 Inspection

The 2007 inspection focussed on assessing the current condition of the different components of the structure. The inspection included visible components of the structure as described in the maintenance manual. It was found that the structure appears to be in a fair to good condition (considering its pre-existing and latent conditions) and that no significant unexpected deterioration since 2003 was identified. The works carried out during remediation of the Jetty appear to be in a good condition and the repairs to beams and slabs are still in place. It appears that very few cracks had developed in the beams and the slabs since the remedial works. It was noted that most of the concrete beams had deflected such that the remedial steelwork provided full or partial support.

Redcliffe City Council previously decided not to carry out remedial works to the fingers of the Jetty and it was noted that these structures were showing further signs of deterioration. It was not expected that the fingers will fail in the short term under normal conditions but the condition of the fingers will need to be closely monitored in particular after significant weather events.

Overall, it was recommended that the Council continue to follow up the recommendations and carry out maintenance and inspections as outlined in the Redcliffe Jetty Maintenance Manual. With minimal maintenance budget available it was decided to postpone the minor maintenance actions identified.

#### 5. 2012 Inspection and Repair Strategy Option Study

Redcliffe City Council was amalgamated within Moreton Bay Regional Council in 2008 and staff changes meant that not all background knowledge and history of the previous work had been passed on. Others carried out an engineering inspection for Council in 2011 and provided advice, which highlighted concerns regarding the visible concrete damage. Recommendations included limiting public and vehicle access to the entire jetty.

Arup was engaged to peer review this advice and provided recommendations to Council on way forward. Council subsequently engaged Arup to undertake a level 3 inspection (including testing and structural

assessment) and to provide costed repair strategy options. The condition of each element of the structure was assessed and the residual life estimated. A number of repair options for each element were used to prepare four different maintenance strategies: “Do Minimum”, “Reactive Maintenance”, “Preventative Maintenance” and “Replacement”. The specific repair applied to each element was varied depending on the overall strategy. The costs and expected life extension of each repair or replacement option were estimated and this led to an overall quantitative analysis of the costs and benefits from each strategy.

Council decided to proceed with the preventative maintenance strategy (for the main jetty), which included an upfront capital maintenance cost with the aim of reducing the long term maintenance cost:

- Crack repair: Epoxy injection of most cracks suitable for crack injection to improve durability.
- Delamination repair: Patch repair of spalling or hollow sounding concrete areas. The spall repairs include breaking back the concrete and repairing the corroded reinforcement.
- Repair steelwork defects and coating.
- Re-apply protective and silane coating to the concrete beams.

This repair option is expected to increase the residual life of the jetty by up to 20 years. Minor maintenance is still to be expected in 5-10 year intervals, such as minor touch-up work.

Arup subsequently prepared the detailed design, cost estimate and tender documentation for the remediation works. Arup assisted Council in the tender assessment and provided technical advice during the construction phase, which was completed in 2014.

## 6. 2013 Breakwater Repair

As a separate but critical preventative measure to maintain the serviceability of the jetty, an assessment the breakwater revealed that this was damaged during a January 2013 storm event, refer **Figure 6**. The design of the jetty relies on the wave protection the breakwater provides. The assessment involved determining the likely immunity of the original breakwater overtopping and rock armour sizing. As a significant amount of rocks had been displaced from the breakwater crest the Council decided to re-instate the original breakwater profile with Arup assisting in completing this work.

**Figure 6. Redcliffe Jetty Breakwater During January 2013 Storm Event. @Arup**

## 7 2013-2014 Fingers Replacement Design

Based on the recommendations for the jetty fingers, Council decided to carry out a life span investigation for the existing structures as well as detailed design of the replacement works, refer **Figure 7** for images of the existing structures.

**Figure 7. Top: Southern Finger. Bottom: Northern Finger with Commercial Tour Operator Vessel (note the independent fender piles). @Arup**

### 7.1 Life Span Investigation

Based on visual inspection and structural calculations, the mode of failure that is of most concern to the fingers are the half joints which are showing signs of significant distress (large cracks). The investigation concluded that the major cracking in the half joints is probably due lack of adequate even bearing area in the half joints, refer **Figure 8**. The cracking observed in the half joints on the fingers seemed limited to the unreinforced edges/corners of the beams. It is believed that the cracking observed

has generally resulted in a relocation of the bearing area from the unreinforced edges/corners of the beam to the reinforced middle section of the beam.

If the fingers experience a significant vertical (crowd) loading, it is possible that further cracking of the half joints may occur. However it is also expected that this cracking will result in an increase in the bearing area. When this cracking occurs, the beams may “settle” which may result in cracking of the in-situ deck slab. In summary, it was not believed that the half joints are at risk of brittle failure and warning signs such as cracking in the slab is expected to be visible locally above the joints.

**Figure 8. Jetty Finger Half Joint Cracking Examples. @Arup**

A strut and tie analysis showed that the half joints have the structural capacity to transfer the 5 kPa vertical load if adequate bearing area is provided. The required bearing area was calculated in accordance with AS3600 with the required strut area which was output of the above strut and tie analysis. Based on observations and measurements from the visual inspection, it appeared that many of the half joints did not have adequate bearing area due to uneven bearing surfaces, precast supported directly on precast, temporary timber packers (not removed) and poor mortar pad grouting.

The movement joints of the main jetty are located at each end of the continuous stems (refer **Figure 1**), and these movement joints were constructed as half joints. This suggests that cracking in the half joints is partially due to shrinkage and temperature movement. For the fingers, the beams along the seaward side of the fingers are continuously restrained (with in-situ joints at the piles), this suggests that the unsupported half joints on the fingers are unlikely to crack to the extent of the main jetty half joints.

Furthermore, it is expected that the majority of the shrinkage in the concrete has already occurred reducing the risk of cracking due to shrinkage. However, there is still an inherent risk that damage can occur to the fingers should excessive lateral movement or loading occur (such as abnormal wave loading).

Arup did not identify a failure mechanism warranting replacement in ‘normal/calm conditions’, however a recommended 6 monthly inspection regime (to monitor the observed defects) has been implemented.

## **7.2 Detailed Design**

The detailed design of the replacement structures focused on re-using the existing piles. Minimal signs of deterioration was observed and demonstrated via testing including assessment of the chloride concentrations. To provide lateral capacity for wave loading, it was decided to adopt a superstructure design consisting of a new reinforced concrete headstock, which supports concrete deck units with a dowel detail designed for the expected movements and loads. This design allowed for a minor improvement of the durability as the soffit of the deck units were raised as much as possible (over 0.5 m higher than the soffit of the existing beams) to be clear of Mean High Water Spring tide level. As the replacement design was ‘like for like’ the basis of design did not include vessel berthing, which means retaining and refurbishing the existing independent fender piles.

The deck alignment was optimised to provide DDA compliance while re-instating the original deck level at the vessel access location. The detailed design was completed in 2014 and this construction work can be tendered by Council when required.

## 8. Conclusion

Over the years, Council and Arup's main objectives have been for the public to continue to safely enjoy this local community icon while adopting a long term value for money maintenance/upgrade strategy.

Having been involved with repairs, maintenance and serviceability for the Redcliffe Jetty over 15 years has provided the opportunity to learn a number of valuable lessons. Specific aspects include:

- To consider the complex movements and forces arising at half joints and other joints.
- To consider piling and other tolerances for pile caps, other bearing joints and dowel details.
- To consider avoiding details with precast supported directly on precast.
- To consider the durability of the key structural members. These concrete members are currently generally in a fair to good condition given the age and exposure to the marine environment.
- To consider and challenge failure mechanisms when observing visible defects and making decisions on load rating.
- The owner of the jetty structure is left with some inherent risks, which while partially mitigated still exist and have to be managed while the jetty is in service.
- In general, marine structures are likely to benefit from preventative maintenance work every 10-15 years with a view of extending the residual life.

Many people have contributed to projects relating to the Redcliffe Jetty over the years. The author thanks everyone involved and for the opportunity to deliver such challenging projects.

# Design of FRP retrofitted concrete structures using AS5100 Part 8

Binh Pham<sup>1</sup>

<sup>1</sup>Principal Structural Engineer, AECOM

**Abstract:** The increasing need to repair and strengthen existing bridges has led to the introduction of AS 5100 Part 8 “Rehabilitation and strengthening of existing bridges”. This standard will cover a range of topics relating to rehabilitation of concrete, steel, timber, and masonry. Appendix A of AS 5100 Part 8 will cover strengthening of reinforced and prestressed concrete structures using fibre reinforced polymer composites (FRP). The Appendix is still going through revisions but it will be a state-of-the-art guide which will address some critical issues with the international design guides that has been used in Australia. It might be possible there would be a surge in the use of this technique in Australia after the release of the code. This paper explains the principles of the new design standard to design FRP strengthening for bending, shear, torsion, and axial actions.

**Keywords:** FRP, strengthening, bridges.

## 1. Introduction

The Standards Australia working group BD-090-08 have been developing a new AS5100 Part 8 to cover rehabilitation and strengthening of existing bridges. Appendix A of AS 5100 Part 8 will cover strengthening of reinforced and prestressed concrete structures using fibre reinforced polymer composites (FRP). The Appendix is still going through revisions but it will be a state-of-the-art guide which will address some critical issues with the international design guides that has been used in Australia.

This paper presents the background and the principles behind Appendix A of AS5100 Part 8. The focus of this paper is on Sections A6 to A10 that cover the design aspects for FRP strengthening.

## 2. Design principles

The basic design principles for an FRP-strengthened element follow those of AS5100.1, AS5100.5 and AS5100.7.

Similar to ACI440 (2), a minimum strength requirement for un-strengthened members is included to ensure that the existing structure without FRP has a nominal strength for the scenarios of accidental loss of FRP.

## 3. Flexural strengthening

### 3.1 Basic principles for strengthening in bending

The principles of the analysis of a reinforced or prestressed concrete section strengthened with FRP under bending are similar to those of a ‘normal’ reinforced or prestressed section, i.e. basing on equilibrium and strain-compatibility conditions with an assumption that plane sections normal to the axis remain plane. In the ‘disturbed’ regions where the plane sections do not remain plane, other analysis and design methods might be used. The bond and anchorage of FRP shall be investigated in all cases.

One fundamental difference between a ‘normal’ reinforced/prestressed section and a section strengthened with FRP is that in most practical cases the ultimate load capacity is achieved not when the concrete top fibre strain reaches its limit but when the FRP strain reaches its bonding limit. As a result, the design of FRP strengthening for concrete members requires that concrete top fibre strains, steel reinforcement strains, and FRP strains are tracked through different load cases and different stages of section build-up. It is worth noting that FRP is often applied after permanent loads have been applied and calculation of strains shall take that sequence into account.

While formulas for a singly reinforced rectangular section are provided in the standard, in practice, formulas for bridge members are not possible due to the complexity of the section shape and construction

sequences. For example, the strengthening of a super-T bridge beam will involve analysing the beam sections at transfer, casting of deck slab, casting of barriers and installation of surfacing, service conditions and ultimate conditions. This can require a number of iterations.

Effects of creep and shrinkage on the behavior of FRP strengthened sections are often insignificant.

It is often necessary to define the concrete stress-strain curve in the analysis of a FRP strengthened section. The curve defined in Section 3 of AASHTO (1) can be adapted.

### 3.2 Strength limit states

It is fundamental the designer understands the failure modes that might occur in a FRP strengthened beam. Compared to a 'normal' reinforced beam, there are much more failure modes (5). All of these modes shall be accounted for in the design.

Figure 1. Summary of failure modes for members strengthened with FRP in flexure

Ductility and capacity reduction factors for FRP strengthened members are treated differently in international design guides. While FRP debonding or FRP rupture can occur in a brittle manner, experiments have shown that FRP strengthened beams resume their original strength and ductility after FRP debonding/rupture. Therefore, as long as the un-strengthened beam is ductile, i.e. it shows adequate warning prior to total collapse, a capacity reduction factor of 0.8 for bending can be adopted. Capacity reduction factors for shear are as defined in AS5100.5.

Guidance for FRP debonding is provided in Section A7.3.5.2 to A7.3.6.3 of the standard. The formula to calculate the FRP strain limit for IC debonding is based on the work by Teng et al. (7). This formula is adapted in ACI440 (2) and has been validated by Pham and Al-Mahaidi (5). For near surface mounted FRP strengthened beams, this limit is often higher due to larger bond area. The limit used in ACI440 (2) for near surface mounted FRP has been adapted in AS5100.8.

The formula to calculate the shear stress limit for end debonding (cover separation and end interfacial debonding) is based on Pham and Al-Mahaidi (6) and other research groups in the United State. This formula is adapted in AASHTO (1). To avoid FRP debonding caused by a high beam shear force, the factored shear force at the termination point of the FRP is also limited to two third of the shear strength of the section ( $V^* > 0.67V_u$ ).

The limits for serviceability are adapted from ACI440 (3) and AASHTO (1). The fatigue stress limit for carbon fibres is 55% of its strength. The fatigue stress limits for glass and aramid fibres are much lower.

FRP strengthening for bending is generally effective for non-composite reinforced or prestressed sections. The maximum percentage increase in bending capacity ranges from 20 to 60% for these sections. The controlling failure is often FRP debonding. The steel strain at ultimate varies but tends to be around 0.005 for reinforced sections and 0.010 for prestressed section.

FRP strengthening for bending is generally not very effective for pretensioned composite girders. The maximum percentage increase in bending capacity is typically less than 10% for these girders. For these girder sections, the fact that the neutral axis is typically close to the top fibre and the effect of construction sequencing lead to FRP reaches its debonding limit while the top concrete fibre strain is still low. For these sections, using thinner FRP and increasing bond areas would improve the strength enhancement. The enhancement is particularly small for highly reinforced and highly prestressed sections.

#### 4. Shear and torsional strengthening

The design of a reinforced or prestressed concrete beam strengthened with FRP in shear and torsion is covered in Section A8 of AS5100 Part 8. Compared to a 'normal' concrete beam, the shear capacity of a strengthened beam has an additional item,  $V_{uf}$ , which accounts for the contribution from FRP.

$$\phi V_u = \phi(V_u + V_{us} + P_v + C_E V_{uf}) \quad (1)$$

The expressions used to calculate the portion of the shear resistance contributed by FRP laminates,  $V_{uf}$ , are based on ACI440 (2).  $V_{uf}$  depends a great deal on the effective strain,  $\varepsilon_{f,e}$ , in the FRP, which is limited to 0.4% to account for stress concentrations or FRP debonding. For FRP not completely wrapped, the effective strain can be lower.  $C_E$  is the environmental reduction factor to take into account the environmental effects on FRP properties.

Figure 2. Examples of shear strengthening

Compared to a 'normal' concrete beam, the torsional capacity of a strengthened beam has an additional item,  $T_{uf}$ , which accounts for the contribution from FRP.

$$\phi T_u = \phi(T_{us} + C_E T_{uf}) \quad (2)$$

The expressions used to calculate the portion of the torsional resistance contributed by FRP laminates,  $T_{uf}$ , are based on Hii and Al-Mahaidi (3).  $T_{uf}$  depends a great deal on the effective strain,  $\varepsilon_{f,\theta}$ , in FRP which is dependent on the FRP modulus and FRP reinforcement ratio.

## 5. Axial strengthening with FRP confinement

By confining a concrete column with FRP, its ultimate strength in compression and in combined compression and bending can be improved. The improvement is resulted from higher confined concrete strength,  $f'_{cc}$ . Lam and Teng's stress-strain model (4) for FRP confined concrete was adapted in ACI440(2) and in AS5100 Part 8.  $f'_{cc}$  is dependent on the confinement pressure and the strain efficiency factor. FRP wrapping is most effective for circular sections.

Figure 3. Typical stress strain curve for confined concrete (ACI-440 (2))

Figure 4. Example of interaction diagrams

## 7. Conclusions

Appendix A of AS 5100 Part 8 will cover strengthening of reinforced and prestressed concrete structures using FRP. The Appendix will be a state-of-the-art document which will provide practical and detailed guidance to design and construct FRP debonding. Designing FRP strengthening requires clear understanding of the system and how it behaves at both service and ultimate limit states.

# Investigation of Corrosion, Repair Assessment and Quality Assurance of a Basement subject to Saline Water Ingress

Jonathon Dyson, NSW Manager, BCRC; Marton Marosszeky, Director, BCRC; Frank Papworth, Director, BCRC

**Abstract:** Seawater penetration around the perimeter of a basement was leading to premature reinforcement corrosion in the boundary walls, adjacent internal beams, columns and slabs. An investigation was undertaken to determine the extent of repairs and develop a suitable repair approach. A key issue was that these repairs early in the life of the structure had to account for deterioration that might occur over the following 40 year life of the structure. Hence even though in some areas corrosion may not yet have commenced, issues of chloride penetration that might cause future corrosion had to be addressed. The exact extent of repairs and detail of the repair methods was determined during the repair management phase. Further extensive wet chemical analysis of chlorides based on cores was going to be both expensive and time consuming, hence the more detailed assessment of chloride penetration across the structure was completed on site using a calibrated silver nitrate colourimetric test. This paper discusses this method and provides reasons for the criteria adopted for the determination of remediation strategies including the extent of cathodic protection required.

**Keywords:** chlorides, profile, diffusion, concrete, corrosion, testing, silver nitrate, colourimetric, repair

## 1. Introduction

Seawater penetration around the perimeter of a reinforced concrete basement was leading to premature reinforcement corrosion in the boundary walls, adjacent internal beams, columns and slabs.

An investigation was undertaken to determine the extent of repairs and develop a suitable repair approach. A key issue was that these repairs early in the life of the structure had to account for deterioration that might occur over the following 40 year life of the structure. Hence even though in some areas corrosion may not yet have commenced, issues of chloride penetration that might cause future corrosion had to be addressed.

Initial methods employed included a combination of visual examination of concrete and reinforcement, laboratory analyses to determine total chloride ion (Cl<sup>-</sup>) profiles from core samples, half-cell potential measurements, cover meter surveys and carbonation testing. This identified that future corrosion issues were primarily associated with chloride ingress around the perimeter of the structure.

This paper discusses the investigation and testing methodologies employed and focusses primarily on the silver nitrate spray method used in field testing to assess chloride ion ingress into the concrete structure, the basis upon which test results were interpreted and how they informed the development of the cathodic protection (CP) scope of works.

## 2. Preliminary investigation

Initially a preliminary program of inspection and testing was completed to gain an understanding of the most likely causes of concrete deterioration and reinforcement corrosion.

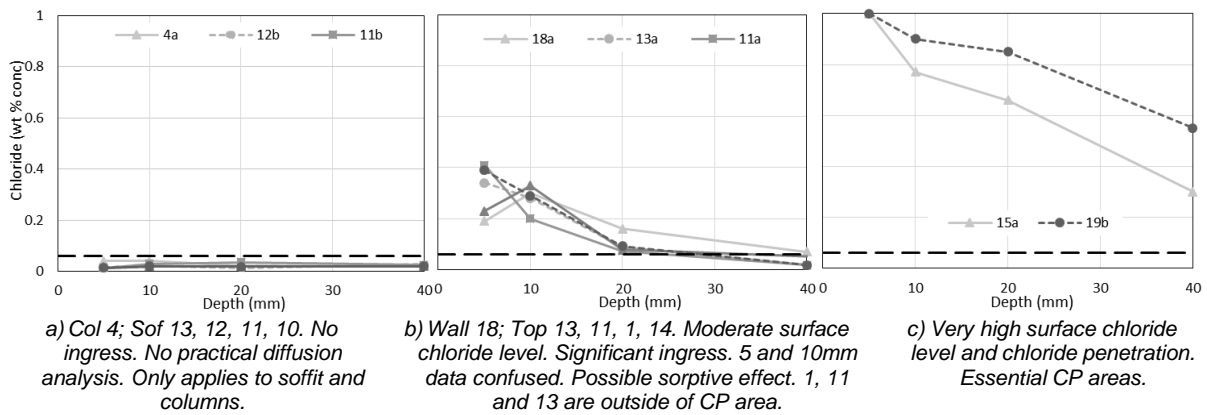

### 2.1. Chloride profile testing

Cores were extracted from various elements of the structure for laboratory analysis of chloride ions at several depth levels below the surface. The results were used to plot chloride profile curves.

The chloride profile plots were grouped into five categories (very low, low, medium, high, very high) to assess patterns of exposure. The “very low” category (*Figure 1(a)*) showed that there were areas of no contamination. It also gave a reasonable estimate of the base chloride level and showed that the original chloride level of the concrete was within code limits. Conversely, in some areas chlorides were very high. The surface chloride level of 1% by weight of concrete (approx. 6% by weight of cement), as shown in *Figure 1(c)*, is equivalent to a severe splash zone exposure.

### 2.2. Other testing (carbonation, half-cell potential, cover survey, visual survey)

Several other inspection and testing techniques were utilised during the preliminary investigation. Firstly, an overall visual forensic survey was completed to assess visual damage to the structure and begin to establish the possible causes of such damage.

**Figure 1** Three of the five different categories of surface chloride exposure found during results analysis.

Carbonation testing on extracted test cores was completed using a 1% phenolphthalein sprayed solution (pH indicator). This determined that for all elements only a small depth of concrete surface layer had been carbonated. Carbonation modelling was completed using a simple root time equation (Equation (1)) and from this it was predicted that the carbonated layer was unlikely to reach the level of steel reinforcement within the 50 year design life except in a few locations where concrete cover was very low.

$$D_c = k(t)^{1/2} \quad (1)$$

Also completed at selected locations were: half-cell potential surveys to assess corrosion risk, cover meter surveys to assess the reinforcement cover distribution, physical measurements of reinforcement cover at certain core locations (to verify cover readings) and visual condition assessments of exposed reinforcement (**Figure 2**).

**Figure 2** As part of the preliminary and subsequent investigations reinforcement was exposed for visual condition assessment. The bar in the left photo showed only slight superficial corrosion whereas the bar coincident with a crack in the right photo showed advanced corrosion.

### 2.3. Preliminary investigation findings

From the preliminary investigations it was determined the primary cause of distress was chloride-induced corrosion of the steel reinforcement in the concrete resulting from seawater inundation. The proliferation of both plastic and drying shrinkage cracks as well as low reinforcement cover in certain locations was found to have assisted in accelerating the structure's deterioration locally but was not the prime issue.

### 2.4. Preliminary CP extent

A preliminary extent of CP was estimated based on the limited initial investigations, in particular, visual confirmation of seawater inundation extent by recording wet areas & staining and chloride depth profile curves from a representative number of test locations around the structure. If a total chloride ion concentration of greater than 0.035% by weight of concrete at the reinforcement depth was observed, the general area was designated as requiring CP as a minimum. This 0.035% criterion was agreed as it was predicted via modelling this would equate to a 0.06% (by concrete weight) Cl<sup>-</sup> concentration at

the reinforcement after 50 years assuming the surface chloride level drops over time as further inundation is prevented and residual chlorides penetrate inward. 0.035% is also approximately equal to the chloride level permitted in AS 1379 [1] for new concrete.

The high chloride levels at reinforcement depth and significant cracking and spalling led to the conclusion that in order to achieve the design life with a normal reliability and minimal future additional disruptive repair CP would be required. Due to the limited extent of testing at this stage the minimum CP extent defined from preliminary tests was to be better detailed following a more extensive program of targeted chloride testing and additional cover surveys.

### 3. Detailed investigation

A second more extensive round of chloride testing was undertaken to confirm the extent of the CP scope of works, ensuring the carpark structure would achieve its 50 year design life while limiting the remedial works to only what was necessary on the basis of modelling. Because this further testing took place in parallel with the repair works, laboratory testing was not feasible (results would take too long). A quick, on-site, colourimetric test method was developed to assess the depth of chloride ion penetration into the concrete.

#### 3.1. Chloride field test method options review/feasibility study

From an initial review of field chloride testing options the authors quickly concluded a silver nitrate spray (colourimetric) test method warranted further investigation to determine its feasibility for this application. The colourimetric method involves spraying an aqueous silver nitrate ( $\text{AgNO}_3$ ) solution, typically 0.1mol/L, on a freshly fractured cross-section of concrete. The silver ions react with the free chloride ions in the concrete to form a white precipitate of silver chloride on the tested surface. When the free chloride ions in the concrete are below a certain concentration, the silver ions instead react with the hydroxyl ions, forming a brown precipitate of silver oxide from immediate decomposition of silver hydroxide. The obvious colour boundary represents a specific concentration of free chloride ions in the concrete.

**Table 1** Comparison of chloride concentration at colour change border for silver nitrate spray tests found by various researchers. This demonstrates the  $C_b$  value varies when using one set of materials let alone from project to project, showing project calibration as a minimum is required.

Researcher	Chloride % at colour border ( $C_b$ )				Comment
	Free (water soluble) chloride		Total chloride		
	Wt % Cem.	Wt % Conc.	Wt % Cem.	Wt % Conc.	
Yang, et al. [3]	Total chloride at the colour change roughly twice that the free chloride				
Otsuki, et al. [4]	0.15				Constant for pastes, mortars and concretes with varying w/c ratios
Kim, et al. [5]		0.045			Sprayed with a 0.1mol/L silver nitrate
Andrade, et al. [6]				0.18 ± 0.2%	
Sirivivatnanon & Khatri [7]	1.2%				Range 0.84% -1.69%
Meck & Sirivivatnanon [8]	0.9%	0.12%			Range 0.28% -1.41% for investigated concretes with different binders.

Chlorides in concrete can be either free chloride ions or combined chloride ions in Friedal salts (bound chlorides). The acid soluble chloride method used for assessing the chloride concentration in concrete in this project detects total (free + bound) chlorides present while in the colourimetric test the silver nitrate reacts only with free chlorides. The free to total chlorides ration is known to vary depending on circumstances. The Transportation Research Board [2] showed it could be as high as 0.8. Hence the two test methods will not always coincide. The total and free chloride ion concentration represented by the colour change boundary in the colourimetric method has been the subject of much research as shown in **Table 1**.

The considerable variation in the  $\text{Cl}^-$  concentration represented by the colour change boundary ( $C_b$ ) in literature may be the result of many factors. For example, the concentration of  $\text{AgNO}_3$  solution and the amount of solution sprayed on the exposed face have both been found to impact the value of  $C_b$  [9]. Others, though, found that different solution concentrations (0.05mol/L and 0.1mol/L) consistently produced almost the same diffusion coefficient when compared across concrete mixes with varying w/c ratios [5]. Because the colourimetric method involves a chemical reaction, varying chemistry of the concrete pour solution between different concrete mixes (e.g. with and without SCMs) likely contributes to variation in the value of  $C_b$ . In particular silica fume, by decreasing the hydroxyl ions in the concrete pore solution by an order of magnitude, may also decrease the  $C_b$  value similarly [10]. This was observed by Andrade, et al. [6]. From a review of the test results of Hamilton III, et al. [11] the authors deemed that inclusion of fly ash in a concrete mix (as in our case) appears not to significantly alter  $C_b$ .

The pH of the concrete has been found to affect the  $C_b$  value. Kim, et al. [5] suggest the colourimetric method is not appropriate when the concrete pH is lower than about 10 or 11 and when carbonation depth is lower than the colour change boundary depth (not an issue in our case). The water/cement ratio (w/c) has also been found to affect the  $C_b$  value, with a higher w/c coinciding with the colour change boundary occurring at a lower  $\text{Cl}^-$  concentration [9]. However, other researchers [5] found varying the w/c ratio had no effect on the value of  $C_b$ . It is also plausible that different test locations with the same concrete mix may have varying  $C_b$  values simply due to the inhomogeneous nature of concrete.

The above demonstrates the variability of the chloride concentration at the colour change boundary. Because of this uncertainty, BCRC conducted a program of trial field tests, calibrating the colourimetric test results against chloride diffusion curves (Figure 3) developed from laboratory analyses of existing and new cores to identify from the chloride depth profiles the average chloride concentration at the colour change boundary for this building.

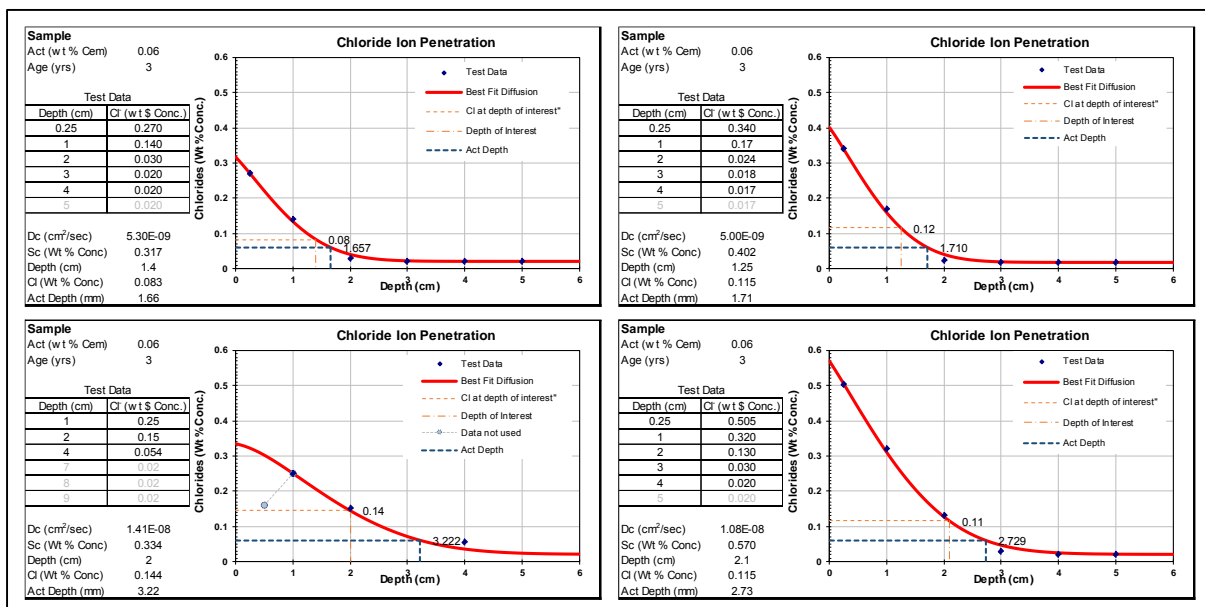

Figure 3 Example best fit diffusion curves developed from BCRC modelling.

### 3.2. Silver nitrate colourimetric test method calibration

Because the  $\text{AgNO}_3$  solution concentration might affect the value of  $C_b$ , it was decided to trial two different solution concentrations - 0.05mol/L and 0.1mol/L – during calibration testing. One solution type would be sprayed on each of the two freshly fractured faces for each calibration core.

The sprayed amount of  $\text{AgNO}_3$  solution may also affect the value of  $C_b$ . It has been suggested that an ideal amount of solution sprayed onto the exposed concrete test surface is a rate of about 0.015g  $\text{AgNO}_3/\text{cm}^2$  [9]. Given the discrepancy between studies as to the value of  $C_b$ , it was important to be consistent in the amount of solution sprayed in each test and to determine the approximate value of  $C_b$  this same amount represented through calibration testing.

The first step in tailoring the test method for this application was to determine the amount of solution imparted per spray in order to calculate the number of sprays required on each test surface. This was done as follows:

1. A decent quality plastic spray bottle suitable for chemical solutions was sourced.

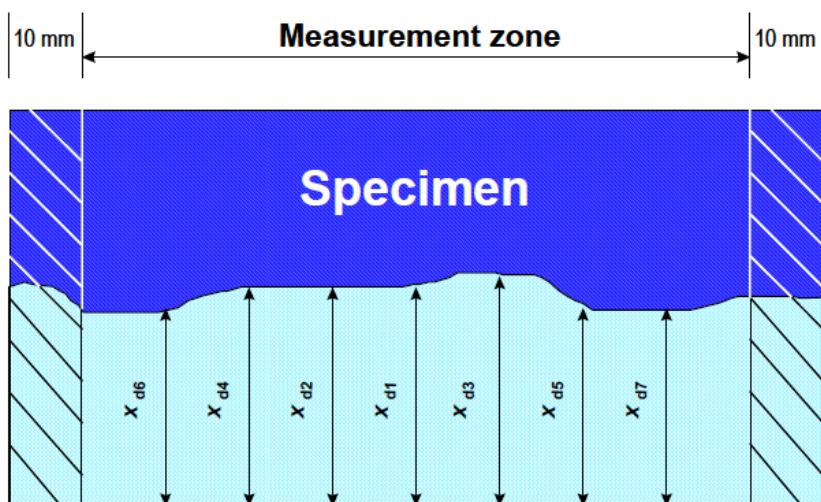

2. A spare dry concrete core was placed on reasonably high precision digital scales and the scales were zeroed.
3. The average weight of solution (water was used in testing) per spray onto the core from a distance of approximately 50-75mm away was calculated over several tests. The core surface was allowed to “dry out” and the scales re-zeroed prior to each further test.

The average weight of aqueous solution imparted onto the core per spray was calculated as 0.09 grams.

The test procedure (detailed in **Additional field chloride testing and cover survey**) included measuring the test surface area (A) and calculating the number of sprays (N) of solution required:

$$N = A \times 0.015g/cm^2 \div 0.09g \quad (2)$$

Nine calibration cores were sampled adjacent to previous lab tested cores. To assess the effect of time between chloride profile development and colourimetric trial testing, three more calibration cores for spray testing were sampled next to three newly lab tested cores. All cores were sampled from slab elements ensuring all calibration tests had the same concrete mix.

**Figure 4** Colour change boundary depth measurement procedure.

The calibration cores were rinsed of slurry, allowed to dry out (on the surface) then split and sprayed on their freshly fractured faces. For each core, one face was sprayed with 0.1 mol/L AgNO<sub>3</sub> solution and the other with 0.05 mol/L solution. The mean colour change boundary depth was measured at 15 mins and again at 24 hours to assess the effect of time on the C<sub>b</sub> value.

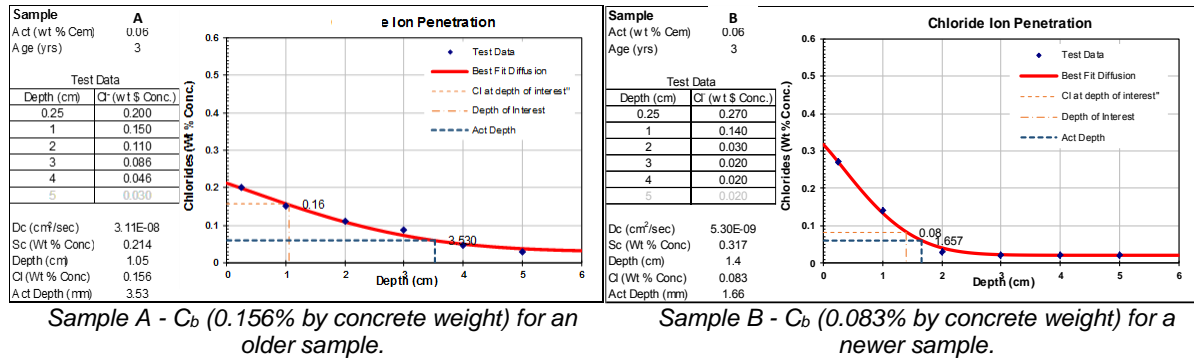

For each measurement, 7 depth readings were taken across the width of the test area and averaged (**Figure 4**), following the procedure detailed in NT Build 492 [12]. If the penetration front was obviously affected by a piece of aggregate, that particular measurement was either relocated or ignored. No measurements were taken within the 1cm or so wide zone at each edge to obviate the potential distortion of results near the external surface of the core from exposure to water during coring and rinsing.

Modelling was completed to plot best fit diffusion curves for the chloride profiles of the adjacent lab-tested cores. Diffusion was calculated based on Fick's 2nd Law of Diffusion with a constant diffusion coefficient and no allowance for sorption effects. This gave a reasonably accurate estimate of the current depth of the selected threshold value and a conservative value of the time to the activation front reaching the reinforcement. The modelling results showed:

- a) The high variation in chloride profiles from location to location, demonstrating the high variation in exposure severity.
- b) In some cases (for example the bottom left curve in **Figure 3**), the chloride concentration measured near the surface did not correlate with a diffusion analysis whereas the deeper measurements did. This may be due to sorption effects near the surface or an irregular surface chloride load (e.g. a short period of high surface chloride exposure followed by a period of low surface chlorides).
- c) The diffusion coefficients varied significantly (from 2 x 10<sup>-8</sup> to 67 x 10<sup>-8</sup> cm<sup>2</sup>/sec.). The variation is likely to be due a combination of variation in mix, placing, curing and exposure.

For each test, the average colour border depth was then overlayed with the appropriate calibration diffusion curve and the chloride ion concentration estimated from the curve (**Figure 3**).

The average  $C_b$  value for all test results was then determined for both the 15 minute and 24 hour measurements. In estimating the “average”  $C_b$  value, the authors gave more weight to the calibration results from the newly lab-tested chloride profile curves on the assumption that calibrating against these was more accurate than calibrating against the older chloride profile curves. The newer calibration curves indicated a lower value for  $C_b$  than the older curves (**Figure 5**). The “average”  $C_b$  value will be referred to hereafter more accurately as the weighted average  $C_b$  value.

**Figure 5** Typical examples of  $C_b$  values derived from calibration against chloride profiles.

The colour change boundary depth was observed on average to be greater after 24 hours than after 15 minutes (**Figure 6**). This suggests that over time following spray application the value of  $C_b$  decreases (assuming a typical chloride diffusion profile for the concrete). This is consistent with Aoki, et al. [9] who also observed in their experiments the colour change boundary depth increasing with time albeit at a decreasing rate. Because of this it was important to consistently take colour border depth measurements at the same amount of time after spray application in the field testing. A 15 minute interval between spray application and colour change boundary depth measurement was included in the testing procedure.

It was concluded from analysis of the calibration test results against the lab test derived chloride diffusion curves that there was a small difference in the weighted average value of  $C_b$  between the two  $AgNO_3$  solution concentrations trialled. The weighted average  $C_b$  was calculated as about 0.08%  $Cl^-$  (by conc. weight) for the 0.05mol/L solution and 0.1%  $Cl^-$  (by conc. weight) for the 0.1mol/L solution. It was decided to use the 0.1mol/L solution in field testing because it was easier to source this concentration of solution and more research data exists relating to experiments at this concentration.

**Figure 6** The colour change boundary 24 hours after  $AgNO_3$  spray application is deeper than after 15 minutes.

To assure the service life for the structure, the level of free chloride ions at the reinforcement ( $C_R$ ) in the concrete at 50 years should be less than 0.06% by weight of concrete (0.4% by weight of cement), the widely accepted threshold at which reinforcement corrosion is predicted to initiate. From the modelling it was determined that to satisfy the  $C_R < 0.06\%$  (by weight conc.) at 50 years criterion,  $C_b$  at approx. 8 years (concrete age at time of field testing) should not occur deeper than 60% into the cover concrete layer above the steel reinforcement.

The authors believe there is inherent conservatism in the above detailed approach due to the use of a constant chloride diffusion coefficient ( $D$ ) and surface chloride concentration ( $C_o$ ) in the Fick's 2<sup>nd</sup> Law based modelling. In reality the observed diffusion coefficient typically reduces with time [13] and, due to repairs implemented to remove chlorides from the slab and slow the rate of seawater intrusion to the basement, the future surface chloride load will be significantly reduced from that assumed in the modelling.

### 3.3. Additional field chloride testing and cover survey

With calibration of the colourimetric field test method complete, testing was completed as per the following procedure. Example colourimetric test specimen images are included in **Figure 7**.

1. Core locations were planned to enable the final extent of CP to be adequately defined based on a sound understanding of the extent of chloride ion penetration into the structure.
2. Reinforcement was located at each core location using non-destructive techniques. Core locations were then finalised and marked on the slab. Most cores were located to miss reinforcement however some cores were located above reinforcement to allow further visual assessment of reinforcement condition. Some cores were located on cracks while others were located away from cracks. This was to assess the effect cracks had on chloride ion ingress into the structure and steel reinforcement corrosion.
3. A cover survey was completed in the vicinity of each core location to assess the minimum cover to top steel.

**Figure 7** Example colourimetric test specimens showing increasing depth of chloride ion penetration from left (no white precipitate, all brown i.e. no colour change border) to right.

4. Cores were extracted. Cores were typically approx. 60mm diameter and varied in length from 20mm to about 100mm.
5. The external surfaces of the cores were rinsed of slurry to minimise contamination of the test surfaces when the cores were split.
6. Cores were numbered and the core number and location noted on a series of colourimetric testing drawings.
7. Cores were split using a bolster and the fresh split faces of the cores were immediately sprayed with 0.1mol/L silver nitrate solution. The amount of solution sprayed on each test area was determined by measuring the area of the exposed internal surface of the core and calculating the number of sprays of solution required using Equation (2). Cores taken on cracks were initially split along the crack, then split again perpendicular to the crack to end up with four segments. All internal fresh split faces were then sprayed (**Figure 8**).
8. Time of spray application was noted and the depth of colour change boundary measured, recorded and photographed approximately 15 minutes after spray application.
9. Relevant test data such as the average ( $d_{b,a}$ ) and maximum ( $d_{b,m}$ ) colour change boundary depth and the minimum cover to reinforcement ( $c$ ) was recorded in a test results spreadsheet.

10. A formula was included in the spreadsheet to calculate whether  $d_{b,a}$  and/or  $d_{b,m}$  were greater than  $0.6c$ , meaning the structure at the test location should be cathodically protected in accordance with the previously established criterion. This is discussed further in Section **CP extent**.

### 3.4. CP extent finalisation

A set of colour-coded chloride test result drawings was produced to assist in finalising the extent of cathodic protection. Colourimetric test results were marked on the drawing in their location in one of three colours: red ( $d_{b,a} > 0.6c$ ), amber ( $d_{b,m} > 0.6c \geq d_{b,a}$ ) or green ( $0.6c \geq d_{b,m}$ ).

Initial lab chloride test results were also included on the drawings using the same colour coding scheme. For the initial lab test results the colour coding criteria related to the level of total chloride concentration (% by concrete weight) at the reinforcement depth ( $C_r$ ) and were: red ( $C_r > 0.06\%$ ), amber ( $0.06\% > C_r \geq 0.035\%$ ) or green ( $0.035\% \geq C_r$ ).

**Figure 8** Example colourimetric test specimens at cracks showing deeper chloride penetration locally at the cracks.

Red test locations indicated CP was required and green locations indicated CP was not required. For amber test locations engineering judgement and consideration of various other factors was used to decide whether CP was required or not in each individual case. For example, for colourimetric tests completed at cracks,  $d_{b,m}$  at the crack would often be significantly larger than  $d_{b,a}$  when calculated from, say, 5mm away from the crack to the other edge of the test area (**Figure 9**). However although  $d_{b,m}$  at the crack was often high, studies have shown there is lower risk of reinforcement corrosion propagation resulting from chloride-transporting cracks that intersect rather than coinciding with a line of reinforcement [14]. Other factors considered included, for example, proximity to other “red” test results, proximity to the harbour side building edge, the extent to which  $d_{b,m}$  was greater than  $0.6c$ , how far the deeper chloride penetration extended away from the crack face and the comparative penetration depth of  $d_{b,a}$ .

Initial colourimetric test cores were located along the boundaries of the preliminary CP extent to confirm whether this CP extent was appropriate. Further rounds of field testing were completed where results from previous testing indicated CP was required but the boundary of CP extent could not yet be defined due to there being insufficient “green” test locations. Such further rounds of testing were conducted until the full extent of CP was able to be confirmed and finalised.

## 4. Benefits and drawbacks of the method

The key strengths of the silver nitrate spray test method are its simplicity, speed, comparatively small cost and practicality for use in the field. In this application, use of the method meant a fast (almost instantaneous) turnaround between testing and results, allowing the CP extent to be finalised much quicker than if laboratory testing was relied upon. This was a necessity considering the detailed investigation phase occurred at the same time as the completion of repairs.

The method does have some potential drawbacks that must be considered when assessing its suitability in any given situation. These include:

- The wide variation in the  $C_b$  concentration represented by the colour change boundary reported in the literature and the need to perform calibration testing to determine the likely  $C_b$  value in each unique situation.
- The method not being suitable for use in situations requiring high precision results, even when calibrated, due to the many previously discussed factors possibly affecting the value of  $C_b$  in each

unique test. Having said this, most field test methods are not suitable where high precision is required anyway, because less control during testing can be achieved than in a laboratory.

- Its unsuitability for use on carbonated concrete.

**Figure 9** Typical example of deeper chloride ion penetration at a crack face quickly reducing to shallower ingress away from a crack.

## 5. Conclusion

A two-stage investigation of a reinforced concrete basement was completed to determine the extent of damage and develop a suitable repair approach to achieve the 50 year service life. Initial methods employed included a combination of visual examination of concrete and reinforcement, laboratory analyses to determine total chloride profiles from core samples, half-cell potential measurements and carbonation testing.

Subsequently, a silver nitrate spray field test method to quickly and more extensively assess chloride penetration into the concrete elements and thus refine the preliminary cathodic protection scope of works was researched. It was concluded the method would be appropriate for use in the project context, provided it was calibrated to more accurately estimate the free chloride ion concentration represented by the colour change boundary given the high variation reported for this value in published literature.

Trial colourimetric tests were completed on the internal (freshly exposed) surfaces of a number of split test cores. The depth of the colour change boundary was calibrated against chloride profile diffusion curves developed from adjacent laboratory analysed test cores to determine the likely chloride ion concentration represented by the colour border. It was concluded that when the colour change border depth was measured 15 minutes after the test surface was sprayed with a 0.1 mol/L  $\text{AgNO}_3$  solution, the weighted average chloride concentration at the colour border was 0.1% by weight of concrete. From modelling on the basis of this value it was concluded that if the average colour change border depth for a test specimen was greater than 60% of the minimum concrete cover depth in the vicinity of the test location, the structure surrounding the test location required cathodic protection. This assumed reinforcement corrosion could commence once a chloride ion concentration of 0.06% (by concrete weight) occurred at the level of the reinforcement.

Following calibration of the method, a field colourimetric testing procedure was developed and iterations of testing were completed until the extent of CP works was finalised.

## 6. Acknowledgements

The authors would like to thank all project stakeholders for their cooperation and for allowing the publication of this paper.

**Abstract:** Carbon Fiber Reinforced Plastic (CFRP) grid is usually used for strengthening of existing concrete structures. This is made by several layers of vertical and horizontal CFRP bars by means of pressing and adhesion. To investigate the behaviour between the CFRP grid and mortar comprehensively, three kinds of tensile tests of the vertical bar are conducted: (1) under bond condition with crossing section; (2) under no-bond condition with crossing section; (3) under bond condition without crossing section. Types of CFRP grids (CR5, CR8, CR13), grid interval (50mm, 100mm) and number of grid nodes (1, 2, 3) are selected as changing parameters. Based on experimental results of 135 pieces of pull-out specimens, influence rules of types of CFRP grids, grid interval and number of grid nodes on anchorage performance of CFRP grids in the mortar are analyzed. In addition, influence factors on the tensile strength utilization of CFRP grid, maximum tensile load growth gradient with increasing number of nodes, anchorage mechanism are discussed.

**Keywords:** CFRP grid, mortar, anchorage performance, tensile strength, pull-out test

## 1. Introduction

Concrete structure is one of most common structure in the world. As we know, many existing concrete structure have reached their planned service life. In order to enhance the safety of these structures, strengthening is necessary. Strengthening method by using sprayed polymer mortar and Carbon Fiber Reinforced Plastic (CFRP) grids has been applied in Japan.

For this strengthening technique, to ensure the oneness of CFRP grid, mortar and existing concrete is very critical. In the past, a lot of researchers studied the bond behaviour between base concrete and repairing material (Uji et al (2007), Ohno et al (2011), Zhang et al (2012, 2013)). Only several researches on bond behaviour between CFRP grid and mortar have been carried out (Sugiyama et al (2011)). The main purpose of this paper is to study the anchorage behaviour of the CFRP grid in the mortar comprehensively. Based on the initial analysis, it is clarified that anchorage actions between CFRP grid and the mortar could be divided into two parts: one is the resistance action of the horizontal bar in crossing section; the other is bond action between the vertical bar and the mortar. In order to investigate the behaviour between CFRP grid and mortar, three different anchorage conditions are conducted and a total of 135 pieces of specimens are fabricated to make pull-out tests.

## 2. Experimental Programs

### 2.1 Test specimens

Three kinds of pull-out tests (be equivalent to three kinds of anchorage conditions) of the vertical bar are conducted: (1) under no-bond condition with crossing section (abbr.: NBW); (2) under bond condition without crossing section (abbr.: BWO); (3) under bond condition with crossing section (abbr.: BW). Types of CFRP grids (CR5, CR8 and CR13), grid interval (50mm, 100mm) and number of grid nodes (1, 2, 3) are selected as changing parameters. Three identical specimens were manufactured for each specimen design. The total number of specimens is  $5$  (grid type and interval)  $\times 3$  (number of nodes)  $\times 3$  (anchorage condition)  $\times 3$  (sample), which is equal to 135.

No-bond condition is realized by wrapping tap around the vertical bar. Take CR8@50 for example, the fabricated grids corresponding to three different anchorage conditions are shown in Figure 1. Steel pipe (internal diameter is 93.2mm; thickness is 4.2mm) is applied to be the pouring mould as well avoiding the fracture of the mortar before the fracture of CFRP grid during the test. Figure 2 shows the pouring device of mortar and representative fabricated specimen.

Take the specimen with three nodes as example (abbr.: NBW-3, BWO-3, BW-3), dimensions are shown in Figure 3. To decrease the influence of inaccurate stress state of the mortar near the loading part when considering the bond action of vertical bar (BWO-type condition and BW-type condition), 30mm-length no-bond parts are conducted by using waterproof material as shown in Figure 3 (b) and (c). For dimensions corresponding to specimens with one node and two nodes, just need to replace  $3i$  with  $i$  and  $2i$  respectively in Figure 3.

Figure 1. Three kinds of anchorage conditions.

Figure 2. Fabricating of the specimen.

Figure 3. Dimensions of specimen with three nodes.

Notes:

$i$ —stands for the grid interval (50mm and 100mm);  
 $h$ —stands for the distance from the side of node to the end of horizontal bar (when grid interval is 50mm and 100mm, this value is taken for 15mm and 30mm respectively);  
 $v$ —stands for the distance from the side of node to the end of vertical bar (when grid interval is 50mm and 100mm, this value is taken for 20mm and 30mm respectively).

## 2.2 Material properties

In order to avoid the mortar occurring failure before the CFRP grid, high strength mortar which is usually used in practical retrofitting is applied. Table 1 provides the mix proportion of mortar. Test results show that the average compressive strength of the mortar is about 106.3 MPa. Table 2 provides the test maximum tensile load and the calculation maximum tensile load of CFRP grids. Calculation maximum tensile load is the product of theoretical tensile strength of CFRP grid (1400MPa) and the average cross sectional area (13.2mm<sup>2</sup>, 26.4mm<sup>2</sup>, 65mm<sup>2</sup> corresponding to CR5, CR8, CR13 respectively).

Table 1. Mix proportion of mortar and compressive strength.

Item	Cement (kg/m <sup>3</sup> )	Water (kg/m <sup>3</sup> )	Sand (kg/m <sup>3</sup> )	Expanding material (kg/m <sup>3</sup> )	Water reducer (kg/m <sup>3</sup> )
Value	1000	309	1000	50	2

Table 2. Tensile maximum load of CFRP grid.

Type of CFRP grid	CR5	CR8	CR13
Test maximum tensile load ( $T_{tg}$ ) (kN)	24.5	45.7	108.8
Calculation maximum tensile load ( $T_{cg}$ ) (kN)	18.5	37.0	91.0
Calculation-test ratio ( $T_{cg}/T_{tg}$ )	75.5%	81.0%	84.3%

## 2.3 Measurement and testing procedures

According to the “Test method for bond strength between reinforcing steel and concrete by pull-out test (JSCE-G503)”, the pull-out test has been developed to investigate anchorage behaviour between CFRP grid and mortar. Figure 4 (a) shows the experimental equipment with 1000 kN load capacity. Figure 4(b) shows the experimental loading method. Displacement-control loading method is applied and the loading rate is set as 1.5 mm/min. Load and displacement data are acquired during the loading process.

(a) Experiment device.

**Figure 4. Experiment device and loading method.**

### 3. Results and discussion

#### 3.1 Maximum load

Average maximum load of all specimens are shown in Table 3.

**Table 3. Maximum load of all specimens.**

Type	CR5@50	CR5@100	CR8@50	CR8@100	CR13@100	
NBW	NBW-1	11.2	12.0	17.0	18.5	48.5
	NBW-2	18.1	18.5	28.3	30.9	67.9
	NBW-3	19.1	21.4	31.3	35.9	79.9
BWO	BWO-1	10.8	22.3	14.0	25.3	34.0
	BWO-2	23.5	21.2	29.5	42.7	80.3
	BWO-3	22.5	24.4	38.6	43.0	96.0
BW	BW-1	19.2	23.2	24.9	35.9	73.3
	BW-2	23.6	23.3	40.9	45.3	110.3
	BW-3	22.8	23.3	42.6	43.5	109.4

Note: NBW-1, NBW-2, NBW-3 stand for the NBW-type specimen with one node, two nodes and three nodes respectively. Others analogize.

#### 3.2 Failure modes

For the external CFRP grid (the vertical bar outside the mortar), failure modes could be divided into three kinds:

- ① stands for the external CFRP grid still keep intact;
- ② stands for the break of the external CFRP grid;
- ③ stands for the smash of the external CFRP grid (It means the grid breaks into more than two parts).

For the internal CFRP grid (the grid inside the mortar), the failure modes also could be divided into three kinds:

- Ⓐ stands for the vertical CFRP bar be pulled out to a certain distance;
- Ⓑ stands for the vertical CFRP bar be pulled out completely;
- Ⓒ stands for the break of the vertical CFRP bar in the mortar.

These failure modes above are shown in Table 4 and Table 5. Representative failure photos are shown in Figure 5.

**Table 4. Failure mode of the external CFRP grid.**

Type	CR5@50	CR5@100	CR8@50	CR8@100	CR13@100	
NBW	NBW-1	①	①	①	①	①
	NBW-2	②	③	②	①	②
	NBW-3	②	③	②	②	③
BWO	BWO-1	①	③	①	①	①
	BWO-2	②	③	②	③	②
	BWO-3	③	③	③	③	③
BW	BW-1	②	③	②	②	①
	BW-2	②	③	②	③	②
	BW-3	③	③	③	③	③

**Table 5. Failure mode of the internal CFRP grid.**

Type		CR5@50	CR5@100	CR8@50	CR8@100	CR13@100
NBW	NBW-1	a	a	a	a	a
	NBW-2	a	a	a	a	a
	NBW-3	a	c	c	c	c
BWO	BWO-1	b	a	b	b	b
	BWO-2	c	c	a	c	a
	BWO-3	c	c	c	c	c
BW	BW-1	a	c	a	a	a
	BW-2	c	c	a	c	c
	BW-3	c	c	c	c	c

**Figure 5. Representative failure photos.**

Combined with the maximum tensile load (as shown in Table 3), It shows that:

- (1) For each type of CFRP grid under the same anchorage condition, the external grid tends to break more and more seriously with the increasing number of nodes. When the maximum pull-out load is close to the maximum tensile load of CFRP grid (as shown in Table 2), the external grid occurs smash-type failure mode (③);
- (2) Maximum tensile load corresponding to break-type failure mode (②) is smaller than it corresponding to smash-type failure mode (③);
- (3) Under no-bond condition with crossing section (NBW), the internal grid tends to be pulled out to a certain distance under relatively lower pull-out load, while under higher pull-out load, the internal grid breaks, even smashes.
- (4) Under bond condition without crossing section (BWO) with one node except CR5@100, all the other internal grids are pulled out completely.

### 3.3 Analysis of tensile strength utilization of CFRP grid

#### 3.3.1 Definition and calculation of tensile strength utilization of CFRP grid

Define the tensile strength utilization  $\alpha$  by equation (1).

$$\alpha = \frac{P_u}{T_{ig}} \times 100\% \quad (1)$$

$P_u$ —average maximum pull-out load for each type of specimen, as shown in Table 3;

$T_{ig}$ —test maximum tensile load for CFRP grid, as shown in Table 2.

Calculation results of tensile strength utilization are shown in Table 6.

According to the calculation-test ratio of maximum tensile load of CFRP grid (as shown in Table 2) and considering the safety of practical engineering, it is regarded that when the tensile strength utilization is approximately equal to or greater than 70%, the tensile strength of CFRP

grid is fully used (underlined value as shown in Table 6).

**Table 6. Tensile strength utilization (%).**

Type		CR5@50	CR5@100	CR8@50	CR8@100	CR13@100
NBW	NBW-1	45.6	49.0	37.8	41.1	44.5
	NBW-2	<u>74.0</u>	<u>75.6</u>	62.8	68.5	62.5
	NBW-3	<u>77.9</u>	<u>87.3</u>	<u>69.4</u>	<u>79.7</u>	<u>73.4</u>
BWO	BWO-1	44.1	<u>91.1</u>	31.1	56.2	31.2
	BWO-2	<u>95.7</u>	86.6	65.5	<u>94.7</u>	<u>73.8</u>
	BWO-3	91.6	99.3	<u>85.7</u>	95.3	88.2
BW	BW-1	<u>78.2</u>	<u>94.6</u>	55.2	<u>79.7</u>	67.4
	BW-2	96.1	95.1	<u>90.8</u>	100.0	<u>100.0</u>
	BW-3	93.2	95.1	94.5	96.5	100.0

Table 6 suggests that in order to make full use of tensile strength of CFRP grid:

- (1) Under no-bond condition with crossing section (NBW), it needs two nodes at least for CR5@50 and CR5@100; it needs three nodes at least for CR8@50, CR8@100 and CR13@100.
- (2) Under bond condition without crossing section (BWO), it only needs one node for CR5@100; it needs two nodes at least for CR5@50, CR8@100 and CR13@100; it needs three nodes at least for CR8@50.
- (3) Under bond condition with crossing section (BW), it needs one node for CR5@50, CR5@100 and CR8@100; it needs two nodes at least for CR8@50 and CR13@100.

### 3.3.2 Influence rules of CFRP grid type on the tensile strength utilization

Figure 6 and Figure 7 compare the tensile strength utilization corresponding to different CFRP grid types under same grid interval (50mm and 100mm respectively).

**Figure 6. Influence rules of CFRP grid type (grid interval is 50mm) on the tensile strength utilization of CFRP grid.**

**Figure 7. Influence rules of CFRP grid type (grid interval is 100mm) on the tensile strength utilization of CFRP grid.**

Theoretically, under the same anchorage condition, the tensile strength utilization must increase with the increasing number of nodes. But from Table 6, Figure 6 and Figure 7, it shows that some values seem to be unreasonable. It shows that the tensile strength utilization decreases with the increasing number of nodes (for CR5@50: BWO-2 → BWO-3, BW-2 → BW-3; for CR5@100: BWO-1 → BWO-2; for CR8@100: BW-2 → BW-3.). Preliminary analysis shows that

with the increasing number of nodes under same anchorage condition, when two successive tensile strength utilization (as shown in Table 6, be equivalent to two successive maximum tensile load as shown in Table 3) is close, the comparative analysis in this part is meaningless. Because in this situation the tensile strength of CFRP grid has been fully used and this indicates that increasing the number of nodes couldn't continue to improve the tensile capacity of pull-out specimens. Therefore, when making comparative analysis of tensile strength utilization, discarding these meaningless data would be more reasonable.

Comparative analysis shows that the tensile strength utilization of CFRP grid decreases with the increasing of cross sectional area (CR5 (13.2mm<sup>2</sup>)→CR8 (26.4mm<sup>2</sup>)→CR13 (65.0mm<sup>2</sup>)).

### 3.3.3 Influence rules of CFRP grid interval on the tensile strength utilization

Figure 8 and Figure 9 compare the tensile strength utilization corresponding to different CFRP grid intervals under same grid type (CR5 and CR8 respectively).

Discarding the meaningless data as part 3.3.2 above, Figure 8 (b) (c) and Figure 9 (b) (c) show that the tensile strength utilization increases with the increasing of grid interval (50mm→100mm). Figure 8 (a) and Figure 9 (a) show that under no-bond condition with crossing section (NBW), the tensile strength utilization corresponding to 100mm grid interval is a little bigger than it corresponding to 50mm grid interval. However, under no-bond condition with crossing section (NBW), the tensile strength utilization should be much closer between two kinds of grid intervals theoretically. Because the elastic modulus of CFRP grid is rather large (about 10<sup>5</sup> MPa) which just could cause very small deformation of the vertical bar under tensile load. Preliminary analysis shows that it isn't the perfect no-bond condition by wrapping tap around the vertical bar, and there must be residual bond action which will increase with the increasing of grid interval. This will illustrate the phenomenon above.

Figure 8. Influence rules of grid interval (CR5) on the tensile strength utilization of CFRP grid.

Figure 9. Influence rules of grid interval (CR8) on the tensile strength utilization of CFRP grid.

## 3.4 Analysis of maximum load growth gradient with increasing number of nodes

### 3.4.1 Definition and calculation of growth gradient of maximum load of CFRP grid

Define the growth gradient of maximum load  $\beta$  by equation (2).

$$\beta = \frac{P_{ij}}{P_{i1}} \quad (2)$$

$P_{i1}$ —average maximum tensile load for  $i$ -type of pull-out specimen with one crossing point (Be equivalent to the average maximum load of specimen NBW-1, BWO-1, BW-1 respectively), as shown in Table 3.;

$P_{ij}$ —average maximum tensile load for  $i$ -type of pull-out specimen with  $j$  crossing point, as shown in Table 3.

Calculation results are shown in Table 7. It is important to note that, as same situation and reasons shown in 3.3.2 part, when making comparative analysis, the meaningless values should be discarded.

**Table 7. Growth gradient of maximum load.**

Type		CR5@50	CR5@100	CR8@50	CR8@100	CR13@100
NBW	NBW-1	1.0	1.0	1.0	1.0	1.0
	NBW-2	1.6	1.5	1.7	1.7	1.4
	NBW-3	1.7	1.8	1.8	1.9	1.6
BWO	BWO-1	1.0	1.0	1.0	1.0	1.0
	BWO-2	2.2	1.0	2.1	1.7	2.4
	BWO-3	2.1	1.1	2.8	1.7	2.8
BW	BW-1	1.0	1.0	1.0	1.0	1.0
	BW-2	1.2	1.0	1.6	1.3	1.5
	BW-3	1.2	1.0	1.7	1.2	1.5

### 3.4.2 Influence rules of grid type and interval on the maximum load growth gradient

Figure 10 compares the growth gradient corresponding to different grid types and intervals under the same anchorage condition. It shows that:

- (1) Under no-bond condition with crossing section (NBW), maximum tensile load corresponding to all types of CFRP grid increases with the increasing number of nodes from 1 to 3.
- (2) Under bond condition without crossing section (BWO), maximum tensile load corresponding to CR5@100 doesn't change much, while to other types of CFRP grids, maximum tensile load increases with the increasing number of nodes.
- (3) Under bond condition with crossing section (BW), maximum tensile load corresponding to CR5@100 nearly doesn't change with the increasing number nodes. Maximum tensile load corresponding to other types of CFRP grids increases obviously when the number of grid node increases from 1 to 2, while it doesn't change obviously when the number of grid node increases from 2 to 3.

Combined with analysis results of tensile strength utilization (3.3.2 part), it shows that when the number of nodes are enough to make full use of the tensile strength of CFRP grid, the maximum load growth gradient wouldn't increase any more with the increasing number of nodes.

**Figure 10. Influence rules of grid nodes on the growth gradient of maximum load.**

### 3.4.3 Influence rules of anchorage condition on the maximum load growth gradient

Figure 11 compares the growth gradient of maximum load corresponding to different anchorage conditions under each grid type and grid interval. It shows that:

- (1) For CR5@100 and CR8@100, maximum tensile load corresponding to NBW-anchorage condition is influenced highly by the number of grid node.
- (2) For CR5@50, CR8@50, CR13@100, maximum tensile load corresponding to BWO-anchorage condition is influenced highly by the number of grid node.

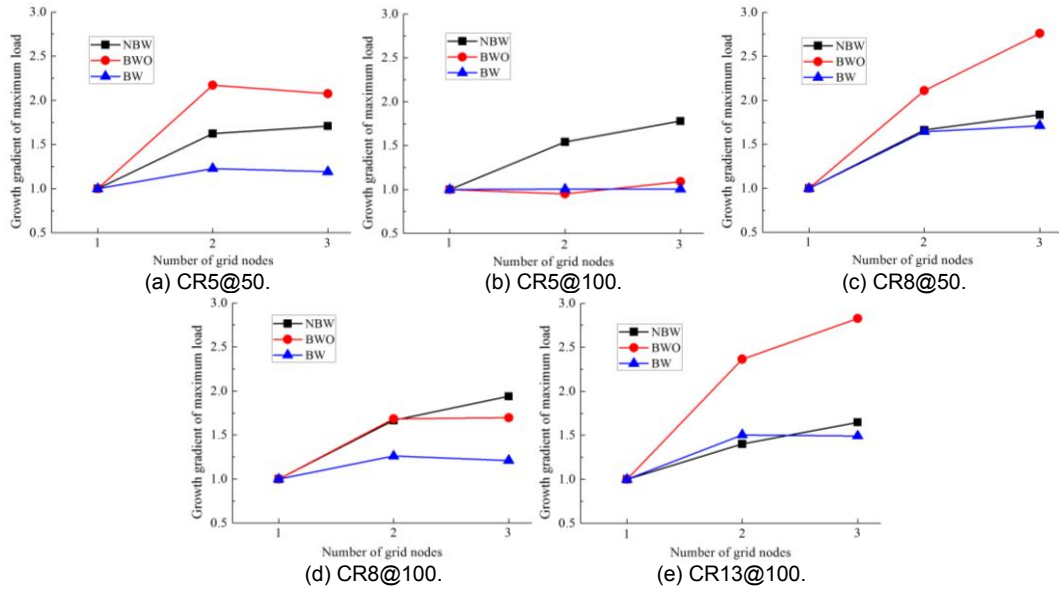

Figure 11. Influence rules of grid nodes on the growth gradient of maximum load.

### 3.5 Relationship of maximum load among three kinds of anchorage conditions

#### 3.5.1 Two kinds of anchorage actions

As above, three kinds of anchorage conditions were analyzed respectively. Based on the initial analysis, it is clarified that anchorage action of BW-type condition mainly be composed with the resistance action of horizontal bar (NBW-type condition) and bond action of vertical bar (BWO-type condition). In order to reveal the anchorage mechanism comprehensively, it is necessary to analyze the relationship of maximum load among three kinds of anchorage conditions.

Taking the maximum load corresponding to NBW-type specimen (under no-bond condition with crossing section) as the standard value, calculate the standardized value corresponding to BWO-type specimen and BW-type specimen. Specific calculation formula is shown as formula (3) below. Calculation results are shown in Table 8.

$$\begin{aligned} \gamma_1 &= \frac{P(NBW_i)}{P(NBW_i)} \equiv 1.0 & i = 1, 2, 3 \\ \gamma_2 &= \frac{P(BWO_i)}{P(NBW_i)} & i = 1, 2, 3 \\ \gamma_3 &= \frac{P(BW_i)}{P(NBW_i)} & i = 1, 2, 3 \end{aligned} \quad (3)$$

$P(NBW_i)$ —average maximum tensile load under NBW-type condition with  $i$  nodes, as shown in Table 3;

$P(BWO_i)$ —average maximum tensile load under BWO-type condition with  $i$  nodes, as shown in Table 3;

$P(BW_i)$ —average maximum tensile load under BW-type condition with  $i$  nodes, as shown in Table 3.

Table 8. Standardized maximum tensile load.

Type		CR5@50	CR5@100	CR8@50	CR8@100	CR13@100
One node	NBW-1	1.0	1.0	1.0	1.0	1.0
	BWO-1	1.0	1.9	0.8	1.4	0.7
	BW-1	1.7	1.9	1.5	1.9	1.5
Two nodes	NBW-2	1.0	1.0	1.0	1.0	1.0
	BWO-2	1.3	1.1	1.0	1.4	1.2
	BW-2	1.3	1.3	1.4	1.5	1.6
Three nodes	NBW-3	1.0	1.0	1.0	1.0	1.0
	BWO-3	1.2	1.1	1.2	1.2	1.2
	BW-3	1.2	1.1	1.4	1.2	1.4

Calculation results show that:

- (1) For all kinds of CFRP grids with three nodes and for CFRP grids with two nodes except CR8@50, the standardized maximum tensile load corresponding to BWO-type condition is greater than 1.0. This indicates that the bond action of vertical bar (be equivalent to BWO-type condition) is the predominant anchorage action;
- (2) For CR8@50 and CR13@100 with one node, the resistance action of horizontal bar is the predominant anchorage action; while for CR5@100 and CR8@100 with one node, the bond action of vertical bar is the predominant anchorage action;
- (3) For CR5@50 with one node and CR8@50 with two nodes, two kinds of anchorage actions divide equally.

### 3.5.2 Coupling effect between two kinds of anchorage actions

In order to make quantitative analysis, the proportionality coefficient  $\eta$  is calculated based on the formula (4) as below. Calculation results are shown in Table 9.

$$\eta = \frac{P(BW_i)}{P(NBW_i) + P(BWO_i)} \times 100\% \quad i = 1, 2, 3 \quad (4)$$

$P(BW_i)$ —average maximum tensile load under BW-type condition, as shown in Table 3;  
 $P(NBW_i)$ —average maximum tensile load under NBW-type condition, as shown in Table 3;  
 $P(BWO_i)$ —average maximum tensile load under BWO-type condition, as shown in Table 3.

**Table 9. Proportionality coefficient (%).**

Type	CR5@50	CR5@100	CR8@50	CR8@100	CR13@100
One node	87.2	67.5	80.2	82.0	88.9
Two node	56.6	58.6	70.7	61.6	74.4
Three nodes	55.0	51.0	61.0	55.2	62.2

Table 9 shows that the coefficient  $\eta$  isn't equal to 100% which indicates that there must be the coupling effect between two kinds of anchorage actions. Besides, the coefficient  $\eta$  decreases with the increasing number of nodes. And this indicates that with the increasing number of nodes, the coupling effect is more and more significant.

## 4. Calculation model of maximum tensile load

Based on the analysis of experimental results above, it is clarified that the anchorage action of CFRP grid ( $P_u$ ) is composed with resistance action of horizontal bar and bond action of vertical bar, which are marked by  $P_r$  and  $P_b$  respectively. As shown in equation (5) below,  $\Phi$  stands for one function relationship, which is related to the coupling effect between two kinds of anchorage actions as analysis above.

$$P_u = \Phi(P_r + P_b) \quad (5)$$

Suppose that the vertical bar has  $n$  nodes.

The calculation model of resistance action could be expressed by equation (6).

$$P_r = mP_0 + \sum_{i=m+1}^n P_i \quad (6)$$

Where  $P_0$  stands for the fracture load of single node;  $m$  stands for the number of fractured nodes under the tensile load.  $P_i$  stands for the tensile load beard by every no-fractured node.

In order to get the specific parameters in equation (6), the key is to reveal the resistance action transfer mode along the vertical bar under tensile load.

The calculation model of bond action could be expressed by equation (7).

$$P_b = f(\tau) \quad (7)$$

Where  $\tau$  stands for the bond stress between the vertical bar and mortar;  $f$  stands for one function relationship. And the bond stress is related to grid type, strength of mortar, anchorage length and other factors. Besides, in practical engineering, the bond condition of vertical bar is different with the condition illustrated in this paper. Three sides of vertical bar are bonded in the mortar, while the fourth side is attached on the surface of existing concrete. This will make the calculation of the bond stress

more complicated.

In order to reveal the anchorage mechanism comprehensively, more experiments and theoretical analysis should be made in late-stage research.

## 5. Conclusions

A total of 135 pull-out specimens were tested in this study. The main purpose was to investigate the anchorage behavior of CFRP grid in mortar under three kinds of anchorage conditions. The following conclusions can be made from the experimental results obtained in this study:

(1) In order to make full use of the tensile strength of CFRP grid: (a) Under no-bond condition with crossing section (NBW), it needs two nodes at least for CR5@50 and CR5@100; it needs three nodes at least for CR8@50, CR8@100 and CR13@100. (b) Under bond condition without crossing section (BWO), it only needs one node for CR5@100; it needs two nodes at least for CR5@50, CR8@100 and CR13@100; it needs three nodes at least for CR8@50. (c) Under bond condition with crossing section (BW), it needs one node for CR5@50, CR5@100 and CR8@100; it needs two nodes at least for CR8@50 and CR13@100.

(2) The tensile strength utilization of CFRP grid decreases with the increasing of cross sectional area, while it increases with the increasing of grid interval.

(3) The maximum tensile load growth gradient wouldn't increase anymore when the number of nodes is enough to make full use of the tensile strength of CFRP grid. Under no-bond condition with crossing section, maximum tensile load corresponding to all types of CFRP grids increases with the increasing number of nodes from 1 to 3.

(4) For CR5@100 and CR8@100, maximum tensile load corresponding to NBW-type anchorage condition is influenced highly by the number of grid nodes; For CR5@50, CR8@50, CR13@100, maximum tensile load corresponding to BWO-type anchorage condition is influenced highly by the number of grid nodes.

(5) For all kinds of CFRP grids with three nodes and for CFRP grids with two nodes except CR8@50, the bond action of vertical bar (be equivalent to BWO-condition) is the predominant anchorage action; for CR8@50 and CR13@100 with one node, the resistance action of horizontal bar is the predominant anchorage action; for CR5@100 and CR8@100 with one node, the bond action of vertical bar is the predominant anchorage action; for CR5@50 with one node, two kinds of anchorage actions divide equally.

(6) The coupling effect exists between the resistance action of horizontal bar and the bond action of vertical bar. And with the increasing number of nodes, the coupling effect is more and more significant.

(7) The anchorage behavior of CFRP grid in the mortar is rather complicated. Further study needs to be done with more experiments and numerical analysis to investigate the anchorage mechanism.

# Influence of Fiber Net Reinforced Mortar Repair Coating on the Crack Opening Resistance of Concrete

Yoshinori Kitsutaka<sup>1</sup> and Yukihiro Oyama<sup>2</sup>

<sup>1</sup>Professor, Tokyo Metropolitan University

<sup>2</sup>Ministry of Justice Associates

**Abstract:** For long-term and effective use of the concrete structure, the concrete wall repairing is getting more important. The use of the fiber reinforced cementitious composite for a repairing material on the cracked concrete surface or the damaged mortar finishing is effective to improve the durability of concrete structures. In this paper, the performance of the fiber net reinforced mortar from the viewpoint of concrete crack resistance was investigated. Three-point bending tests on pre-notched concrete beam specimens which coating the fiber net reinforced mortar on surface were performed. Load-load displacement curves were measured and the fracture toughness was evaluated. It was found that the toughness of cracked concrete was improved by coating the fiber net reinforced mortar. Material properties and the density of fiber net were important factors for improving the toughness of cracked concrete. Also the compiling direction of the fiber net was important factor for improving the toughness of cracked concrete. An analysis method to calculate the load-displacement relationship on the surface repaired concrete by the fiber net reinforced mortar was proposed and a good relationship was obtained between the test results and the analysis results.

**Keywords:** fiber net reinforced mortar, repair, coating, fracture toughness.

## 1. Introduction

Repairing of tiled and mortar external building walls has become increasingly important for the demand of long-term use of building structures and utilization of the existing building stock. The pin-net repairing system is a composite external wall repair system and is developed to prevent delamination of tiled and mortar external walls. The performance of individual pin-net repairing systems has been investigated in the literature, but comparison among various materials used for each method has not been well studied. Also, the resistance of netting to the propagation of tensile cracks in setting mortar and concrete is important from the aspect of a delamination-inhibiting effect.

The failure of fiber net containing mortar is characterized by being more ductile than that of conventional mortar finishing, bridging of fibers, which continues to transfer the tensile stress after cracking. The transferred stress may even increase after cracking, which is known as strain hardening (Kitsutaka and Oh-oka, 1998). In such a state, partial hardening in the failure process of a mortar causes new cracks in other parts of the mortar, dispersing the fracture area. This increases the energy-absorbing capacity of the mortar during failure, while avoiding brittleness due to localization of cracking, thereby leading to an ideal mode of failure.

The behavior of fiber net reinforcing mortar coatings during the tensile cracking process of the concrete substrate can be experimentally evaluated by the three-point bending tests on pre-notched concrete beam specimen which coating the fiber net reinforcing mortar on surface. The effect of fiber net reinforcing mortar coatings on tensile crack resistance can be evaluated by the load-load point displacement (L-LPD) curves obtained from the three-point bending tests. Also an area surrounded by L-LPD curve can evaluate the total energy consumed in the process of concrete cracking and this energy can be the evaluation index on the crack resistance of fiber net reinforcing mortar coating.

In this study, three-point bending tests were conducted on mortar specimens, to which multiaxial fiber netting was applied, with the aim of comparing the netting's effects of inhibiting tensile crack propagation in setting mortar and concrete.

## 2. Experiments

### 2.1 Outline of specimens

Table 1 gives the outline of fiber nets. Nine types of specimens were fabricated: Six with six net types, one with no net (P), one with VF3-10 netting rotated 90° and one with VF2-10 netting rotated 45° to examine the effect of the direction of fiber nets, and types of fiber were vinylon, polypropylene and glass normally used for pin-net repairing system. Fig. 1 shows the directions of fiber net application.

**Table 1. Outline of fiber nets.**

Name of specimen	Sign	Net intervals (mm)	Properties of fiber					
			Weight (g/m <sup>2</sup> )	Diameter (μm)	Tensile strength (MPa)	Strain (%)	Young's modulus (GPa)	Dens. (g/cm <sup>3</sup> )
Plain	P	-	-	-	-	-	-	-
Vinylon fiber-3axis	VF3-10	10×10	88	13	1580	7.2	36.3	1.3
Vinylon fiber-3axis	VF3-15	15×15	57	13	1580	7.2	36.3	1.3
Vinylon fiber-2axis	VF2-10	10×10	100	13	1270	6.6	26.4	1.3
Vinylon fiber-2axis	VF2-15	15×15	70	13	1270	6.6	26.4	1.3
Polypropylene fiber-3axis	PP3-10	10×10	-	12	430	-	10.5	-
Glass fiber-2axis	GF2-5	5×5	150	10	2500	-	74.0	-
Vinylon fiber-3axis-90°rotate	VF3-10(90)	10×10	88	13	1580	7.2	36.3	1.3
Vinylon fiber 2axis-45°rotate	VF2-10(45)	10×10	100	13	1270	6.6	26.4	1.3

**Figure 1. Directions of fiber net application.**

Table 2 shows the mixture proportions and basic properties of polymer cement mortar. Fig. 2 shows the outline of a fiber net reinforcing mortar coating. In this study, in order to reduce the deviation of crack propagation caused by the coarse aggregate, mortar was selected for base specimens, which measured 200 by 100 by 100 mm. After curing base specimens as specified, a notch was cut to a depth of 25 mm in the longitudinal center of each of the four sides of each specimen. Nets were then applied to two opposite sides with polymer cement mortar following the instructions of the pin-net repairing system. Carbon fiber sheets were applied using epoxy.

**Table 2. Properties of polymer cement mortar**

Material	Contents	Properties
Polymer cement mortar	Cement	Cement : Admixture : Water 100:10:20(Weight ratio)
	Kation type SBR latex	Compressive strength 2 weeks : 28.3 (MPa)

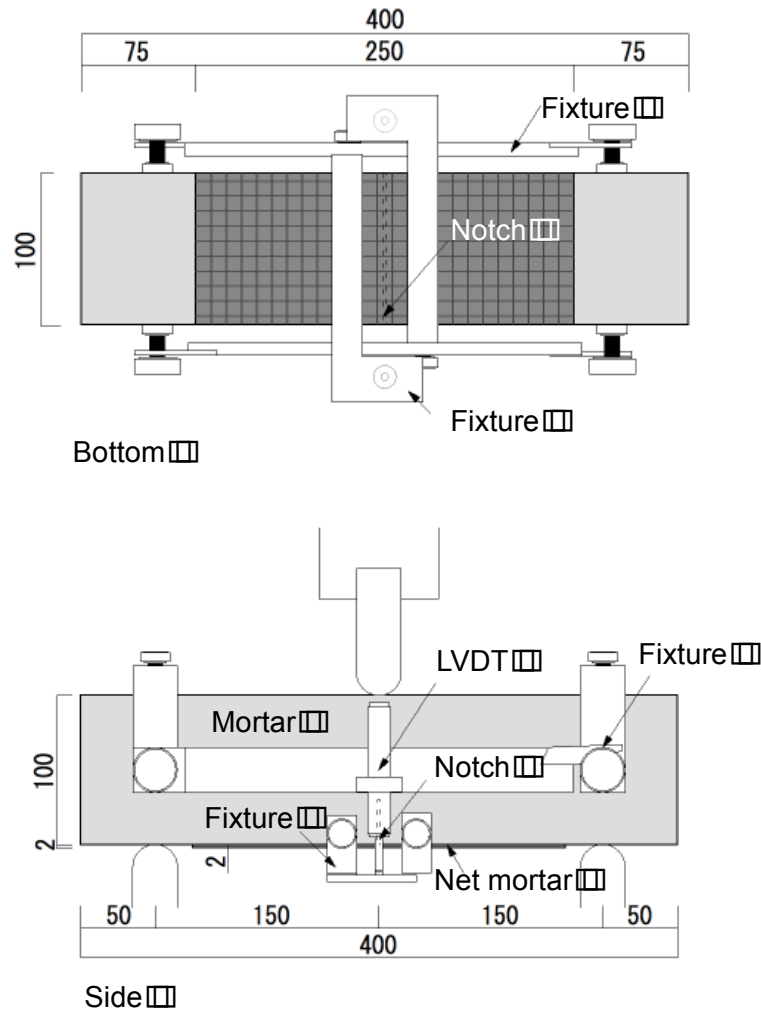

**Figure 2. Fiber net reinforcing mortar coatings**

## 2.2 Outline of tests

Three-point bend tests for the center notched beam specimen with net mortar on the notched surface were conducted to measure the load versus load point displacement (L-LPD) curves. Fig. 3 shows the outline of a specimen and the three points bending test. Photo 1 shows the actual appearance of three points bending test. A displacement-controlled load testing machine with a capacity of 250 kN was used for three-point loading. Specimen size, span length, notch length were 100 x 100 x 400mm, 300mm, 30mm according to the JCI standard (2003). LPD was measured by using two LVDTs with 0.001mm sensitivity. LVDT were attached on a support hanging on a specimen to avoid the displacement measurement error caused by load point caving (Fig. 3). The loading rate of the crosshead was 0.02 mm/min. The loading control was based on the displacement at the loading point.

**Photo 1 Three points bending test**

**Figure 3. Outline of specimen and three-point bending test**

### 3. Test results and discussion

Fig. 5 shows the L-LPD curves of the specimens of every test conditions. In Fig. 5, the specimen with fiber netting, no netting (p) were shown. No appreciable difference is observed between the maximum strengths of specimens with and without fiber netting. The differences between the maximum strengths of specimens with different fiber netting types are not significant either.

Plain specimens (p) underwent brittle failure after reaching the maximum load. In comparison, the LPD data of specimens with netting were measured to large displacement values, as a crack were restrained by the net layer to induce stable failure even after a crack propagation was formed. Also, the load of p specimens with no netting decreases after the maximum load, whereas no rapid reductions in the load after the maximum load are observed with specimens having netting. This can be attributed to the bridging effect of fibers composing the netting. This tendency is particularly evident with GF specimen with a high elastic modulus. Also GF specimen shows the hardening behavior, but those failure after the second maximum load is brittle. Because the fiber used for GF specimens is a high tensile strength fiber and shows a brittle failure.

From the comparison between VF3-10 and VF3-15V or F2-10 and VF2-15, the net intervals of fiber netting becomes lower the post peak crack resistance of specimens becomes higher. The post peak crack resistance of specimens with different fiber netting angle are not significant.

**Figure 5. Load and load point displacement curves**

Calculated L-LPD curves were shown in Fig. 5 by bold line. L-LPD curves have been calculated by the crack analysis (Kitsutaka, 1997) using the tension softening property of concrete substrate and tensile properties of fiber net reinforcing mortar coatings which were obtained by the direct tensile test. The original L-LPD curves and the calculated curves are agreed well, so this analysis method is considered to be an appropriate method to predicting L-LPD curves of pre-notched specimen adopting the fiber net reinforcing mortar coatings in three point bending test.

### 3. Conclusions

In the range of the specimen geometry and the materials used in this study, the following were found:

- (1) The maximum loads under three points bending testing of both specimens with and without fiber net reinforcing are similar.
- (2) Fiber net reinforcing improves the resistance to crack propagation of concrete substrate.
- (3) Fiber netting specimen made of a glass fiber with a high elastic modulus and high tensile strength shows the hardening behavior.
- (4) Interval of fiber netting becomes lower the post peak crack resistance of specimens becomes higher.
- (5) The observed L-LPD curves and the calculated L-LPD curves obtained from a crack analysis are agreed well.

# Performance of Fire-damaged Concrete Members Strengthened with NSM Laminates Embedded in Epoxy Adhesive

Awad Jadooe <sup>1,2</sup>, Riadh Al-Mahaidi <sup>3</sup> and Kamiran Abdouka <sup>4</sup>

<sup>1</sup>PhD Candidate, Swinburne University of Technology, Melbourne, Australia

<sup>4</sup>Senior Lecture, Swinburne University of Technology, Melbourne, Australia

**Abstract:** The repair and strengthening of existing concrete structures has become more common during the last decade. The most common application of FRP for the strengthening has been externally-bonded (EB) systems, where sheets or laminates of FRP are bonded to the external surface of the concrete with an epoxy adhesive. Despite the popularity of EB FRP strengthening techniques, they have a number of important limitations in practice and a limited ability to develop the full tensile strength of the FRP sheet. Near-surface mounted (NSM) systems have been proven to overcome the limitations of EB systems. The NSM technique was used in this research, where FRP laminates were bonded via an epoxy or cement-based adhesive in grooves cut into the concrete surface. Twenty fire-damaged concrete prisms were tested using a single-lap shear test. The results were compared with 20 reference specimens without fire damage. The results demonstrate that the residual tensile strength after the repair of fire-damaged concrete with rough CFRP is 94%, 79%, and 49% for temperature exposure of one hour at 200 °C, 400 °C, and 600 °C, respectively. The corresponding values for two hour exposure are 86%, 77% and 41% respectively.

**Keywords:** Fire, NSM, CFRP, Rehabilitation, Epoxy adhesive.

## 1. Introduction

Recent years have seen increased emphasis on the repair and refurbishment of all types of structures in preference to demolition and rebuilding. Concrete structures are no an exception. Since one of the problems facing buildings is exposure to high temperatures, they should be provided with sufficient structural fire resistance to withstand such circumstances, or at least to give the occupants enough time to escape before strength and or stability failure ensue (Tovey (1); Tovey and Crook (2); Haddad et al (3); Leonardi et al (4); Allen et al (5); ACI224 (6)).

After a fire, an appraisal is normally required as soon as the building can be safely entered and generally before the removal of debris. To ensure safety, temporary false work may be required to secure individual members and stabilize the structure as a whole.

The primary on-site investigation technique is visual inspection, which is used to classify the degree of damage for each structural concrete member. Visually apparent damage induced by heating includes collapse, deflection, spalling, cracking, surface crazing, colour changes and smoke damage. A visual survey of reinforced concrete structures is performed using a classification scheme from Gosain et al. (7), as shown in Table 1. This scheme uses visual indications of damage to assign each structural member a class of damage from 0 to 4. Each damage classification number has a corresponding category of repair, ranging from decoration to major repair

**Table 1. Physical effect of temperature on concrete Gosain et al. (7).**

Temperature	Color Change	Changes in Physical Appearance and Benchmark Temperatures	Concrete Condition
0 to 550 °F (0 to 290 °C)	None	Unaffected	Unaffected
550 to 1100 °F (290 to 590 °C)	Pink to red	Surface crazing: 570 °F (300 °C); Deep cracking: 1020 °F (550 °C); Popouts over chert or quartz aggregate: 1070 °F (575 °C)	Sound but strength significantly reduced
1100 to 1740 °F (590 to 950 °C)	Whitish Grey	Spalling, exposing not more than 25% of reinforcing bar surface: 1470 °F (800 °C); Powdered, light colored, dehydrated paste: 1650 °F (575 °C)	Weak and friable
1740+ °F (950+ °C)	Buff	Extensive spalling	Weak and friable

Due to the main advantages of FRP, such as its durability, high strength, low weight, easy installation and the basically unlimited availability of different shapes, it has been extensively used in structural repair and strengthening (Kodur and Baingo (8); Hashemi and Al-Mahaidi (9); Al-Abdwais and Al-Mahaidi (10)). Moreover, the reduction of the cost of FRP has seen it being used more frequently in civil engineering, especially to repair damage and strengthen outdated buildings. Carbon fiber can be produced in different shapes such as bars, sheets, textiles and laminates, as shown in Figure 1. Therefore, it has been effectively used for different purposes, especially the strengthening of members.

**Figure 1. Types of CFRP materials**

The main purpose of the present research is to study the suitability and effectiveness of the CFRP NSM laminate strengthening system to repair reinforced concrete (RC) members after exposure to high temperature and/or fire. This research investigates the residual strength of RC members after exposure to fire with and without CFRP NSM laminates. Many variables were encountered in this investigation, which covered the following aspects:

- Investigation of the behavior of the bond properties and mode of failure of concrete prism specimens between CFRP NSM laminates embedded with epoxy and substrate concrete after exposure to temperatures of 200, 400, 600, 800, and 1000°C for exposure periods of one and two hours.
- Investigation of the effect of fire and/or high temperature on direct tensile strength values using a single-lap shear for testing after exposure to temperatures of 200, 400, 600, 800, and 1000°C for exposure periods of one and two hours.

## **2. Experimental Program**

In this section, the details of the experimental program are presented, including the materials used, the mix proportions, the preparation and curing of specimens and the testing program. Limited previous experimental work has been carried out on the effect of burning by fire on the mechanical properties of normal strength concrete such as compressive strength and splitting tensile strength to investigate the most effective repair techniques and the best bond properties. The following properties were investigated:

1. Compressive strength;
2. Splitting tensile strength;
3. Axial deformation;
4. Ultimate tensile load capacity.

The experimental variables investigated for the concrete prisms were:

1. Fire temperature (200, 400, 600, 800 and 1000 °C);
2. Period of exposure to fire (1.0 and 2.0 hours).
3. Strengthening with NSM laminates embedded in epoxy adhesives.

## **3. Materials and Mixes**

### **3.1 Introduction**

The properties of materials used in any structure are of considerable importance (Neville (11); ACI 211(12)). The properties of materials used in the current study are presented in this chapter. Standard tests according to the American Society for Testing and Materials (ASTM) and Australia Specifications (AU) were conducted to determine the properties of materials. The following sub-divisions describe types and properties of materials used in the research:-

### 3.1.1. Concrete

A target compressive strength of 35 MPa was specified. The concrete mix was designed according to the American mix design method ACI 211(12) specification with a 0.57 water cement ratio of 1(cement): 1.67(fine aggregate): 2.73 (coarse aggregate). The following sub-sections describe the ingredients of the concrete used.

### 3.1.2. Cement

General Purpose Ordinary Portland cement (OPC) (Type GP) manufactured in Australia was used for the concrete mix throughout the present work.

### 3.1.3. Aggregate

Crushed coarse aggregate of 14 mm maximum aggregate size and 1610 Kg/m<sup>3</sup> density was used.

### 3.1.4. Fine Aggregate

Well-graded natural sand from Australia was used for concrete mix.

### 3.1.5 Water

Tap water was used in the concrete mix.

### 3.1.6. FRP Laminate

The FRP laminate used had a rough texture. The rough FRP laminate was supplied by BASF Construction Chemicals Australia Pty Ltd). The dimensions of the CFRP laminate were 20\*1.4 mm<sup>2</sup> and the effective bond length equaled 175mm. The material properties of the rough CFRP laminates as provided by the manufacturer are presented in Table 2.

**Table 2. Properties of rough CFRP laminate**

Typical tensile strength MPa	3300
Typical tensile modulus GPa	210
Ultimate deformation %	1.4
Density g/cm <sup>3</sup>	1.6
Inter laminar sheer strength MPa	80
Thermal expansion	0.6*10 <sup>-6</sup>
Fiber content %	70

### 3.1.7. Adhesive

Epoxy resin adhesive for the FRP laminate system was used for exposed and unexposed concrete for this investigation. The typical properties provided by the manufacturer are presented in Table 3.

#### 4. Program of the Work

During this research, the experimental work on the effect of fire on the behavior of concrete was based on 20 damaged concrete prisms cast in the laboratory and compared with 20 references not exposed to fire. The dimensions for all prisms were 250 mm in length and a square cross-section of 75×75 mm. The concrete prisms were designed to approximate the set-up for single-lap shear testing. A concrete mix with a target compressive strength of 35 MPa was designed, and the specimens were cast, cured for 14 days, and then air-dried in the laboratory. Forty concrete prisms were subjected to fire inside a large furnace as shown in Figure 2 for 45 days with temperature levels of 200, 400, 600, 800 and 1000 °C and for two exposure periods of one and two hours.

Figure 2. Exposure furnace

After exposure to fire, the specimens were repaired with NSM laminates that were embedded in epoxy adhesives. All damaged concrete prisms were repaired with working grooves inside the concrete prisms, such as slits on the surface of substrate concrete. The dimensions of the grooves were 250 mm in length 25 mm deep and 5 mm wide. All grooves were cleaned using air pressure to remove the dust from the surface of the concrete prisms. Epoxy resin primer with a mix ratio of 3:1 (A-B) was then placed inside the grooves to increase the adhesion between the epoxy resin and the surface of the concrete. MBrace laminate adhesive was applied inside the groove where the FRP should be in the center of the groove to ensure a straight FRP when the specimen was tested under the machine. Finally, the fibers were inserted in the center of the slits, and wire tie spacers were used to ensure a good bond between the adhesive and the FRP laminate.

#### 5. Effect of High Temperature on Compressive and Splitting Strength

In order to obtain a better understanding of the behavior of RC members in flexure after exposure to fire damage, it is important to first study the mechanical properties of concrete subjected to fire (Arioz (13); Chan et al (14); Li et al (15)). In the present study, three cylinders of concrete with dimensions of 100x200 mm of normal strength concrete were fired at each level of heating for each period to obtain the compressive and splitting strength of concrete after heating and to predict the effect of fire on the mechanical properties. Figures 3 and 4 show the relationship between compressive strength and fire temperature. It is clear from the results that the compressive strength decreases with exposure to fire temperature and splitting tensile strength is more sensitive to fire than compressive strength.

## 6. Test Set –up

Three days before testing, the concrete prism surfaces were cleaned and coated with white paint to clarify the propagation of cracks and make crack viewing easier. The prisms were then placed in a position using a single-lap shear for testing, as shown in Figure 5, to supply direct pull-off load with trend of FRP Laminate. The rate of the load used in the test was 0.2 mm/min. All the specimens were tested using an MTS 250 dynamic UTM model 819 high rate test machine.

Figure 3. Relationship between compressive strength, tensile strength and fire temperature for (1) hour period.

Figure 5. Single Lap test set-up

## 7. Test Result

The main objective of the current research is to investigate the effect of high temperature on direct tensile strength. Another objective is to repair damage after exposure to fire using NSM CFRP embedded with epoxy adhesive.

**8. Burning at 200 °C Fire Temperature:**

The residual direct tensile strength values were recorded for two series, for reference and damaged prisms strengthened with NSM CFRP using epoxy. The group is described in Table 4. The results show that residual strength decreased slightly when the prisms were exposed to 200 °C. The table also shows that the stiffness of concrete is little affected when the prisms are exposed to 200 °C. In the first period (one hour), the percentage of the residual direct tensile strength was 94%. In the second period (two hours fire exposure), the percentage of the residual direct tensile strength was 86%. Figures 6 and 7 illustrate the relationship between tensile force and displacement for damaged and undamaged concrete prisms. The failure mode for all the prisms subjected to fire was debonding at the interfacial zone between the concrete and the epoxy adhesive associated with cracking and peeling of adhesive at the surface.

**Table 4. Details of prism specimens under temperature 200°C using epoxy adhesive and rough laminate.**

Specimen Type	Ultimate Pullout Load (kN)	Average Ultimate Load(kN)	Average Bond Strength(MPa)	Reduction in Bond Strength	Maximum Displacement (mm)
RE25-A	47	47.5	6.8	6%	3
RE25-B	48				2.9
RE200-1H-A	45	44.5	6.4		2.8
RE200-1H-B	44				2.9
<hr/>					
RE25-A	47	47.5	6.8	14%	3

**Figure 6. Relationship between tensile force and displacement before and after fire using epoxy adhesive for one hour and 200 °C.**

**Figure 7. Relationship between tensile force and displacement before and after fire using epoxy adhesive for two hours and 200 °C.**

**9. Burning at 400 °C Fire Temperature:**

When the temperature was raised to 400 °C, the residual direct tensile strength value for repairs with rough CFRP laminate was 79% for one hour. After two hours, the residual direct tensile strength value for repair with rough CFRP laminate was 77%. The group is described in Table 5. It is obvious from the results that after exposure to fire temperatures of 400 °C, the tensile strength decreases by 9-15 % for one and two hours, more than fire temperatures of 200 °C. It is generally agreed that the stiffness

of concrete decreases with compressive and splitting strength, as shown in Figures 8 and 9. The failure mode was similar to that of specimens subjected to 200 °C.

**Table 5. Details of prism specimens under temperature 400°C using epoxy adhesive and rough laminate**

Specimen Type	Ultimate Pullout Load (kN)	Average Ultimate Load(kN)	Average Bond Strength(MPa)	Reduction in Bond Strength	Maximum Displacement (mm)

RE400-2H-B	39.5				2.9

R: rough FRP, E: Epoxy adhesive, 25: Reference, 400: Temperature in degrees C, 1 and 2: duration times

**Figure 8. Relationship between tensile force and displacement before and after fire using epoxy adhesive for one hour and 400 ° C.**

**Figure 9. Relationship between tensile force and displacement before and after fire using epoxy adhesive for two hours and 400 ° C.**

### 10. Burning at 600 °C Fire Temperature:

When the temperature was raised to 600 °C, the residual tensile strength of the prisms was 49% after repairing them with rough CFRP laminate using epoxy adhesive. However, the residual tensile strength was 41% for two hours. The group is described in Table 6. It can be seen that tensile strength for the 600 °C fire temperature decreases by 34-45 % after one and two hours, more than at a fire temperatures of 200 °C, whereas it decreases by 22-30 % after one and two hours, more than at a fire temperature of 400 °C, as shown in Figures 10 and 11. The failure mode for all the prisms subjected to fire at 600 °C was concrete crashing when epoxy adhesive was used.

**Table 6. Details of prism specimens under temperature 600°C using epoxy adhesive and rough laminate.**

Specimen Type	Ultimate Pullout Load (kN)	Average Ultimate Load(kN)	Average Bond Strength(MPa)	Reduction in Bond Strength	Maximum Displacement (mm)
RE25-A	48.3	48.6	6.9	51%	3.8

RE25-A	48.8	48	6.9	59%	3.8
RE25-B	47.1				3.6
RE600-2H-A	19.4	19.5	2.8		2.7
RE600-2H-B	19.6				1.8

**R:** rough FRP, **E:** Epoxy adhesive, **25:** Reference, **600:** Temperature in degrees C, **1and 2:** duration times

**Figure 10. Relationship between tensile force and displacement before and after fire using epoxy adhesive for one hour and 600**

**Figure 11. Relationship between tensile force and displacement before and after fire using epoxy adhesive for two hours**

### 11. Burning at 800 and 1000 °C Fire Temperatures:

When the temperature was raised to 800 and 1000 °C, the compressive strength and splitting tensile strength decreased sharply. Therefore, cracks were wide-spread along the concrete prism surfaces and inside the concrete cores, as shown in Figure 12. Due to the high magnitude of damage to concrete at temperatures of 800 and 1000 C, the efficacy of repairing using the NSM technique is limited. However, these prisms may not represent the full behavior of the concrete in actual full-scale members due to the propagation of cracks on the surface of the concrete prisms. Furthermore, plain concrete without reinforcement causes premature cracks before achieving the full ultimate load.

**Figure 12. Cracks after exposure to high temperature/ fire.**

## 12. Conclusions

The main objectives of the current research are to investigate the effect of high temperature on direct tensile strength, and to repair damage after exposure to fire using NSM CFRP embedded with epoxy. Based on the test results of the present study, the following conclusions can be drawn:-

- When the temperature is raised to 800 and 1000 °C, the efficacy of repairing with NSM is limited. However, these prisms may not represent the full behavior of the concrete in actual full-scale members due to the propagation of cracks on the surfaces of the concrete prisms.
- The residual tensile strength of the prisms was 49% for one hour after repairing them with rough CFRP laminate and epoxy adhesive. However, the residual tensile strength was 41% for two hours when the temperature was raised to 600 °C.
- The residual direct tensile strength value for repair with rough CFRP laminate was 79% for one hour. After two hours, the residual direct tensile strength value for repair with rough CFRP laminate was 77% when the temperature was raised to 400 °C,
- When the prisms were exposed to 200 °C, the percentage of the residual direct tensile strength in rough CFRP laminate with epoxy was 94%. In the second period (two hours), the percentage of the residual direct tensile strength in rough CFRP laminate was 86%.
- Although compressive strength and splitting tensile strength decrease sharply when the prisms temperatures increase, splitting tensile strength is more sensitive to fire exposure than compressive strength.

**Abstract:** This paper reports on an experimental program that investigated the confinement effect of fiber reinforced concrete as a surface repair material. The effect of the repair material and the horizontal reinforcement (stirrup) ratio were studied. A total of 24 cylindrical concrete specimens were strengthened using jacketing technique by means of four different repair materials, including a type of ultra-high performance-strain hardening cementitious composite and three types of engineered cementations concrete. The effect of stirrup was studied by considering different reinforcement ratio, ranging between zero and 1.7%. All specimens were tested under uniaxial compression. According to the results, the specimens included both stirrups and fiber in the repair layer exhibited a better response and provided a higher strain capacity. This group of specimens presented a ductile failure represented by stable post peak behavior and gradual strength degradation. Moreover, the failure was characterized by small distributed cracks. This research concluded that a combination of surface repair using reinforced fiber reinforced concrete material and a level of reinforcement ratio can significantly improve the behavior of squat columns and effectively enhance the ductility and strength.

**Keywords:** engineered cementations concrete, UHP, squat columns

## 1. Introduction

As a result of advancement in the world of science and technology, new materials and techniques are developed which can be applied to structures for repair purposes. Fiber reinforced concrete (FRC) is one of the material which has been captured the attention of researchers. For concrete structures FRC is particularly favorable as it is compatible with the substrate concrete in terms of behavior and mechanical and physical properties [1, 2]. Repairing structures using a crack-free jacket of high-performance materials such as FRC will effectively protect the inner re-bar from corrosion and substrate concrete from carbonation. In this research two types of FRC jackets were considered. Ultra High Performance Strain Hardening Cementitious Composites (UHP-SHCC) and Engineered Cementitious Composite (ECC). Both materials are considered as composite materials with remarkable mechanical behavior and protective performance. Most research on surface repair using FRC has been focused on flexural members [3-5]. It has been found that a combination of strain hardening cementitious composites (SHCC) and a small amount of steel reinforcement helps develop higher strain in the strengthening layer at ultimate load and eliminates the formation of early cracks due to strain localization [3]. The technique of repair layer using high strength fiber reinforced concrete has been applied to other structural members such as columns [4, 6]. Kunieda et al. [6] developed a rapid jacketing technique to repair RC columns and investigated the behavior of the repaired column under cyclic load. The repair method involved spraying of high performance concrete to the column surface. The authors demonstrated that due to its inherent high tensile capacity, high performance repair layer, can significantly increase the strength and enhance the ductility of flexural members [6]. Moreover, due to high strain capacity, it is shown that FRC jacket can be considered as effective repair material to provide a free-crack surface in flexural members. However, no experimental research has focused on the behavior of axially loaded members retrofitted with high performance repair layer. For members basically subjected to axial stresses, surface repair jacket confines the substrate core and, hence, enhance the strength and ductility. This retrofit method can provide a free-crack compression member which is particularly favorable for bridge columns exposed to aggressive environment. Using FRC as a free-crack water-proof surface repair material of squat columns can not only preserve the substrate from steel corrosion and concrete carbonation and erosion but also potentially enhance the ductility and the strength of the member.

Wrapping with FRP is another method to enhance the behavior of columns. However, the brittle behavior of FRP wrapped columns, incomplete wet-out of the fabric and difficult release of trapped air bubbles and also uncertainty of the durability of the FRP material in aggressive environment are some of the main shortcomings of concrete columns wrapped in FRP [7]. In terms of physical properties and mechanical behavior, the cement based materials, such as UHP and ECC are well-matched with the substrate

concrete. Moreover, compared with FRP-wraps, FRC can effectively flow into the holes and fill the gaps and fix imperfections of the substrate surface. Moreover, using FRC material a designer can cope with different shapes and sections. Furthermore, the repair layer can protect the inner steel and prevent corrosion in aggressive environment.

This study intended to investigate the effect of surface repair material as well as the effect of horizontal reinforcement ratio (stirrup). The primary objectives of the research presented in this paper are:

- To observe the impact of different FRC material type on the stress-strain response of short concrete cylinders loaded in uniaxial compression
- To study and determine the effectiveness of thin layer of surface repair
- To investigate the impact of confinement provided by different surface repair materials and reinforcement ratio on crack formation, strain distribution, ductility and load-carrying capacity of squat columns

## 2. Experimental program

The experimental program consisted of uniaxial compressive tests on 24 concrete cylinders strengthened with four types of FRC jacket and three different ratios of horizontal reinforcement. The surface repair material included one type of UHP (UHP-SHCC) and three types of ECC with different fiber content (0.0%, 1.0% and 2.0% in volume). While the vertical reinforcement ratio was 0.87%, the horizontal reinforcement ratios of 0.00%, 0.56% and 1.70% were considered. The thickness of the strengthening jacket layer of all specimens was 25 mm. **Table 1** shows the notations used to specify the specimens. Each specimen identified by three parameters: Type of material, reinforcement ratio and the number of strain gauges. E0, E1, E2 and U account for the material type of ECC0, ECC1 ECC2 and UHP, respectively. R0, R1 and R2 represent the horizontal reinforcement ratio of 0.00%, 0.56% and 1.70% respectively. The last digit indicates the type of the specimen according to the number of strain gauges used. While specimens of Type 2 consisted of both internal gauges on the substrate surface and external gauges on the repair surface, the Type 1 specimens included only external strain gauges on the repair surface.

**Table 1. Specimens' identifiers and specifications**

Surface-Repair Material	Horizontal Reinforcement ratio (stirrup)			Type
	0.00%	1 $\phi$ 6 (0.56%)	3 $\phi$ 6 (1.70%)	
ECC0	E0-U-1	E0-R1-1	E0-R2-1	Type 1
	E0-U-2	E0-R1-2	E0-R2-2	Type 2
ECC1	E1-U-1	E1-R1-1	E1-R2-1	Type 1
	E1-U-2	E1-R1-2	E1-R2-2	Type 2
ECC2	E2-U-1	E2-R1-1	E2-R2-1	Type 1
	E2-U-2	E2-R1-2	E2-R2-2	Type 2
UHP	U-U-1	U-R1-1	U-R2-1	Type 1
	U-U-2	U-R1-2	U-R2-2	Type 2

The substrate concrete made from a mix of high-early-strength Portland cement, natural sand and gravel, as outlined in the mix proportion of

Table 2. All substrate concrete cylinders were cast from C40/50 ready-mix concrete with a maximum aggregate size of 24 mm. Steel cylinder molds 100 mm x 200 mm were used for casting concrete test substrate concrete. A total number of 27 concrete cylinders made from the same batch of concrete. The average compressive strength of the substrate concrete based on the tests results of three cylindrical specimens was 46.1 MPa, corresponding to an axial load of 362 kN. Using the average slope of the

stress-strain curve corresponding to stresses of less than 20% of the ultimate strength, the elastic modulus determined to be about 22700 MPa.

**Table 2. Mix properties of substrate material**

Material	Unit contents (kg/m <sup>3</sup> )					
	W/C	Water Content	Cement	Sand	Coarse Aggregate	AE Agent
Substrate Concrete	0.45	170	377	780	903	0.97

After water curing of concrete cores, the steel cages were fabricated and assembled as is presented in Figure 1. All strengthened specimens included three vertical  $\phi 6$  re-bars corresponding to a vertical reinforcement ratio of 0.87%. The specimens having horizontal ratio of 0.56% and 1.7% contained one and three  $\phi 6$  stirrups, respectively. The tensile yield strength and Young's modulus of the steel was 368 MPa and 186 GPa, respectively according to tensile test results of rebar specimens.

Specimen Type 2  
(without internal strain gauges)  
Stirrup: 3 $\phi 6$  (1.7%)

Specimen Type 1  
(consist of strain gauges on the core surface)  
Stirrup: 1 $\phi 6$  (0.56%)

**Figure 1. Details of the specimens, the substrate core and the external mold**

The mix proportions of materials used as the jacket surfaces are presented in **Table 3**. Material type of ECC0 representing a plain concrete without fiber which can be regarded as “mortar material”. Material type ECC1 and ECC2 included 1% and 2% of fiber content.

**Table 3. Mix Properties of the surface repair material**

Material	Unit contents (kg/m <sup>3</sup> )											
	W/C	Water Content	Cement	Sand	Coarse Aggregate	Fly Ash	Air Entrainment	Super-plasticizer	Air reducer	Viscosity Agent	Fiber	Silica Fume
<b>UHP</b>	0.22	340	1313	155	-	-	-	15.4	0.062	-	14.6	232
<b>ECC0</b>	0.45	384	599	630	-	255	5.99	-	-	1.9168	0	-
<b>ECC1</b>	0.45	384	599	604	-	255	5.99	-	-	1.9168	13	-
<b>ECC2</b>	0.45	384	599	577	-	255	5.99	-	-	1.9168	26	-

As some of the specimens included strain gauges which were sensitive to water, wet covering curing method used in the second stage of the curing (curing of the cover layer). To obtain the stress-strain curves, uniaxial compression test performed using a hydraulic testing machine. The specimens were tested using a 2000 kN compression machine and the data were monitored using an automatic data acquisition system (Figure 2). The bottom jaw of the testing machine was fixed. The top jaw was adjustable in the vertical direction and was attached to the loading actuator to record the applied load. The specimens were subjected to monotonically increasing axial concentric load. As shown in Figure , only the substrate core was subjected to the compression load.

**Figure 2 . Test setup**

### **3. Test results and discussions**

The strength of the cover materials was obtained using 50 mm x 100 mm cylindrical samples.

Table 4 presents the compressive strength of the jacket materials. According to the results, the maximum compressive stress carried by UHP material is considerably higher than that of the material type ECC0, ECC1 or ECC2.

**Table 4. Compressive strength of the surface-repair materials**

Cover Material	Specimen	maximum compressive stress (MPa)	avg. of maximum compressive stress (MPa)
ECC0	Sample 1	42	39.7
	Sample 2	40	
	Sample 3	37

	Sample 2	30	
	Sample 3	26	
ECC2	Sample 1	26	28.3
	Sample 2	40	
	Sample 3	19	
UHP	Sample 1	112	99.0
	Sample 2	95	
	Sample 3	90	

The test results of the strengthened specimens are provided in Table 5 and Figure 3. Experimental results indicate an increase in the load carrying capacity of all strengthened specimens compared to the average of 362 kN in the control specimens.

Figure 3(a) compares the load carrying capacity of the specimens. As a general trend, as the stirrup ratio increases, the compressive load capacity increases. The average load carrying capacity of specimens with stirrup ratio of 0.56% (R1) and 1.7% (R2) was approximately 11% and 24% higher than the corresponding values of the unreinforced specimens (without stirrups), respectively. Moreover, the ratio of the average compressive strength of the retrofitted to the core specimen was 1.16%, 1.28% and 1.44% for specimens with zero, 0.56% and 1.7% stirrup ratio, respectively.

Figure 3(b) compares the load carrying capacity of the specimens retrofitted with different types of jacket layers. As shown, by increasing the fiber content from 0 in ECC0 to 1% in ECC1 and to 2% in ECC2, the load carrying capacity increased by about 5% and 11%, respectively.

**Figure 3. Load carrying capacity of the specimens in specimens**

**Table 5. Compressive strength and Elastic Modulus**

### 3.1 Failure mode and damage pattern

In this section the failure mode of the specimens are described. Figure 4 shows the final cracking pattern of the tested specimens. As it is indicated in Figure 4 (a), specimens with neither fiber nor stirrup in the jacket layer, exhibited a very explosive and sudden brittle failure. The specimens with zero fiber content but with stirrups in the cover layer, the failure was sudden and brittle, but less explosive than specimens without stirrups. All specimens without horizontal reinforcement showed a brittle failure, no matter if the cover layer contained fiber Figure 4 (b)) or not (Figure 4 (a)). In these specimens, as a result of Poisson's effect and the expansion of the substrate layer, strain localization occurred in the strengthening layer, which prevented the stress distribution, led to a brittle failure characterized by a wide vertical crack (Figure 4 (b)) or an explosive failure (Figure 4 (a)). The same immature type of failure was reported by Kamal [1] for strengthened beams. For these brittle categories of specimens, in which the specimen lacks fiber or stirrup or both, when the stress reached to ultimate, the compressive capacity drops to zero suddenly and the specimen fails without any sign of post-peak strength.

On the other hand, a more ductile type of failure was detected for the specimens in which the cover layer included both fiber and stirrup, characterized by a more stable post peak response and a gradual degradation of the strength after it reached the maximum strength. For the specimens with a ductile behavior, as is specified in

also presents the strength ratio of the specimens at strain equal to 2% (which is four to five times of the peak strain) to the peak strength.

For specimens having fiber, the following modes of failure were observed:

- Having one stirrup  $1\phi 6$  (0.56%): Vertical cracks started from the bottom or top end, then deviated from the vertical direction to about 45 degree and extended to the mid-height of the specimen. The width of the crack was generally smaller than that in specimens without stirrup (Figure 4 (c)).
- Having three stirrups  $3\phi 6$  (1.7%): Inclined small cracks mostly extended up to the point in which horizontal steel was located. The horizontal steel extensively prevented the cracks to open-up. At the failure, larger number of cracks was observed compared with other specimens (Figure 4 (d)).

Stirrup and fiber caused the distribution of the cracks in macro and micro scale, respectively. As it is shown in Figure 4 (c) and Figure 4 (d), the stirrups resulted in formation of number of cracks with limited length and smaller width rather than a wide large crack. While the location and orientation of the large cracks are governed by the position of horizontal reinforcement, the distribution, direction and the location of small micro cracks are controlled by the fiber content ratio, properties, length, orientation and content.

### 3.2 Force-displacement response

The force displacement response of the tested specimens is presented in Figure 5-9. Comparing the ultimate strength of the substrate specimens (Figure 5) with that of retrofitted specimens (Figures 6-8), demonstrate that the strengthening method was successful in increasing the compressive strength. The repair layer confined the substrate concrete and hence caused an increase of 16% to 44% in compressive strength. Figure 6, Figure 7 and Figure 8 present the force displacement curve of specimens having stirrup ratio of zero, 0.56% and 1.7%, respectively. The slight slope of the tail of the force-displacement curves at the post-peak region of Figure 7 and Figure 8 indicates a more ductile response and stable post peak behavior of specimens having horizontal reinforcement compared with the response of specimens contained no horizontal steel (Figure 6). Figure 9 compare the force-displacement curve of the specimens

with surface repair material type of ECC0, ECC1, ECC2 and UHP. It can be seen that while the failure mode of the specimens retrofitted with material type ECC0 (zero fiber) is brittle (Figure 9), the specimens strengthened using fiber reinforced concrete exhibits a ductile response only if horizontal reinforcement is also provided.

Figure 10, presents the stress versus axial and hoop strain recorded for specimen E2-R2-1. The graph is presented as a sample as other specimens exhibited approximately the same trends. As shown in the figure, as can be predicted, throughout the test the tensile hoop strain increased as the axial stress increased. However, the behavior in the axial direction was completely different. The compressive axial strain increased as the axial stress increased. The rate of increase in the axial strain decreased prior to the peak strength. After the specimen reached the peak strength, the compressive axial strain started to decrease and became tensile toward the end of testing. The increasing compressive strain before the peak strength is due to the contribution of the jacket layer to carry axial stress, which attributed to the friction between the cover and the core layer by means of which the compressive stress can be transferred. At the peak strength, the compressive axial stress developed in the cover layer together with the radial stresses applied from the enclosed core, results in partially separation of the core and cover layers which reduce the friction and prevent a higher compressive stress develop in the cover layer. From this point onward, the compressive strain provided by friction reduces, and the tensile strain develops in the vertical direction as a result of core expansion.

#### 4 Conclusion

- The main conclusion of this study is that the combination of fiber reinforced concrete and stirrup used in a repair jacket can significantly improve the behavior of concrete columns.
- The stirrup confines the core and hence increases the compressive strength. The average compressive strength of specimens having 0.56% and 1.7% stirrup ratio, determined to be 11% and 24% higher than the corresponding value for unreinforced specimens, respectively. Moreover, the ratio of the average compressive strength of the retrofitted specimens to the core specimens were 1.16%, 1.28% and 1.44% for specimens having zero, 0.56% and 1.7% stirrup ratio, respectively.
- Although the horizontal reinforcement enhanced the compressive capacity, it did not improve the ductility of the specimens having zero fiber content. For specimens having higher fiber content, increasing of horizontal reinforcement was more effective in terms of improving the post peak behavior, residual strength and ductility.
- Using FRC as a free-crack water-proof surface repair material in squat columns can not only preserve the substrate from steel corrosion and concrete carbonation and erosion, but can also enhance the behavior of the member under axial stresses.

# Failure Mode and Risk Analysis

# A Review of Limit State Design Principles and Practice

Doug Jenkins<sup>1</sup>

<sup>1</sup>Principal, Interactive Design Services

**Abstract:** The intent of the limit state design method is to provide adequate performance for the worst combinations of load and environmental conditions and material behaviour, having regard to the expected frequency of conditions and consequences of failure. The advantage of this approach is that design may be optimised to suit the worst combination of conditions, rather than providing a single arbitrary “factor of safety”. To achieve the greatest benefit of this approach design procedures should be appropriate to the type of loading, and load and reduction factors should take account of all sources of uncertainty.

In this paper the provisions of Australian and international concrete design codes are reviewed, in particular with regard to their provisions for dealing with unpredictable load conditions, and uncertainties in materials properties. It is concluded that whilst provisions are made for specific extreme load conditions, these are not handled in a consistent way within the principles of limit state design, and codes do not take adequate account of unknown sources of variability in structural resistance.

Recommendations are made to allow the full benefit of the limit state design approach to be achieved, including: 1) Design for expected maximum loads, and for extreme unpredictable loads should be recognised as two separate limit states, the former requiring adequate strength in all structural members, and the latter requiring adequate robustness to prevent collapse in the overall structure. 2) Load and reduction factors should take account of unknown sources of variation, as well as known statistical variations.

**Keywords:** limit state design, risk, uncertainty, consequences of failure, robustness

## 1. Introduction

The limit state design method identifies events or conditions that may have an adverse effect on the performance of a structure and seeks to reduce the risk of these outcomes as far as reasonably practicable, having regard to their expected frequency and the consequences of their occurrence. A number of “limit states” are specified, together with load magnification factors, material strength reduction factors, and any other design parameters appropriate to the particular limit state. The potential benefits of this approach, compared with methods relying on limiting material stresses with a single “factor of safety”, are:

- The design may be optimised to minimise the overall risk, allowing improved reliability at no additional cost, equal reliability at reduced cost, or some combination of the two.
- The focus on limit states and modes of failure encourages the use of design features appropriate to the particular mode of failure.
- In particular, where a structure requires additional ductility, energy absorption, or stability under extreme conditions, the limit state method is more likely to identify and provide these requirements than methods that focus on the strength of isolated sections under expected loads.

The limit state method also has a number of potential disadvantages:

- Analysis and design procedures are likely to be significantly more complex than those required by traditional “allowable stress” methods.
- Where limit state factors are closely calibrated against the results of earlier design methods there may be no significant improvement in the cost or safety of completed structures.
- Conversely, if design factors are optimised based on recognised risks there may be an overall reduction in safety due to risks not considered in the calibration process.

- Differing approaches to risk minimisation between technical documents and legal requirements for risk minimisation may increase the possibility of engineers being considered legally liable for structural failures, even if they have followed specified design procedures with due diligence.

## 2. Practical Significance

This paper examines the application of the limit state method as specified in Australian concrete codes, and in concrete and other structural codes in New Zealand, Europe, and the USA, with the intent to:

- Identify significant differences in the application of limit state design principles.
- Identify areas where changes to the application of limit state principles could be significantly improved.
- Make recommendations for changes to Australian structural codes to enhance the benefits of the limit state method, and reduce the likelihood of adverse outcomes.

It is found that although the basis of the limit state method is stated in similar terms in most of the codes, there are significant differences in the method of application. In particular, the Ultimate Limit State provisions in all codes largely consist of simplified procedures requiring the calculation of maximum design actions and design capacity at isolated sections, rather than a consideration of the collapse behaviour of the whole structure.

It will be argued that the Ultimate Limit State should be divided into two separate limit states, with different load factors and acceptance criteria:

- The Strength Limit State: considering maximum expected loads and minimum design strength of isolated sections.
- The Collapse Limit State: considering the behaviour of the whole structure under collapse conditions.

This recognition will provide a more logical framework for provisions that already exist; for instance for seismic and impact loads. It will also provide a better basis for ensuring that all structures are designed and detailed with an appropriate level of resistance to unexpected events, including gross overload, ductility demand, or deviations from specified construction or maintenance procedures.

## 3. Limit State Terminology and Definitions

The terms and definitions given in this section are based on Australian usage, in the structural concrete codes. Significant differences in other codes are discussed in later sections.

In AS/NZS 1170.0:2002 (1) the following definitions are given:

**Limit states:** States beyond which the structure no longer satisfies the design criteria.

**Limit states, serviceability:** States that correspond to conditions beyond which specified service criteria for a structure or structural element are no longer met.

**Limit states, ultimate:** States associated with collapse, or with other similar forms of structural failure. NOTE: This generally corresponds to the maximum load-carrying resistance of a structure or structural element but, in some cases, to the maximum applicable strain or deformation.

**Structural robustness:** Ability of a structure to withstand events like fire, explosion, impact or consequences of human errors, without being damaged to an extent disproportionate to the original cause.

Section 6 of AS/NZS 1170.0 provides general requirements for design and detailing of the “force-resisting system”:

- Structures shall be detailed such that all parts of the structure shall be tied together both in the horizontal and the vertical planes so that the structure can withstand an event without being damaged to an extent disproportionate to that event.
- The design of the structure shall provide load paths to the foundations for forces generated by all types of actions from all parts of the structure, including structural and non-structural components.

Other standards use the term “progressive collapse” and require (under some circumstances) provision of “alternative load paths”.

There is broad agreement between the international standards regarding the basic concept of limit states, and the specification of two limit states that must be satisfied; that is the serviceability and ultimate limit states. Detailed provisions for the Serviceability Limit State vary widely between different codes, but these detail differences are outside the scope of this paper. There are also significant differences in the wording of requirements for the Ultimate Limit State, which are examined in detail in the next section.

#### **4. Code Provisions for Limit State Design**

##### **4.1 AS-NZS 1170.0 and 1170.0 Supplement**

Section 7 of AS-NZS 1170.0 (1) provides requirements for two classes of Ultimate Limit States:

- 7.2.1 Stability: When considering a limit state of static equilibrium or of gross displacements or deformations of the structure, it shall be confirmed that ...
- 7.2.2 Strength: When considering a limit state of collapse, rupture or excessive deformation of a structure, section, member or connection it shall be confirmed that ...

Note that the overall stability of the structure, total collapse of the structure, and failure or excessive deformation of a single member or connection are all treated as examples of failure of the same limit state.

The Supplement to AS-NZS 1170.0 (2) provides further background information to the requirements of the standard. It states:

“The Standard incorporates the fundamentals of the limit states method and enables the designer to confirm the design of a structure. The intention is that confirmation establishes the ability of the proposed structure to resist known or foreseeable types of action appropriate to the intended use and design working life of the structure.”

It quotes ISO 2394 (3) as follows:

“In particular, they shall fulfil, with appropriate degrees of reliability, the following objectives:

- (a) They shall perform adequately under all expected actions.
- (b) They shall withstand both extreme actions and frequently repeated actions occurring during their construction and anticipated use.
- (c) They shall have structural robustness.’

These three objectives enunciate the serviceability, ultimate and fatigue, and progressive collapse (structural robustness) aspects of design.”

Section 6 of the Supplement provides more specific advice on design for structural robustness:

“... The potential damage may be avoided or limited by use of the following: ...

- (c) Selecting a structural form and design that can survive adequately the accidental removal of an individual element or a limited part of the structure or the occurrence of acceptable localized damage.
- (d) Avoiding as far as possible structural systems that may collapse without warning.

The design should provide alternate load paths so that the damage is absorbed and sufficient local strength to resist failure of critical members so that major collapse is averted. ...

Connections for example should be designed to be ductile and have a capacity for large deformation and energy absorption under the effect of abnormal conditions.”

Section 7 divides “Strength ultimate limit states” into 3 sub-classes:

- “(a) Attainment of the maximum resistance capacity of sections, members or connections by rupture (in some cases affected by fatigue, corrosion, and similar) or excessive deformations.
- (b) Transformation of the structure or part of it into a mechanism.
- (c) Sudden change of the assumed structural system to a new system (e.g., snap through).”

Appendix CA (Special Studies) states:

“Accidental actions include explosions, collisions, fire, unexpected subsidence of subgrade, extreme erosion, unexpected abnormal environmental loads (flood, hail, etc.), consequences of human error and wilful misuse. It is impractical to design for all accidental actions as they are very low probability events.

However, precautions should be taken to limit the effects of local collapses caused by such actions, that is, to prevent progressive collapse (see Section 6 and its commentary).”

## **4.2 AS 3600**

The Australian Standard Concrete Structures Code, AS 3600 (4) refers to the Loading Code, AS-NZS 1170.0 (1), for definitions and principles of the limit state method. Code clauses where the general provisions of the Loading Code are significantly amplified or varied are noted below:

Clause 2.2, Design for Strength, requires that:

“2.2.1 General: Strength checks for concrete structures and their component members shall be carried out ..., as appropriate to the strength check procedures being used.”

“2.2.5 The strength check procedure for use with non-linear analysis of framed structures at collapse shall be carried out as follows: ...”

The provisions of Clause 2.2.5 require consideration of the behaviour prior to collapse of the structure as a whole, including the margin between first yielding and peak load.

Clause 6.5, Non-Linear Frame Analysis, requires analysis of the structural behaviour at three separate levels: “This Clause applies to the non-linear analysis of framed structures at service load, at overload, and at collapse.”

The supplement to AS 3600 (5) contains the only specific requirement that the removal of one member from a framed structure should not result in a progressive collapse:

“C2.1.3 Design for robustness: A structure is to be designed such that ... , should one member be removed, the remainder of the structure would hang together and not precipitate a progressive collapse.”

## **4.3 AS 5100**

The Australian Standard Bridge Design Code, AS 5100 (6) includes detailed provisions for general design principles, loading, and the design of concrete structures, which whilst they generally follow the requirements of other Australian Standards (1,2,4,5), include significant variations where considered appropriate for the differing load conditions and longer design life of bridge structures. The extracts below relate to the major differences in wording and requirements for the ultimate limit state, and design for robustness:

### **4.3.1 Part 1: Scope and general principles**

Clause 6.3.2 Ultimate limit states:

“The ultimate limit states include the following:

- (a) Stability limit state, which is the loss of static equilibrium by sliding, overturning or uplift of a part, or the whole of the structure.
- (b) Strength limit state, which is an elastic, inelastic or buckling state in which the collapse condition is reached at one or more sections of the structure. Plastic or buckling redistribution of actions and resistance shall only be considered if data on the associated deformation characteristics of the structure from theory and tests is available.

Clause 11.3 Collision from railway traffic:

(b) ... supports adjacent to railway tracks may be permitted subject to ...

(i) Alternative load paths are available through the structure to ensure that the superstructure does not collapse in the event of removal of the supporting piers or columns as a result of collision...

### **4.3.2 Part 2 Design Loads**

Clause 14.7.5: Structural detailing requirements for earthquake effects; Ductile behaviour: “For bridge structures in BEDC-2, BEDC-3 and BEDC-4, a clearly defined collapse mechanism shall be established. The structural members shall be ductile at the potential plastic hinge locations defined in the mechanism.”

### **4.3.3 Part 5 Concrete**

Clause 2.11: Design Requirements and Procedures; Other Design Requirements:

“Requirements, such as progressive collapse and any special performance requirements, shall be

considered where relevant and, if significant, shall be taken into account in the design of the structure in accordance with the principles of this Standard and appropriate engineering principles.”

Clause 7.7: Seismic Analysis Methods:

“For a bridge structure in earthquake design category BEDC-4, the collapse mechanism shall be defined using a post-elastic analysis and it shall be ensured that there is a unique and enforceable strength hierarchy within the structural system.”

#### **4.4 NZS Codes**

The New Zealand loading codes are jointly published with Australian Standards (1, 2), but the New Zealand Concrete Structures Standard, NZS 3101 (7) is totally separate from the Australian Standard, other than referring to the same loading codes. NZS 3101 contains extensive requirements for design and detailing of structures under different levels of earthquake loading, but for the purposes of this paper only general requirements relating to the specification of limit states have been reviewed.

The code defines an “ultimate limit state”, rather than “limit states” as used in AS/NZS 1170.0 (1). The definition relates to the structure as a whole, rather than individual members or sections: “ULTIMATE LIMIT STATE. The state at which the design strength or ductility capacity of the structure is exceeded, when it cannot maintain equilibrium and becomes unstable.”

Clause 2.6 lists additional requirements for earthquake effects:

“2.6.1.1 Deformation capacity: In addition to the requirements of 2.3.2 for strength, the structure and its component parts shall be designed to have adequate ductility at the ultimate limit state for load combinations including earthquake actions.”

Clause 2.5 lists fatigue requirements as a serviceability limit state:

“2.5 Other design requirements: ...

2.5.2 Fatigue (serviceability limit state) “

#### **4.5 Eurocodes**

The Structural Eurocode series consists of ten documents covering the basis of structural design and application to different materials and load conditions. This paper examines the contents of EN 1990, Basis of Structural Design (8), and EN 1992, Design of Concrete Structures (9).

Code clause numbers followed by (P) in the quoted extracts below indicate clauses that are defined as “Principles” comprising:

- general statements and definitions for which there is no alternative, as well as ;
- requirements and analytical models for which no alternative is permitted unless specifically stated.

EN 1990 defines ultimate limit states as follows:

“1.5.2.13 ultimate limit states: states associated with collapse or with other similar forms of structural failure. NOTE They generally correspond to the maximum load-carrying resistance of a structure or structural member.”

Section 2 lists basic requirements, including:

2.1 Basic requirements ...

“(4)P A structure shall be designed and executed in such a way that it will not be damaged by events such as :

-explosion,  
- impact, and  
-the consequences of human errors,  
to an extent disproportionate to the original cause.

(5)P Potential damage shall be avoided or limited by appropriate choice of one or more of the following:  
avoiding, eliminating or reducing the hazards to which the structure can be subjected;  
selecting a structural form which has low sensitivity to the hazards considered;  
selecting a structural form and design that can survive adequately the accidental removal of an individual member or a limited part of the structure, or the occurrence of acceptable localised damage;

avoiding as far as possible structural systems that can collapse without warning; tying the structural members together.”

Section 3 lists ultimate limit states as follows:

### “3.3 Ultimate limit states

(1)P The limit states that concern:

- the safety of people, and/or
- the safety of the structure

shall be classified as ultimate limit states.

(2) In some circumstances, the limit states that concern the protection of the contents should be classified as ultimate limit states.

...

(3) States prior to structural collapse, which, for simplicity, are considered in place of the collapse itself, may be treated as ultimate limit states.

(4)P The following ultimate limit states shall be verified where they are relevant:

- loss of equilibrium of the structure or any part of it, considered as a rigid body;
- failure by excessive deformation, transformation of the structure or any part of it into a mechanism, rupture, loss of stability of the structure or any part of it, including supports and foundations;
- failure caused by fatigue or other time-dependent effects.”

EN 1992, Eurocode 2-1 (9) has the following requirement for prevention of progressive collapse:

#### “9.10.1 General

(1)P Structures which are not designed to withstand accidental actions shall have a suitable tying system, to prevent progressive collapse by providing alternative load paths after local damage. The following simple rules are deemed to satisfy this requirement ...”

## **4.6 ACI 318**

The ACI building code, ACI 318 (10) does not define design limit states; nonetheless its requirements for provision of adequate strength and resistance to collapse correspond to the ultimate limit state requirements in the other codes examined in this paper.

Requirements for strength design are stated in terms of the strength of individual members:

“8.1.1 — In design of structural concrete, members shall be proportioned for adequate strength in accordance with provisions of this Code, using load factors and strength reduction factors  $\phi$  specified in Chapter 9.”

Chapter 21 covers design of earthquake resistant structures, including provisions to prevent progressive collapse:

“21.1.1.1 — Chapter 21 contains requirements for design and construction of reinforced concrete members of a structure for which the design forces, related to earthquake motions, have been determined on the basis of energy dissipation in the nonlinear range of response.”

“R21.8.4 ... The design procedure should identify the load path or mechanism by which the frame resists gravity and earthquake effects.”

## **5. Limit State Provisions in Other Codes and Documents**

Whilst the great majority of structural design codes follow the practice of dividing limit states into the “serviceability” and “ultimate” categories, there are a number of documents that define a “collapse limit state”, either in addition to, or in place of the ultimate limit state. This usage is generally limited to those codes where design actions are much higher than can be accommodated by a strength design approach (such as earthquake loading in high seismic regions), or where the probability and/or consequences of failure are particularly high (such as off-shore drilling structures).

Documents related to seismic design of concrete structures, that include reference to a specific collapse limit state include:

- EN 1998-3, Eurocode 8: Design of structures for earthquake resistance – Part 3 (11) lists three limit states: “Near Collapse”, “Significant Damage”, and “Damage Limitation”. It states that “The definition of the Limit State of Collapse given in this Part 3 of Eurocode \* is closer to the actual collapse of the building than the one given in EN 1998-1: 2004 and corresponds to the fullest exploitation of the deformation capacity of the structural elements.”
- Procedures developed by The Engineering Advisory Group set up following the Christchurch earthquakes require consideration of building performance at the ultimate limit and collapse limit states (see Oliver et al. (12)).
- A paper presented to the Australian Earthquake Engineering Society 2011 Conference (Fardipour et al. (13)) deals with the “Collapse Limit State Assessment of Lightly Reinforced Concrete Columns”.
- The commentary to Part 5 of the AS-NZS Loading Code, NZS 1170-5 (S1), (13) states that “it is not currently considered practical to either analyse a building to determine the probability of collapse or base a code verification method around a collapse limit state ... it is possible to consider a limit state at a lower level of structural response, ... and then rely on margins inherent within the design procedures to provide confidence that acceptable collapse and fatality risks are achieved. In this Standard this limit state is referred to as the ultimate limit state (ULS).”
- Clause 2.1 of NZS 1170-5 (S1) states: “It is inherent within this Standard that, in order to ensure an acceptable risk of collapse, there should be a reasonable margin between the performance of material and structural form combinations at the ULS and at the collapse limit state. For most ductile materials and structure configurations it has been assumed that a margin of at least 1.5 to 1.8 will be available. This is intended to apply to both strength and displacement.”

The concept of separate “ultimate” and “collapse” limit states is further discussed in the Interim Report of The Canterbury Earthquakes Royal Commission (14).

Outside of earthquake design requirements, a number of codes and technical papers deal with requirements for an “accidental collapse limit state” and for prevention of “progressive” and/or “disproportionate” collapse, for example references 15 – 19.

## **6. Risk Management**

### **6.1 Approaches to Risk Management**

In “Safety of Structures, and a New Approach to Robustness” (20) Beeby writes: “It is proposed that the provision of adequate safety in structures depends on the satisfaction of three independent requirements: adequate safety factors, adequate control of the design and construction process, and adequate robustness.... The risks from failure may not be greatly changed by changes in safety factor”. This statement highlights the two main areas in which structural design codes may fail to minimise the risk of building collapse:

- Statistical analyses used to calibrate code load and resistance factors do not include significant sources of risk, such as failures in the design and construction process, or unforeseen events after completion.
- Increasing design loads, or reducing design strength capacity may have little effect on the risk of collapse where extreme conditions require ductility and energy absorption, or the ability to distribute loads to alternative load paths.

Analyses of risk in other areas arrive at similar conclusions. In “The Black Swan” (21) Taleb examines risk in global financial management, and finds (immediately before the start of the Global Financial Crisis) that focus on expected risks leaves institutions with increased susceptibility to collapse from the unexpected. He writes “the idea is not to correct mistakes and eliminate randomness ... *The idea is simply to let human mistakes and miscalculations remain confined*, and to prevent their spreading through the system, ...” (author’s emphasis).

## 6.2 Legal Requirements

Legal requirements to minimise risk have developed largely independently of structural design codes, and may have requirements that are inconsistent with the approach of the national codes. In some cases specific legal frameworks have developed over time as the result of a single incident. The most influential such incident is the Ronan Point Collapse of 1968, leading to widespread research into disproportionate and progressive collapse mechanisms, and specific requirements in the UK National Building Regulations, contained in “Approved Document A” (22).

In the Australian context requirements for prevention of collapse are much less well defined, however recent national safety in design legislation (23) requires that all risks be eliminated or minimised “so far as is reasonably practicable”, and this requirement applies to the design of structures, both for the construction stage and after completion.

The phrases “so far as reasonably practicable” (SFARP, or SFAIRP) and “as low as reasonably practicable” (ALARP) have a long history of use in the UK, which is documented in a publication by the Centre for the Protection of National Infrastructure (24). This document, and other reviews of the UK and Australian legislation (25, 26) suggest that the two phrases have effectively the same meaning. A recent paper by Robinson (27) however suggests that the two phrases reflect fundamentally different approaches to the design process, and that in the event of a structural failure the hazard focussed ALARP approach is unlikely to be found (in hindsight) to have satisfied the statutory requirements of the precaution focussed SFAIRP approach.

These issues remain to be resolved, but to minimise the risk of legal action against design engineers who have performed their duties with all due diligence (SFAIRP) it is highly desirable that design code provisions should be consistent in their requirements and terminology, and that where different levels of precaution are required for different classes of structure, these differences should be explicitly stated.

## 7. Summary and Conclusions

The design codes examined in this paper have a similar approach to the statement of the limit state method (other than ACI 318 (10), which does not use this terminology). They also have a similar approach in the application of design procedures to different classes of structure. They all shared an inconsistent approach towards design for the Ultimate Limit State in that:

- The Ultimate Limit State is characterised as a requirement to avoid structural collapse, but the great majority of the detailed code provisions relate to strength at a single cross-section, or in a single member (after limited allowance for load distribution).
- Code provisions for earthquakes and impact loads allow significant damage to the structure, provided that partial or total collapse is avoided, but these requirements are treated as being the same limit state as those that require the design strength of every section to be greater than the maximum design actions.

Of the codes examined in this paper only Eurocode 2 (9) contains specific general provisions (outside seismic or impact load requirements) intended to ensure resistance to disproportionate collapse after localised failure. In the UK further detailed provisions are given in the Building Regulations Approved Document A (22).

In Australia and New Zealand the joint loading codes (1,2) require structures to be robust, and to provide “alternate load paths”, but do not provide any specific guidance on how this should be achieved, or on the levels of robustness appropriate to different classes of building. In the Australian Concrete Structures Code and Commentary (4, 5) the code contains only general requirements for robustness, but the recently published commentary requires that “should one member be removed, the remainder of the structure would hang together and not precipitate a progressive collapse.”

Recent Australian legislation relating to “Safety in Design” (23) requires that all known risks should be removed or minimised “so far as is reasonably practicable”. Only very general guidance is given on how the limit of practicability should be determined and applied, and it has been argued that the design approach given in current standards and codes of practice is inherently incompatible with the legislated requirements (27).

In order to make design code procedures more internally consistent, to improve consistency with legal requirements, and to provide specific guidance on what measures should be considered practicable, the following changes to the Australian loading and structural design codes are recommended:

- Three separate levels of limit state should be specified:
  - Serviceability: the level at which unscheduled maintenance or repair is required, or specified performance requirements are no longer met.
  - Strength: the level at which any member fails or suffers excessive deformation.
  - Collapse: the level at which a structure is on the point of substantial or total collapse.
- Consideration of the Collapse Limit State should not be limited to seismic and impact loading, but should include all potential causes of collapse, including loss of support, deterioration of material properties, improper construction procedures, effects of fire, and extreme loads due to any cause.
- Where the degree of collapse resistance is considered to be related to the classification of the structure and the consequences of failure, specific guidance should be provided in the code regarding the type of analysis and the level of robustness required for different types of structure.

The advantages provided by these changes include:

- The limit state principles would be consistent with the actual requirements of the structures design codes.
- The code requirements would also be more consistent with the Safety in Design legislation.
- The risk of design engineers being held legally liable for failures due to unexpected causes would be reduced.
- A general increase in structural robustness would allow a review of load and reduction factors for the Strength Limit State, potentially allowing a significant improvement in design efficiency.

# Fasteners to Concrete: Failures and Solutions

Heath, D. J.<sup>1</sup>, Gad, E. F.<sup>2</sup>, Lee, J.<sup>3</sup>

<sup>1</sup> National Technical Manager, Australian Engineered Fasteners and Anchors Council

<sup>2</sup> Chair of Department of Civil and Construction Engineering, Swinburne University of Technology

<sup>3</sup> Training and Development Manager, Australian Engineered Fasteners and Anchors Council

**Abstract:** Safety-critical fasteners to concrete are widely used in construction from small retro-fit applications to large infrastructure projects. To compromise their function endangers life and leads to considerable financial consequences, including disruption to the structure. The contributing factors to failures are largely avoidable through an awareness of the factors that influence fastener performance. This awareness is the cornerstone of risk mitigation strategies in the fastener industry and is achievable by reviewing education materials that are readily available. At present, there is a real risk that failures will continue to occur if lessons from past failures are not learned. The absence of guidance in Australian design standards and codes of practice and the lack of training and supervision during fastener installation dramatically increases the risk of failures occurring. Manufacturers, suppliers, design engineers, installers and field engineers may all be implicated in a failure investigation where ignorance is not a valid defence. The Australian Engineered Fasteners and Anchors Council was founded to address shortcomings in the industry and has developed technical guidance for specification and an installer certification program to lift quality and safety standards. This paper reviews a series of case studies of anchor failures from around the world, identifies the links with problems frequently encountered within the Australian construction industry and offers best practice solutions to prevent further failures from occurring.

**Keywords:** Post-installed, cast-in, anchor, fastener, failure

## 1. INTRODUCTION

Structural fasteners used in safety-critical applications involving metal inserts into a concrete or masonry substrate should be designed and detailed by a competent structural engineer. Applications are defined as 'safety-critical' when their failure may cause risk to human life and/or have considerable economic loss. Fasteners must be fit for purpose; durable, robust, and possess sufficient integrity for all design actions [1]. Structural fasteners in concrete or masonry are commonly referred to as anchors and form the focus of this paper.

In concrete, anchors may be grouped according to their installation method into cast-in-place and post-installed. Post-installed anchors may be further classified into two groups; direct installation (power actuated) fasteners and a much larger ensemble being drill installation fasteners which covers chemical bonded anchors and mechanical anchors (such as expansion and screw anchors).

The Australian Engineered Fasteners and Anchors Council (AEFAC, [www.aefac.org.au](http://www.aefac.org.au)) is an industry initiative that was formed in 2012 to introduce governance to the industry with support and guidance to be provided for design engineers, contractors, suppliers, installers and field engineers.

This paper outlines the details of a number of fastener failures that have been published, identifying common themes and lessons that should be learned from these failures to prevent them from occurring again. A summary is also provided of two new initiatives developed by AEFAC that are relevant to the case studies and will help lift safety standards in the Australian anchor industry. These include the development of the proposed AEFAC Standard for design engineers and the development of the AEFAC Installer Certification Program for installers of anchors.

## 2. ANCHOR FAILURES

The absence of suitable guidelines for anchors in safety-critical applications overseas has contributed to catastrophic failures ([2], [3], [4]). The following section outlines six different failure case studies that are relevant to fasteners and identifies common factors contributing to the failures.

### 2.1 Case study #1: prequalification

In 2012 a brace fixing bolt was being tightened to a ferrule when the ferrule fractured approximately 60 mm inside the panel at the location of minimum cross-sectional area corresponding to the hole for reinforcing bar (refer to Figure 1). A subsequent investigation was performed by WorkSafe Victoria

revealed that the product contained no marking as recommended by AS 3850:2003 [5], making identification and traceability difficult, particularly for reference to the specification and manufacturer's installation instructions, as well as reducing the possibility for product substitution [6]. Further, failure of the ferrule posed a crush hazard. A separate incident involving the erection of precast concrete panels highlighted this crush hazard when multiple panels collapsed into an adjacent car park (refer to Figure 2). Inspectors of the second incident were unable to confirm key details concerning the collapse including the choice of brace inserts (fasteners) supporting the temporary braces that pulled out of the concrete slab.

**Figure 1. Ferrule that fractured during installation (source: [7]).**

**Figure 2: Precast panel failure during erection crushes cars (source: [8]).**

The ferrule failure demonstrates not only the dangers of using fasteners without appropriate markings, it also highlights the need for a robust and transparent approvals scheme to demonstrate that the product is fit for its intended use. An example scheme employed in Europe for post-installed fasteners to concrete that provides this level of confidence is ETAG 001 [9]. This scheme includes quality assurance during manufacturer through factory production control, plus robust product assessment through standardised testing and evaluation procedures. The scope of this scheme covers tests addressing tolerances on installation practice and tests for admissible service condition to ensure that the fastener remains serviceable throughout its design life.

## **2.2 Case study #2: Canopy-fence failure on 17<sup>th</sup> Street Bridge**

At 11.20pm on August 13, 2011 approximately 190 feet (58 metres) of a canopy fence structure detached from the 17<sup>th</sup> Street Bridge in Atlanta, falling onto the roadway below [10]. There were no injuries and no damaged vehicles as a result of the collapse. The remaining canopy-fence on the 700 foot (213 metre) long overpass was removed a short time later. The bridge was opened in 2004 and spans over the Interstate Highway 75/85 which comprises 20 lanes of traffic. The southern side of the bridge includes the canopy-fence that was connected to the parapet wall. Each support frame for the canopy-fence was spaced 10 feet, six inches (3.2 metres) apart. A total of 19 support frames detached from the parapet during the collapse.

Wiss, Janney, Elstner Associates, Inc. were engaged to undertake a forensic examination of the collapse. The investigation into documentation revealed numerous shortcomings in the design and fabrication documents. One drawing referenced 7/8" (22 mm) anchor rods with sufficient embedment to develop 4 kips (17.8 kN) for the connection of the canopy-fence to the parapet, however the hole diameter and embedment depth as well as the anchor material and type of chemical system were not specified. A structural analysis revealed the eccentricity of the resultant load from the canopy structure relative to the fixture generated a net overturning moment that resulted in a sustained in-service tensile load equal to 1053 pounds (4.7 kN) on the bottom fasteners attaching each support frame of the canopy-fence. The Georgia Department of Transportation Office of materials and Research found that there were 15 different epoxy-resin products that met the standard specification and "Acceptance of Miscellaneous Construction Items".

Anchor rods from the fixtures were examined both in cases of failure as well as in fixtures that remained attached to the parapet. Failed anchor rods and those extracted from the fixtures remaining attached to the parapet were either 11" (279 mm) threaded rod or a combination of 6" (152 mm) threaded rod plus 5" (127 mm) smooth unthreaded rod. Of the 168 anchor rods remaining attached to the canopy after the failure, 112 had measureable withdrawal between 1/16" (1.6 mm) to 1.75" (44.5 mm). Holes that had experienced anchor pull-out were frequently observed to have voids between 1 –

1.5" (25.4 – 38.1 mm) in length plus uncured epoxy was extracted from the rear of three holes in the failure area.

(a) Canopy fence collapsed onto roadway.

(b) Threaded and smooth anchor rods.

(c) Typical column-cantilever assembly detail.

**Figure 3. Canopy fence failure on Interstate Highway 75/85 in Atlanta (source: [10]).**

Laboratory tests confirmed the concrete was well consolidated and included well graded concrete with a compressive strength equal to 6787 psi (46.8 MPa). Analysis of the composition of the chemical anchors revealed differences in material composition from different sample locations, with results also suggesting hardener-rich areas and resin-rich areas. A creep test confirmed that the product used was susceptible to creep under sustained tensile loading.

The failure was attributed to: i) chemical anchors having poor resistance to long-term creep under sustained loading, ii) disproportionate and incomplete mixing of chemical anchor components, and iii) large voids in the chemical resulting in reduced embedment length and a greater effective shear stress needing to be resisted by the chemical anchor. The sustained in-service loads resulted in anchors withdrawing resulting in an increase in the eccentricity of loading, further increasing the magnitude of sustained load applied to the anchors.

The 17<sup>th</sup> Street Bridge canopy-fence failures case study is important because it highlights shortcomings in the specification, procurement and installation of the product. The specification for a chemical anchor should be accurate and contain a sufficient level of detail to ensure that there is no ambiguity for anchor procurement [11]. The type of product used was also found to be creep-sensitive and thus unsuitable for sustained in-service loads. The findings from the investigation also revealed shortcomings with the installation including poorly mixed products, excessive entrained air and product substitution without the written consent of the design engineer. Collectively, these factors resulted in safety being compromised for the project.

### 2.3 Case study #3: Awning collapse in Queensland

In 2012 an awning on a shop front swung down as the result of an anchor failure, resulting in one fatality and injuries to five other people. The awning was constructed in the 1970s and was fixed to adjacent reinforced concrete beams via torque-controlled expansion anchors. A safety alert published by Workplace Health and Safety Queensland revealed the structure had deteriorated with rust causing the fasteners to be prised out [12]. The design of the awning was such that fasteners were obscured from view making inspection difficult. The investigation that followed the failure revealed incorrect hole diameter and depth for the fasteners with the position of reinforcement in the concrete preventing

drilling from achieving the required depth. It was also established that additional sails had been added to the awning resulting in an increase in applied loads.

(a) Structure that swung down.

(b) End of awning with anchors showing.

**Figure 4: Awning collapse (source: [13]).**

This failure highlights the importance of a number of key requirements for fasteners:

1. Inspection and maintenance programs are necessary, especially for aging assets.
2. The selection of an anchor requires consideration of all likely loads encountered during the intended service life. Any variation to this constitutes change management, requiring a revision of the fastener design by the responsible engineer.
3. The installer needs to be aware that failing to achieve the correct drill depth may compromise the safety of the fixture and requires proper change management procedures to be followed, including notifying the responsible engineer. Further, there are strict tolerances on hole diameters for post-installed mechanical anchors – including torque-controlled expansion anchors – such that exceeding these tolerances may prevent the fastener from functioning as intended. If drilling meets refusal prior to achieving the required drilling depth, the responsible engineer should provide written approval for an alternative specification.

#### **2.4 Case study #4: Ceiling collapse in educational building**

A large educational building in the UK had been constructed when the suspended ceiling in a large teaching hall collapsed shortly before the opening of the building. There were no casualties since nobody was in the building at the time of collapse. The installation of the suspended ceiling was a variation on the original design intended to reduce noise levels from footfall impact in the facility. A report of the findings from the investigation that followed the failure was submitted to Confidential Reporting on Structural Safety (CROSS) in the UK [14]. The investigation found that the mechanism of failure was progressive collapse. Several key factors contributed to the collapse. Firstly, the specification was reportedly only partially complete. Secondly, although the correctly rated fixture had been procured, the fixture was appropriate for compression-only loads, not tensile loads.

**Figure 5: Ceiling collapse in educational building (source: [14]).**

Although the suspended ceiling was non-structural, it should be deemed to be safety-critical due to the potential consequences of failure. The lessons from this failure were the importance of a complete specification, as well as appropriate supervision on site to monitor installation.

### **2.5 Case study #5: Uster swimming pool concrete ceiling collapse**

The heavy concrete ceiling over a swimming pool in Uster, Switzerland had been in service for a period of 13 years when it suddenly collapsed, resulting in 12 fatalities and 19 people injured. The ceiling had been supported by a tension hanger system including stainless steel hanger rods. The failure investigation revealed that chloride stress corrosion cracking had severely weakened the austenitic stainless steel rods supporting the ceiling, leading to the collapse ([15], [16]). The condition is brought about by evaporation of chlorinated water with water vapour condensing in cooler regions of the interior space. With successive cycles, a concentration of chlorine deposits built up on the stainless steel components leading to localised corrosion and fine cracks developing. Stress corrosion cracking is a condition that may form in the presence of three conditions: i) inappropriate grade of stainless steel, ii) relatively high tensile stress developed in the element relative to yield strength, and iii) presence of a specific aggressive environment.

**Figure 6: Collapse of heavy concrete ceiling in swimming pool facility (source: [17]).**

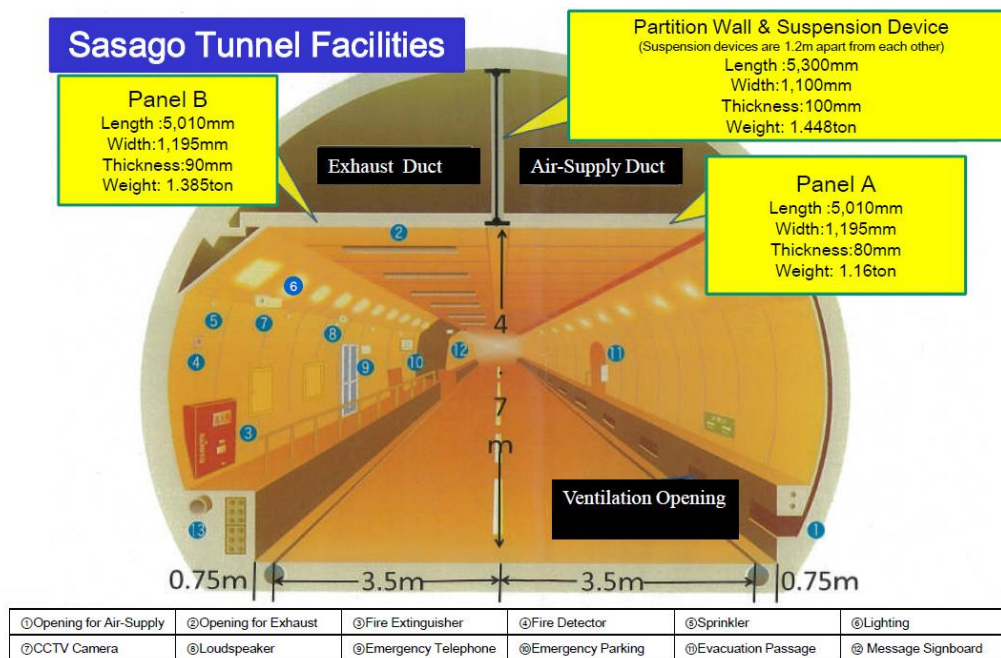

Although the failure occurred in the tension rods, the fasteners often form part of the tension system and are therefore an equally important consideration during design. General statements in project requirements result in the specification of austenitic stainless steel grades such as AISI 304 or AISI 316 that are inappropriate for corrosion conditions in an indoor swimming pool environment and render the fasteners susceptible to stress corrosion cracking. Since the collapse of the Uster swimming pool ceiling in 1985, other swimming pool ceilings have failed due to stress corrosion cracking such as the Steenwijk swimming pool in the Netherlands in 2001 [17]. These events reinforce the need for correct specification of material grades by consulting the fastener supplier's technical staff, as well as implementing an appropriate inspection and maintenance program.

### **2.6 Case study #6: Partial collapse of Sasago tunnel ceiling**

On December 2<sup>nd</sup>, 2012 a 130 metre section of concrete ceiling panels collapsed in the Tokyo-bound (inbound) Sasago Tunnel, 1.7km from the east portal of the 4.7km long tunnel (refer to Figure 7). Construction of the main body of the tunnel was originally completed in 1976 with the ceiling panel installation completed in 1977. The precast concrete panels were installed for the tunnel ventilation system and included ceiling panels and partition walls, weighing between 1.16 – 1.448 ton (refer to Figure 8). Chemical anchors were used to support the ceiling panels and partition walls [18]. In response to the collapse the "Research and examination committee for tunnel ceiling collapse incident" was formed to investigate the cause of collapse and to propose preventative measures to avoid recurrence. A preliminary report of the event published by the Ministry of Land, Infrastructure, Transport and Tourism of Japan noted that the incident caused three vehicles to be crushed, two of which caught fire, resulting in nine fatalities and two additional people injured [19]. Both inbound and outbound tunnels were immediately closed, with the outbound tunnel re-opened on 29<sup>th</sup> December, 2012 and the inbound tunnel re-opening on February 8<sup>th</sup>, 2013 more than two months after the failure.

**Figure 7: Partial collapse of concrete panels in Sasago Tunnel (source: [20]).**

**Figure 8: Structural system of Sasago Tunnel (source: [21]).**

As a safety precaution, ceiling panels in the outbound and inbound tunnels were removed and an investigation found 632 defects associated with the anchors securing the ceiling panels in the outbound tunnel and 1028 defects associated with anchors securing the ceiling panels in the inbound tunnel. Typical defects reported included loose anchors, missing anchors and cracked concrete.

Key findings from the investigating committee suggested the following factors contributed to the partial collapse:

1. Pressure differential between the two chambers separated by the partition wall had not been factored into the original design resulting in greater loading on the fasteners supporting the partition walls.
2. Inconsistencies were present among specifications, design reports and final drawings for the chemical anchors, with some anchor rods recovered onsite being shorter than the required length leading to insufficient tensile strength.
3. Insufficient level of detail in the specified performance requirements for the chemical anchor product.
4. Deterioration of the chemical compound in the chemical anchors attributed to repeated loading caused by operation of the ventilation system and pressure from passing vehicles as well as hydrolytic degradation of the chemical compound due to the aggressive environment.
5. No close visual testing or site testing of anchors for 12 years prior to the collapse.

The combination of the number of defects present in the structure and the lack of an inspection and maintenance program meant that a catastrophe was inevitable. The report of preliminary findings

revealed failure of the safety-critical fasteners resulted not only in injury and loss of human life, but also significant disruption to the facility and considerable economic impacts. Poor monitoring and programs have also contributed to other published failures such as the partial collapse of ceiling panels in the Interstate-90 connector tunnel ('Boston Big Dig') in Boston, Massachusetts, U.S. and the partial collapse of a steel structure in the Balcombe Rail Tunnel in the U.K. ([22], [23]).

Fasteners to concrete are manufactured to resist various conditions including highly aggressive environments and prolonged exposure to cyclic loads [9]. Additionally, guidance is available that provides the appropriate methodology to calculate the performance of these products under the application-specific requirements and to assist in the determination of appropriate maintenance programs ([24], [25]). These guidelines combined with technical support offered by reputable suppliers provide the engineer specifying a fastener with a high level of confidence that the fastener will remain fit for its intended use throughout its design life. Further, they provide important information to assist in developing an appropriate inspection and maintenance plan for the asset.

## 2.7 Summary

The case studies described above demonstrate the safety-critical nature of fasteners and the importance of learning from mistakes that have resulted in failures. A number of common themes are present:

- *Product prequalification:* A robust product approval process ensures the product is fit for purpose. The cast-in ferrule that failed (case study #1) not only lacked traceability, its failure during installation also demonstrated excessive variability in product performance that was not controlled to an acceptable level.
- *Product substitution and change management:* A proper change management procedure involving written consent by the responsible engineer must be followed for any deviation from the specification. The 17<sup>th</sup> Street Bridge in Atlanta (case study #2) had threaded rod substituted for only partially threaded rod, reducing mechanical interlock of the anchor rod with the chemical product that compromised performance and contributed to the collapse.
- *Quality of installation:* All fasteners to concrete exhibit some degree of sensitivity to installation such that their performance is limited to a certain degree by the quality of their installation. The installer needs to understand the dangers of deviating from the installation instructions. Poor installation technique for chemical anchor installation was identified in the 17<sup>th</sup> Street Bridge in Atlanta resulting in chemical compound that had not cured and the presence of large air voids. The collapse of the awning (case study #3) highlighted the danger of reducing drilling depth due to hitting reinforcement since the fastener cannot achieve its rated performance at the reduced depth.
- *Accurate and detailed specification:* A specification with insufficient information may lead to the same type of product being procured that exhibits very different performance. The limited information provided in the specification for chemical anchors for use in the 17<sup>th</sup> Street Bridge in Atlanta resulted in the potential to procure 15 different products. Further, the need to avoid creep-sensitive chemical product was not identified. Insufficient detail in the specification of fixtures to secure a suspended ceiling in an educational building (case study #4) was found to contribute to the ceiling's collapse. A proper understanding of project-specific requirements is imperative for fastener specification by the responsible engineer. The collapse of heavy concrete ceiling panels in a swimming pool (case study #5) was attributed to the selection of an inappropriate grade of stainless steel in the tension assembly supporting the concrete panels.
- *Inspection and maintenance program:* In the event that defects do occur, an inspection and monitoring program provides an early detection mechanism and the opportunity to undertake remedial work before defects escalate to a collapse situation. The corrosion of fasteners securing the awning that collapsed in Queensland had been in service for more than three decades but could not be easily inspected. Findings reported from the preliminary investigation into the Sasago tunnel collapse (case study #6) revealed an inspection and monitoring program had not been enacted during the 12 years preceding the collapse and that during the ensuing investigation 1028 defects were found in the fasteners securing the concrete panels remaining in the tunnel that experienced the collapse.

## 3. LIFTING QUALITY AND SAFETY STANDARDS

Internationally, failures of fasteners to concrete have been the catalyst for regulation such as collapse of a stair structure in Ireland in 2002 (one fatality) leading to the Code of Practice for the Design and installation of Anchors [26], and the Boston Big Dig leading to training for installers [27] and the inclusion of design provisions for adhesive anchors in ACI-318:2011 [28]. AEFAC has been formed to introduce the necessary measures to ensure that the risk of failure in the anchor industry is acceptably low. Two key initiatives that have been introduced to improve safety are discussed below.

### 3.1 AEFAC Standard

Until now, guidelines for the design and evaluation of anchors in Australia have been minimal. The anchor industry has been self-regulated, relying on suppliers of products for information and performance data. However, this is often confusing for engineers due to there being a lack of consistency in testing and evaluation of products, as well as differences in terminology and design methodology. AS 3600 [29] states shallow anchorage failure should be investigated but provides no further guidance.

The proposed AEFAC Standard is closely based on prEN 1992-4:2013 [24] with a scope covering cast-in headed fasteners and anchor channel plus post-installed mechanical fasteners and chemical fasteners to concrete. Products eligible for use with the design methodology require strict quality assurance program at the factor as well as a robust testing and evaluation program to determine product performance ([9], [30]). The methodology underpinning the proposed AEFAC Standard is the Concrete Capacity (CC) Method that has been adopted in Europe and the United States for the design of cast-in and post-installed anchors ([24], [28], [31]). The document requires that the design engineer identifies the decisive mode of failure. The modes of failure for consideration under tensile loading are illustrated in Figure 9(a) for cast-in and post-installed fasteners with additional modes for consideration for anchor channel illustrated in Figure 9(b). Figure 10(a) illustrates the modes of failure requiring consideration for cast-in and post-installed fasteners under shear loading with additional modes of failure for anchor channel illustrated in Figure 10(b). A design check on combined loading must also be considered. A comprehensive overview of the design methodology has been presented elsewhere [32]. The proposed AEFAC Standard is due for publication in 2015.

**Figure 9: Modes of failure considered for fasteners to concrete under tensile loading.**

**Figure 10: Modes of failure considered for fasteners to concrete under shear loading.**

### 3.2 AEFAC Installer Certification Program

Anchor products that have been installed incorrectly will most likely perform in an unpredictable manner that differs from the specifier's intent. An awareness of this danger is critical. Most types of anchors that are presently used are reasonably sensitive to installation practice. The training of installers is frequently overlooked which may cause gross errors during installation that exceed tolerances acceptable by product suppliers and in turn could have catastrophic consequences [9].

The AEFAC Installer Certification Program has been developed specifically for installers of anchor products to ensure that the installation is consistent with the supplier's installation instructions. The training program is based closely on the ACI/CRSI Adhesive Installer program from the U.S. which is a requirement for installers of chemical anchors for use in sustained load applications, including orientations from horizontal to vertical ([27], [28]).

Installation by a certified installer provides the engineer with the peace of mind that the quality of installation allows the fastener to achieve its performance potential. The AEFAC Installer Certification Program ensures the installer possesses the following skills: i) ability to read, understand and execute anchor installation in accordance with a manufacturer's installation instructions, ii) understand risks of non-conformance with manufacturer's installation instructions, and iii) demonstrate practical competence for anchor installation including blind overhead installation of chemical anchors. A more comprehensive overview of the AEFAC Installer Certification Program and its background are included in [33]. The implementation of this training program together with appropriate prequalification and the design guidelines outlined in this paper, form a quality assurance system for the anchor industry.

#### 4. CONCLUSIONS

This paper seeks to raise awareness of problems that are commonly encountered in the anchor industry that have resulted in failures. The six case studies presented have highlighted the safety-critical nature of these fasteners whereby their failure has resulted in death, severe injury or substantial damage to property and disruption to the function of the structure. Factors contributing to failure of fasteners that are commonly encountered include a limited or no product prequalification, product substitution without following proper change management procedures, poor quality installation practice, insufficient and inadequate specification of products and a lack of inspection and maintenance programs to detect defects when they arise.

AEFAC is the peak body for the Australian anchor industry and has introduced two major initiatives to lift safety standards. The first is the proposed AEFAC Standard for the design of safety-critical cast-in and post-installed fasteners to concrete. The second initiative is the AEFAC Installer Certification Program to directly target installers of fasteners to ensure that the product performance is consistent with the specifier's expectations. Collectively, these initiatives will lift safety standards and reduce the risk of further failures from occurring in the Australian anchor industry.

#### 5. ACKNOWLEDGEMENTS

The authors wish to acknowledge the technical input from the following additional members of the AEFAC Technical Committee: Brett King (Allthread Industries), Gilbert Balbuena (Simpson Strong-Tie Australia), Hany Genidy (Ancon Building Products), Joe Rametta (Hilti – Aust.), Kamiran Abdouka (Würth), Neil Hollingshead (ITW Construction Systems), Ramil Crisolo (Hobson Engineering Co.), Tarun Joshi (Powers Fasteners Australasia). The authors would also like to acknowledge the ongoing financial support of the AEFAC Founding Members: Ancon Building Products, Hilti (Aust.), Hobson Engineering Co., ITW Construction Systems, Powers Fasteners Australasia and Würth, and Supporting Members: Allthread Industries and Simpson Strong-Tie Australia.

**Abstract:** Performance of post-installed anchors in concrete and masonry is highly dependent on the way the anchors are installed. Failure of anchors often occurs due to incorrect installations. In recent years, there have been increasing awareness regarding poor installation practices leading to unreliable bonded anchors performance. As part of the industry's effort to enhance the standard of installation of post-installed anchors in Australia in line with international practice, the AEFAC Anchor Installer Certification Program is initiated to train and equip installers with necessary knowledge and skills to perform installation at the highest level. The AEFAC Anchor Installer Certification program is designed to verify that certified installers possess the necessary skills to properly install bonded and mechanical anchors as per manufacturer's recommendations. This paper outlines the steps for proper installation and commonly made mistakes by installers that will be highlighted in the training program. With the AEFAC Anchor Installer Certification Program in place to promote best practice for installation, the quality of installation of post-installed anchors will be lifted and this will help to safeguard human life against catastrophic anchor failures that had happened around the world in the past.

**Keywords:** post-installed anchors, safety-critical, installation, training, certification.

## 1. Introduction

Post-installed anchors are installed after concrete has been poured allowing greater flexibility for fixture alignment as compared to cast-in anchors. Two main types of post-installed anchors are mechanical anchors and bonded anchors as shown in Figure 1. Some common examples of safety-critical applications of post-installed anchors in the building industry are connection of structural steel floor members to a precast concrete core and connection of steel columns to concrete footings. Failure of safety-critical anchors may cause injury or death to human beings and lead to considerable economic loss. The structural performance of post-installed anchors are sensitive their installation. Installations of post-installed anchors are largely carried out on ad-hoc basis by tradesman without proper training resulting in many incorrect installations as observed by engineers and anchor suppliers and manufacturers in the industry. Anchor products that have been installed incorrectly will most likely perform in an unpredictable manner that differs from the design engineer's intent.

On the other hand, the skill set for welding industry is well established in Australia. Welding is the process of connecting steel members together and has been recognised as an area needing tradesmen to undergo specific training to become qualified welders. The AS1796 Certification of Welders (1) provides a curriculum and test regime for certification of personnel performing structural welding of connections and steel members and also for supervision of welders (2). Welding certification or qualification is an important part of the overall compliance to occupational health and safety obligations based on Statutory Law. It can be seen that although welds and post-installed anchors serve to connect structural members together, in the case of welding it is steel to steel connection whilst in the case of post-installed anchors, it is typically steel to concrete connection, the qualification or certification requirement for welders is not present for anchor installers; this resulted in varying competencies among installers which may cause gross errors during installation that in turn could have catastrophic consequences.

The best anchor product is only as good as its installation. Anchor failures have occurred both internationally and locally and sometimes with fatal consequences. In 2006, the Big Dig Tunnel ceiling collapsed in Boston (refer Figure 2) whereby 26 tonnes of concrete ceiling panel and debris fell, killing a motorist and causing a section of the tunnel to be closed for almost a year. A local failure documented by WorkSafe Victoria (4) in 2002 is shown in Figure 3 whereby a precast panel weighting 35 tonnes collapsed onto a crane during erection due to improper use of a coil anchor as a bracing insert. Following the collapse of the Big Dig Tunnel ceiling, the installation quality of bonded anchors was called into question. The American Concrete Institute (ACI) partnered with the Concrete Reinforcing Steel Institute (CRSI) developed the Adhesive Anchor Installers certification program (ACI,5). It is a regulatory

requirement in the USA for overhead anchors with sustained tension load to be installed by a certified installer and the inspection of anchor installation by specially approved inspectors.

The Australian Engineered Fasteners and Anchors Council (AEFAC, [www.aefac.org.au](http://www.aefac.org.au)) is an industry initiative that was formed in 2012 to introduce governance to the industry with support and guidance to be provided for engineers (specifiers), manufacturers, installers and field engineers. As part of the industry initiative to enhance the installation of structural anchors in the Australian construction industry, the AEFAC Anchor Installer Certification Program was initiated. This certification program is based on the

ACI-CRSI program but it has been extended to include mechanical anchors and adapted for Australian practice.

## 2. Installation Requirements

Bonded anchors are widely used in the construction industry due to their smaller edge and spacing requirements compared to mechanical anchors. However, they are prone to poor installation practices that have contributed to a number of failures in the past. An installer needs to properly understand the limitations and sensitivity of the product. The product should always be installed in accordance with the MII.

### 2.1 Performance considerations

In general, bonded anchors are sensitive to dust, roughness of drilled hole, water and temperature of substrate while mechanical anchors are sensitive to drilled hole tolerances. If water is present in the drilled hole, the installer needs to check whether the specified product is compatible with water. Most adhesive does not work well with the presence of water. Temperature of the substrate will affect the curing time of the adhesive, with a higher temperature leading to a shorter curing time. There is an allowable temperature range to install bonded anchors that installers need to adhere to. Figure 5 shows an example of capacity of bonded anchors decreasing with elevated temperature. Other factors that may affect the suitability of the product would be the type of substrate (refer Figure 4), whether it is concrete, masonry or lightweight concrete. Certain products may not be suitable for use in lightweight concrete. It is very important for installers to be aware of the different factors affecting performance of post-installed anchors during installation.

Figure 4: Different types of substrate for bonded anchor installations.

Figure 5: Graph showing example performance of anchors relative to temperature. At elevated temperature, performance decreases, necessitating a reduction in safe working load.

## 2.2 Drilling the hole

Good bonding between concrete surface and adhesive is correlated to roughness of drilled hole. The rotary hammer drill is the most common drilling method. Other drilling methods are rock drilling and core drilling. Using a rock drill will produce a rougher hole while a core diamond drill will produce a smoother hole which may reduce bond strength. This is not allowed unless explicitly permitted in the MII or if the design engineer has specified this method. Selecting the correct drill type and bit is important for drilling the correct sized hole and to achieve the appropriate hole roughness. Figure 6 illustrates the different bond strength that may be obtained from different drilling method.

Some anchor systems particularly mechanical anchors are sensitive to drilled hole tolerance. Using a worn drill bit may result in an elliptical shaped hole or an undersized hole whilst not steadying the drill while drilling may result in a hole that is not straight. For bonded anchors, the anchor rod may not be able to be inserted into the hole due to limited tolerances between the anchor and the hole size. The bit diameter can be measured with a caliper gauge to make sure that it is within tolerances. It is a good practice to insert an anchor rod into the hole to make sure the anchor can fit before injecting adhesive into the hole. Note that for bonded anchors the annular gap is typically several millimetres, meaning that if the anchor rod is a tight fit, it is highly likely that an incorrect drill diameter has been used or the hole has not been drilled straight. Bonded anchor holes are drilled oversize (relative to the steel insert) to ensure sufficient adhesive is between the steel insert and hole wall. Mechanical anchors on the other hand require strict adherence to specified drilled hole diameter to achieve their intended capacity; an oversized hole will result in the anchor not engaging the hole wall sufficiently thus significantly reducing the load carrying capacity of the anchor while in an undersized hole, the anchor may generate high expansion stress in the concrete such that concrete spalling may occur.

Performance of anchor system relies on specified embedment into the concrete as specified by the design engineer. Hitting reinforcement while drilling is a very common occurrence normally denoted by a change in the colour of dust, metal filings are observed or there is an increase in difficulty in drilling. The embedment depth of an anchor should never be reduced, i.e. anchor bars should never be cut short. Reducing embedment depth of the anchor dramatically reduces its strength; unfortunately leaving the anchor bar short of the designed embedment depth is a common practice in the industry. One such example is shown in Figure 7 whereby the anchor has an incorrect protruding length compared to other adjacent anchors and the mark on the anchor rod which should be level with the concrete surface to indicate that the anchor rod has achieved its designed embedment depth can be seen in the photo. The appropriate course of action when obstruction is met while drilling would be to cease drilling immediately and the design engineer should be consulted to determine the appropriate action. Options are drilling through the reinforcement if it is allowed by the design engineer or otherwise the hole needs to be relocated.

**Figure 6. Bond-stress displacement curves for 20mm diameter bonded anchors installed in holes with different drilling methods. All anchors are drilled in 20MPa concrete with 200mm embedment except for anchors in core drilled holes with 300mm embedment in 50MPa concrete (Wollmershauser,6).**

**Figure 7. Incorrect protruding length, anchor has not achieved required embedment depth.**

### **2.3 Hole cleaning**

Hole cleaning is a critical step in the installation procedure for bonded anchors and special care must be taken to ensure that cleaning instructions as per the MII have been followed. Cleaning accessories for post-installed anchors are shown in Figure 8. Improper hole cleaning is frequently a major source of poor bonded anchor performance. Figure 9 shows cut sections of installed bonded anchors. The photo on the right shows a layer of drill dust sticking to the face of the concrete indicating that the hole was not cleaned properly. This prevented good bonding between the adhesive and concrete to form, thus greatly reducing the performance of the anchor system. Figure 10 shows data from a sensitivity test carried out on a specific injection system product in dry concrete. The hole without cleaning resulted in a 60% reduction in bond strength.

The usual method of cleaning is blow-brush-blow i.e. blowing out the hole with sufficient clean compressed air followed by brushing the hole with a clean full brush then blowing the hole again. The MII will specify the sequence and number of brushing and blowing required for the product to best remove debris and dust particles from the drilled hole. Commonly encountered problems are installers using the wrong brush size, worn brushes, blowing into the hole through a straw or modified leaf blower and not following the number of times required for brushing and blowing when cleaning a hole which is detrimental to the performance of the bonded anchor system. Installers need to be mindful that water could adversely affect bonding of the adhesive. During the cleaning process if the hole is damp or filled with water, installers need to check the MII to determine if the product may be installed in wet conditions, if not water should be thoroughly removed and the hole should be dried out before installation can proceed.

From past experiences, cleaning deep holes and/or core drilled holes filled with slurry have posed great challenges to installers. Common problems are residual fines remaining on hole wall or a dust plug remaining in the bottom of the hole due to an incorrect cleaning method or unsuitable cleaning tools especially for deep holes.

**Figure 8. Cleaning tools.**

**Figure 9. Cut sections of installed bonded anchors. The photo on the right shows a layer of drill dust between the adhesive and concrete (Courtesy of IWB, University of Stuttgart).**

**Figure 10. Graph showing sensitivity of a specific cartridge injection system product in dry concrete to cleaning method. (Data derived from (Eligehausen,7)).**

## **2.4 Injection of adhesive and inserting anchor**

For each bonded anchor product, the manufacturer's product specific complete installation system must be used. Components from one system may not be interchanged with those from another system, even though they may look and operate in a similar manner. Each system has been designed to deliver the correct proportion of components to ensure the correct mix ratio. Incorrect use of equipment or modification in any form may result in incorrect mix ratios that will reduce bonded anchor performance.

Installers need to first check the expiration date on the cartridge before placing it into an injection tool or dispenser. The cartridge needs to fit properly in the dispenser. After the cartridge has been inserted into the dispensing gun, the static mixer nozzle is attached. For injection into deep holes, an extension tube may be affixed to the mixing nozzle. Once the system has been correctly assembled, the first few trigger pulls of mixed adhesive from the dispenser should be discarded to ensure the correct mix ratio has been achieved as shown in Figure 11. If this initial material is not discarded, the quality of bonding achieved can be very poor. This is a very important step and is often overlooked by installers, especially when changing cartridge for installation of subsequent holes.

The mixing nozzle must reach the bottom of the hole, adhesive injected at a constant rate and the mixing nozzle is slowly withdrawn to prevent air voids from forming. Figure 12 shows air voids in injection which are detrimental to bonded anchor performance. The nozzle should be carefully removed when the hole is about two-thirds full followed by insertion of the anchor rod with a twisting motion. It is good practice to insert the anchor rod into the hole immediately after the hole is filled with adhesive to ensure that the

working time for the adhesive is observed. A clean, straight anchor rod must be used for installation. Contaminated anchors will hinder proper bonding with adhesive. Other common problems include anchors over tightened or overhead anchors not supported properly which may prevent proper bonding of adhesive to the anchor.

**Figure 11. Typical dispensing system.**

**Figure 12. Voids in injection**

## **2.5 Curing**

After the anchor rod is inserted, anchors must be protected from disturbance during curing and should not be loaded, tightened or tested until curing time has elapsed. Curing times are product specific. Higher temperature will lead to faster curing while lower temperature will slow down the curing process. When the temperature gets too cold, the reaction rate between the components of the adhesive may stop and this may result in the adhesive not adequately cured to achieve its designed strength and form proper bonding. This may cause premature failure to the anchor. The MII lists the minimum permissible ambient temperature for installation which must be adhered by the installers. Bonded anchors may appear to have cured at times shorter than the manufacturer's specification. However, it is not acceptable to load the anchor before the stated time.

## **3. AEFAC Anchor Installer Certification Program**

The AEFAC Anchor Installer Certification Program has been developed to verify that certified installers possess the necessary skills to properly install bonded and mechanical anchors as per manufacturer's recommendations. The training and certification are intended for safety-critical applications. Illustrations of proper installation practices for a standard bonded anchor are shown in Figure 13.

An AEFAC Certified Installer will be able to demonstrate the following with the assistance of the Manufacturer's Installation Instructions (MII):

- Ability to understand and follow instructions
- Understand how to assess site conditions that impact installation (moisture in holes, drilling method, obstructions such as reinforcement, temperature of product and substrate, etc.)
- Demonstrate proper cleaning technique and hole preparation
- Demonstrate proper selection and assembly of equipment for the installation of injection-type and capsule-type chemical anchors

- Assess product storage conditions and shelf life, including when the product should be rejected.
- Demonstrate proper mixing technique
- Successful application of product in holes are various orientations (including vertical overhead) to the required depth using proper technique and equipment to minimise air voids
- Proper technique to install the anchor element in the chemical product to minimise air voids
- Recognise time limits for mixing, installation, positioning of anchor element and curing time
- Demonstrate the protection required of the anchor during curing
- Successfully tighten fixture to the anchor at the appropriate time and to apply the correct installation torque.

**Figure 13. Illustrations of proper hole preparation and installation practice for a standard bonded anchor.**

### 3.1 Assessment

AEFAC will grant certification only to those applicants who pass both the written and practical examination (refer Figure 14). The written examination is a closed book exam comprising of 65 multiple choice or true/false questions for completion within 60 minutes. All assessment material is covered by the Installer Training Manual (AEFAC,8).

The practical examination is a two part process testing the individual's competence with the installation of bonded anchor systems including assembly of tools and equipment, proper drilling and cleaning technique, proper injection technique and correct setting of the anchor component. Part one of the exam tests the ability of installers to install a bonded anchor in a vertical down orientation according to the MII and Material Safety Data Sheet (MSDS) (refer Figure 15) while part two of the exam test ability of installers to inject adhesive overhead using a piston plug (refer Figure 16). A maximum of two trials are permitted for each part of the practical examination. The examiner will advise the installer of a pass/fail outcome and advise on the error(s) made.

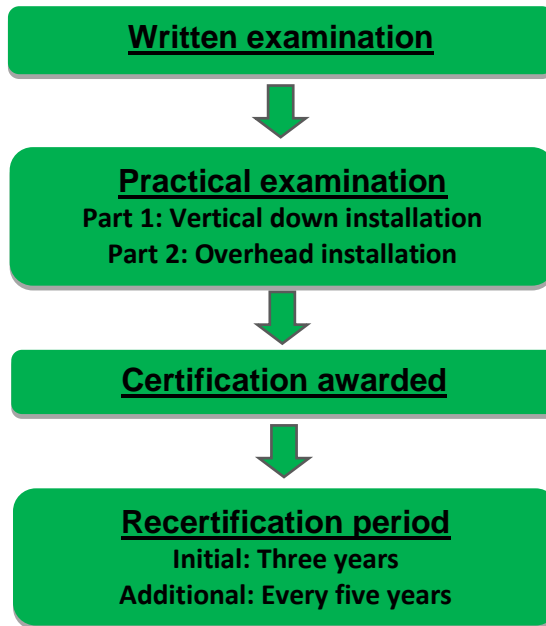

Figure 14. Process of Certification and Recertification

Figure 15. Vertical down bonded anchor installation

Figure 16. Overhead injection with a piston plug, tube is sliced after curing time is complete to check for voids.

### **3.2 Recertification**

Recertification requires the certified installer to re-sit the written and practical examinations periodically. The first recertification is required three years after initial certification, and every five years thereafter. Failure to comply with proper installation practices after being awarded certification would result in certification status being revoked and potential legal implications.

## **4. Recommendations**

As part of AEFAC initiative to lift quality and safety of anchors, it is recommended that safety-critical anchors shall be installed by AEFAC certified installer in strict accordance to the MII. Anchor products shall have the relevant prequalification such as an European Technical Assessment/Approval (ETA) or equivalent. An ETA is a certification that a product has been rigorously tested and independently confirmed to satisfy the requirements of European Technical Assessment Guideline 001 and demonstrated to be fit for its intended purpose (9). Current standard notes on engineering contract drawings allow the use of equivalent product in lieu of the specified anchor product by the design engineer. It is recommended that the substitution of equivalent products must be approved by the design engineer and have the appropriate prequalification. The implementation of this training program together with appropriate prequalification and the design of anchors, form a quality assurance system for the anchor industry.

# Guide to Seismic Design & Detailing of Reinforced Concrete Buildings in Australia

Scott Munter<sup>1</sup>, John Woodside<sup>2</sup> and Peter McBean<sup>3</sup>

<sup>1</sup> Executive Director, Steel Reinforcement Institute of Australia

<sup>2</sup> Principal, J Woodside Consulting Pty Ltd

<sup>3</sup> Joint Managing Director, Wallbridge and Gilbert, Adelaide

**Abstract:** The original Guide on the Seismic Detailing for Reinforced Concrete Buildings in Australia was published in 1995 by the SRIA following the publication of the second Australian earthquake standard AS 1170.4. There have been two revisions of AS 3600 Concrete Structures and a new earthquake standard AS 1170.4 since the original document. There have been significant advances in the analysis software for buildings, and the understanding of earthquake design has improved through advances in research, and actual seismic performance. AS 3600, provides Australian designers with the design rules for earthquake design to meet the typically lower seismicity of Australia. Most Australian commercial buildings are cast in situ reinforced concrete, designed and detailed to comply with AS 3600, for regions of lower seismicity, deeming the structure to have adequate ductility as a life safety measure.

The fundamental principle of concrete design is that the design and the detailing are inseparable. Appropriate detailing is required to ensure that the structure will respond under the seismic loading as assumed in the design. Technology and reduced design times can shift the focus away from the vital reinforcement detailing phase of the project.

The Guide's overall aim is to enable cost effective, simple design solutions by giving the designer the practical detailing information to efficiently determine requirements for the overall structural performance under seismic loadings. Reinforcement scheduler input in this specialised field provides current practice for graduate, practicing engineers with little seismic experience and senior engineers requiring refreshment. This paper describes the revisions to the Guide.

**Keywords:** Reinforcement, seismic, detailing, concrete.

## 1. Introduction

Unfortunately in Australia there is a generation of engineers, contractors and clients who do not believe that earthquakes occur in Australia, despite the long history of earthquakes in Australia and the 1989 Newcastle Earthquake (1,2). Because they have never experienced an earthquake, and with the pressures of modern design and construction, it does not allow them time to think about the issues as well as they should. It is anticipated and hoped that this Guide will provide the necessary design information to improve the design and detailing of reinforced concrete buildings for seismic loads.

Fortunately significant earthquakes in Australia are rare and probably will not occur during the average lifetime of a building. A major earthquake will generate the most severe structural demand ever experienced by a building. Given the rare and extreme nature of earthquakes, for economic reasons, designers are largely concerned about preserving life and preventing structural collapse. For most concrete structures, this will require the structural system to resist the imposed deformation in-elastically over a number of load cycles.

The first Guide on the Seismic Detailing for Reinforced Concrete Buildings in Australia was published in 1995 in response to the second Australian earthquake code AS 1170.4 (3). The updated and rewritten Guide is intended to assist graduate engineers, practicing engineers and other designers with limited seismic experience and senior engineers seeking to refresh themselves of the current developments and practical aspects of reinforcement design and detailing for seismic actions in Australia.

Since 1995, there have also been significant advances in analysis software; our understanding of earthquake design has improved through advances in research and combined with actual performance of buildings under seismic loads. AS 3600 (4) and AS 1170.4 (5), provides Australian designers with the minimum design rules for earthquake design for buildings to meet the typically lower seismicity of Australia. Most commercial buildings in Australia are in situ reinforced concrete, designed and detailed in accordance with AS 3600. Complying with the Standard for regions of lower seismicity deems the

structure to have adequate ductility [as a life safety measure](#). However, this concept of life safety is often poorly understood or not properly articulated by designers.

For lower values of the ductility factor  $\mu \leq 2$ , detailing of the concrete is only required in accordance with the body of the Standard and for higher values of ductility factor  $\mu$ , detailing is required in accordance with Appendix C of AS 3600. Levels of ductility  $\mu > 3$  are outside the scope of the Standard, and design and detailing to NZS 1170.5 (6), and NZS 3101 is suggested.

The fundamental principle of concrete design for the successful performance of a concrete structure under seismic actions is that [design and the detailing are inseparable](#). Appropriate detailing is crucial to ensure that the structure will respond under seismic loading in the manner for which it has been designed. Time and time again, earthquakes have shown that correct detailing of reinforced concrete structures can significantly improve the capacity of the building to resist seismic actions, even for a poorly designed structure.

This Guide is not a complete document covering all design situations or requirements, but an assortment of basic seismic principles, design advice, and fundamentals to assist and help designers. It also suggests further study of the principles and practice of seismic design and detailing. This information is presented by focusing on the key, functional and practical aspects of seismic design and detailing of reinforcement with references to specialist information. Technology and reduced design and construction times can shift the focus away from the vital reinforcement detailing phase of the project. The overall aim is to enable cost effective, simple design solutions by giving the designer the practical detailing information in order to efficiently determine the requirements for the overall structural performance under seismic loadings.

## **2. Risk mitigation and low damage design for buildings**

Unfortunately, clients and societies expectations compared with the reality of seismic performance may not match the minimum requirements of the Standards for life safety, as shown in Christchurch. For instance, does a building in the event of an earthquake require protection of irreplaceable contents such as a museum or is there a need for the continuing use of the building such as a hospital after the event or in the extreme condition that it contains dangerous materials such as a biological laboratory dealing with dangerous viruses. These are issues that the designer must consider in the early phase of the design.

The highest level of protection for a building available is base isolation, but it has not been used in Australia. The next level of protection is to minimise the damage by using a more robust and regular structure with a higher level of ductility. This will protect the primary structure even in the most severe earthquake with many alternative load paths and backup systems designed and detailed for greater forces than the minimum required by the Standard. The great advantage of this approach is that the structure should be operational and repairable; insurance may be less, and the mitigation of the risk of structural damage and business continuity is achieved but at an increased cost to the original construction of reinforced concrete building. It is thought that the increased order of the total cost would be as little as 1% to 3% of the total construction cost of a concrete building over the lowest level of protection required by the Standard. This assumption is based on a structural cost being 25% of the total cost of the building, and the additional design and detailing would result in an increased structural cost in the order of 5-10% including professional fees.

## **3. Analysis and design**

The aim of the analysis and design is to produce a safe, serviceable, aesthetic, economical and sustainable structure. Simple design does not mean elementary design but rather well conceived and quality design and adequate detailing including the earthquake design. Designers should always strive for simplicity, clarity and excellence in their design and detailing and maintain a strong focus on the detailing of reinforcement for seismic loads, as part of the design process.

Traditionally earthquake design has been based on a [quasi-static](#) forces approach where [hypothetical](#) static loads are applied to simulate the dynamic forces of an earthquake. Unfortunately, this may bear no resemblance to the actual earthquake forces when they occur, as earthquakes do not know about

Standards, methods of design or indeed the building being designed. For this reason, the earthquake actions will almost certainly not be those specified by the Standards.

There are a number of fundamental problems with the force-based method of analysis. These include choosing the right model, the selection of appropriate member stiffnesses and determining the static forces that are appropriate for the design being considered. Member stiffnesses cannot be resolved until the design is complete, and yet they will change during a seismic event. In addition, the static design forces applied to the structure may not bear any relationship to the actual dynamic forces applied. The distribution of local forces is based on elastic estimates of stiffness. This tends to concentrate the strength in elements of the greatest potential of brittle failure, such as walls.

There have been large advances in the past 20 years in our understanding of how concrete performs under seismic loads, in the technology and design of concrete, changes to reinforcement and enormous advances in computers and software and analysis tools. The computing power and software now available to designers has led to far more elaborate and sophisticated analysis and design of buildings and indeed more refined design.

This technology can lull the designer into a false sense of security, believing they fully understand how the structure will act under dynamic loads of an earthquake, when the actual effects of an earthquake may be far different from the computer model. This is because the structure is sized on non-seismic load considerations; member stiffnesses will change during the earthquake and other factors such as local failures will affect the model. This may result in the model and sophisticated analysis being entirely inappropriate in a major earthquake event.

Analysis is only part of the design process. Good designers know there is far more to design than just analysis and designers must understand the behaviour of each member and how they are expected to resist all of the applied actions and why these members need to be detailed for the seismic actions. In a real structure, the behaviour under load of individual elements can be complex depending on the materials used and many other factors, which will change under earthquake actions. Idealised computer models of the frame or structure are used for the analysis of a structure to simulate how the real structure may behave, but they can be very crude when assessing the structure under seismic loads.

#### **4. Reinforcement and concrete**

For a structural ductility factor  $\mu \leq 2$ , AS 3600 Appendix C, allows the structure to be designed and detailed in accordance with the main body of the Standard and both Class L and N reinforcement can be used. Although, not covered by AS 3600, any chord members, collector reinforcement or drag bars used in diaphragm action should be Class N reinforcement, because of the anchorage requirements and ductility demands for this reinforcement.

For a structural ductility factor,  $2 < \mu \leq 3$ , structures have to be designed and detailed in accordance with the main body of AS 3600 and Appendix C. Although Class L reinforcement is allowable under AS 3600 for walls and slabs, where Class L reinforcement is used for loadbearing walls and suspended floors and slabs when acting as diaphragms, designers need to ensure the reinforcement is capable of meeting the increased ductility and drift demands. For IL4 buildings, Class L reinforcement is not recommended in structural elements except as fitments for beams and columns, shrinkage reinforcement, for reinforcement to steel metal decking or non-structural elements, because of the increased ductility demands.

While structures will have concrete strengths typically in the range of 25 to 40 MPa, high strength concrete up to 100 MPa is allowed under AS 3600. High strength concrete is principally used in columns and walls where the size of such elements needs to be minimised. Designers should be careful using high strength concrete in columns and walls for buildings designed for a structural ductility factor  $\mu > 2$  or with a post disaster function, as high strength concrete is a brittle material requiring additional detailing of the reinforcement to prevent brittle failure.

## 5. Robustness

Structural robustness is discussed briefly in the commentary to AS 1170.0 (7) but is not well defined. There are no specific requirements for design for structural integrity (the prevention of progressive collapse) or robustness in the BCA (8) or AS 3600. The AS 3600 Commentary (9) has some limited information on this requirement. Nevertheless, because of overseas experience and failures, designers must consider the robustness of reinforced concrete building including reinforcement detailing.

In simple terms a structure should be safe and the Eurocode provides the following definition of robustness *“the structure shall be designed and executed in such a way that it will not be damaged by events like fire, explosion, impact, or the consequences of human error, without being damaged to an extent disproportionate to the original cause.”*

Progressive and disproportionate collapse must be avoided at all times. This means that the failure of one member should not set off a chain of events where the structure progressively collapsed as occurred in the failure of the columns of the Newcastle Workers Club in 1989, Melcher and Woodside (10,11) .

Robustness will require that all structures have a resistance to lateral loadings, and if none are specified, then a notional percentage of the vertical loads should be adopted. Redundancy is also an important issue as a failure of any load-bearing member must not lead to the collapse of the entire structure.

The building structural form will significantly affect its robustness and for this reason needs to be considered at the concept stage. An example of this might be a large transfer beam supporting a large part of the building so failure of this element would be catastrophic and should be avoided if possible or the design robust enough to provide a considerable reserve of strength.

Columns and walls should not be heavily loaded and designed so that the design values are below the balance point and well detailed (12). Compatibility of drift must also be considered.

Precast and tilt-up structures are more susceptible to the effect of abnormal actions than some traditional forms of construction because of the presence of joints between the structural elements. However, experience has shown that it is possible to manage these issues by effectively tying together the various elements of the structure and correct detailing. (13, 14)

Buildings should have sufficient robustness to survive without collapse if subjected to the ground motion in excess of that specified by Australian Standards. Well-proportioned and well detailed in-situ reinforced concrete structures are inherently robust. It is important to ensure that the structure is tied together; can resist some notional lateral load, and the failure of a particular element will not lead to progressive collapse. There are several overseas documents on structural robustness and progressive collapse (15, 16).

Reinforcement detailing for robustness also needs to address some basic requirements as follows:

- Minimum reinforcement should be provided in both faces of horizontal members such as beams and floor slabs even if the design does not require it or detailing is not required in the Standard.
- Detailing in accordance with Appendix C of AS 3600 will be required for buildings with a post-disaster function and for buildings where the ductility  $\mu > 2$ .
- Critical members should be reviewed for their role in the structure, detailed as required, and alternative load paths considered.
- Eliminate punching shear failures at columns at flat slabs and similar by providing additional bottom face reinforcement

## 6. Acceptable drift limits

AS 1170 .4 sets out the maximum drift requirements for buildings. However, the maximum inter-story drift due to reduced stiffnesses must not exceed 1.5% of the storey height at each level at the ultimate limit state. These lateral displacements can be large (in the order of 30 to 50 mm). Many structures may not be

able to accommodate such drifts without premature failure of structural elements. Also, calculations associated with drift are often poorly understood, and stiffness assumptions are sometimes wrong.

Even if a part of a structure is not designed specifically to withstand seismic forces, it must be designed for the full drift (deflection) of the whole structure calculated in accordance with Clause 5.4.2, Clause 5.5.4 or Clause 6.7.1 of AS 1770.4. Moment frames systems are much more flexible than shear wall systems and need careful review for drift especially with associated shear walls.

## 7. Ductility demands

One of the issues when designing structures in an area of low seismicity such as Australia is that when a major earthquake occurs which exceeds the design return period (annual probability of exceedance of 1/500 or 1/1000 years), then the increase in peak ground acceleration over the design event can be significant and therefore the increase in the lateral forces can be large. For a rare event with say a return period of 1/2500 years, this can be of an order of 3 or more. This increase is shown in Figure 1 Pauly and Priestley (17). For structures however designed in areas of high seismicity, the increase in peak ground acceleration is not as significant, perhaps 30%.

**Figure 1. From Pauly & Priestley, 1992.**

## 8. Structural systems

Structural systems should be as simple as possible with readily understood gravity and lateral stability load paths. Some structural systems are more satisfactory than others in resisting earthquake-induced forces. One of the early tasks of the structural designer is to select a structural system that results in the best system for seismic performance of the building within the constraints dictated by the architect, the site and other conditions. Wherever practicable, alternative structural configuration should be considered at the concept stage to ensure that an undesirable geometry or structural form is not adopted before the detailed design of the building begins. In particular, structural irregularities both vertically and horizontally must be considered early in the design phase, and sound structural engineering principles applied to avoid or mitigate these effects.

AS 1170.4 specifies that all parts of a structure shall be interconnected, in both the horizontal and vertical directions. Connections between structural elements are typically the weakest chain in the link and should be detailed to fail in a ductile manner to avoid rapid degradation of strengths under earthquake actions.

**Figure 2. Failure of Transfer Beam, Copthorne Hotel, Christchurch**  
**(Photograph courtesy Peter McBean, Wallbridge and Gilbert).**

The connections must be capable of transmitting the calculated horizontal earthquake force in order to provide load paths from all parts of the structure, and the earthquake forces carried to the footings and foundation. In turn, the foundations must be robust enough to accommodate the overload due to large events without catastrophic loss of strength.

In Australia, stair and lift cores are typically constructed with concrete walls because of the fire rating and construction techniques, which have developed over many years. As a result, most buildings in Australia will be either a concrete shear wall system or a combination of concrete shear walls and moment frames or moment frame only. The designer has to choose whether the shear walls are ductile or limited ductile elements. Once the structural system is chosen, the structural ductility factor  $\mu$  and structural performance factor  $S_p$  can be determined in accordance with Table 6.5 (A) of AS 1170.4 or Table C3 of AS 3600. Ductile shear walls are often chosen where earthquake forces are higher than wind as the seismic reduction factor will lead to smaller members particularly foundations and the detailing is not too onerous. The decision as to which design route to take is left to the designer.

Because of the ratio of Structural Ductility Factor,  $\mu$ , to the Structural Performance Factor  $S_p$ , the earthquake design actions will be increased by about 73% if the designer chooses an OMRF over an IMRF. Ordinary Moment Resisting Frames (OMRF) are deemed to require no further detailing consideration from the detailing required in the body of AS 3600.

One problem with moment resisting frames (MRF) is their lack of lateral stiffness and the large displacements (or drift) under earthquake actions often together with incompatibility of the rest of the structure in resisting such drifts. This can result in significant damage to adjoining structural elements and non-structural parts and components. In addition, the importance of any plastic hinges forming in the beams and not the columns in an extreme event. Band beams usually are significantly stiffer than the columns, making the concept of strong columns and weak beams difficult to achieve.

Also where excess strength is provided above that theoretically required by the design through rationalising the design, less ductility is required for the element e.g. due to the provision of additional reinforcement for tying, or extra thickness or depth of section for fire requirements or deflections. Therefore, less detailing for seismic resistance may help buildability.

## 9. Responsibility for the design

It is recommended in the Guide that if a number of designers are working on the design and detailing of a concrete structure for seismic actions the overall responsibility for the structural aspects of the project should be taken by one structural engineer called the Principal Designer.,.

The principal designer and the design team should preferably carry out all the structural design of the building. Where part of the design is assigned or subcontracted to others, the principal designer needs to understand and fully coordinate those designs and take overall responsibility for them. Examples of design by others are the design of precast concrete elements and post-tensioned floors.

The failure of the CTV building in Christchurch where 115 people lost their lives in this extreme event is attributed to the designer of the building who was not experienced in earthquake design and did not fully understand what was required and the senior engineer did not supervise the inexperienced designer (18).

## 10. Detailing and drafting of concrete elements

Conceptualisation, structural analysis and design are the first part of the overall design process of a structure and detailing and drafting the second part. Detailing and drafting consists of satisfactory plans, elevations, sections and details and an understanding of how each part of the structure will perform under seismic loads.

Detailing of the reinforcement is a vital part of the seismic design process for reinforced concrete. There must be sufficient transverse steel to prevent shear or crushing failures, anchorage of reinforcement into areas of confined concrete and buckling of compression steel, once the cover to the concrete has been lost due to cyclic movements. The main steel bars must not lose their anchorage into the surrounding concrete during the repeated reversing loading cycles they would be subjected to in a major earthquake. The anchorage lengths combining various parts of the structure together must be sufficient and allow for local failures.

The art of reinforcement detailing is to provide the reinforcement in the right places required by the design and to meet the expected earthquake demands. If the reinforcement is correctly placed and fixed; the concrete correctly placed around the reinforcement which has not moved, then the structure will comply with the intent of the design and should perform satisfactorily during its design life including seismic actions, assuming it has been designed correctly.

Detailing involves practical and detailed considerations on how and where the reinforcement should be placed. Experienced designers who understand the overall design and the seismic requirements of the building should be responsible for the overall detailing. Detailing must not be carried out by graduate, inexperienced engineers or drafters without senior supervision.

*The basic assumption in any reinforced concrete design is that the designer is responsible to detail clearly and specify the reinforcement requirements on the drawings.*

The designer is responsible for ensuring that the information on the drawings and specifications is sufficiently clear so that each concrete element can be correctly constructed on the site, and the final structure will comply with the design requirements.

With the correctly detailed structural drawings, the reinforcement processor can then process the reinforcement using the reinforcement schedules produced by the scheduler from the structural drawings and deliver it to the site. This will allow the steel fixers to fix the reinforcement correctly and the builder/contractor to place the concrete around the reinforcement.

The detailing of reinforcement of concrete elements often occurs reasonably late in the documentation phase, after the design is substantially completed, and the final drafting of the structure has commenced.

Where possible, the structural design, including the drafting and detailing of the reinforcement should be completed prior to construction commencing.

Designers must allow enough time to complete the structural design and to detail the reinforcement adequately for all concrete elements, together with suitable checking and coordination. Checking should occur prior to issue of the drawings for construction and manufacture of reinforcement.

The detailing requirements of AS 3600 generally follow those of ACI 318 (19). With the trend to prefabrication of reinforcement off-site, attention needs to be given by designers as to how the components can be prefabricated and joined by drop in splice bars, known as loose bar detailing (20).

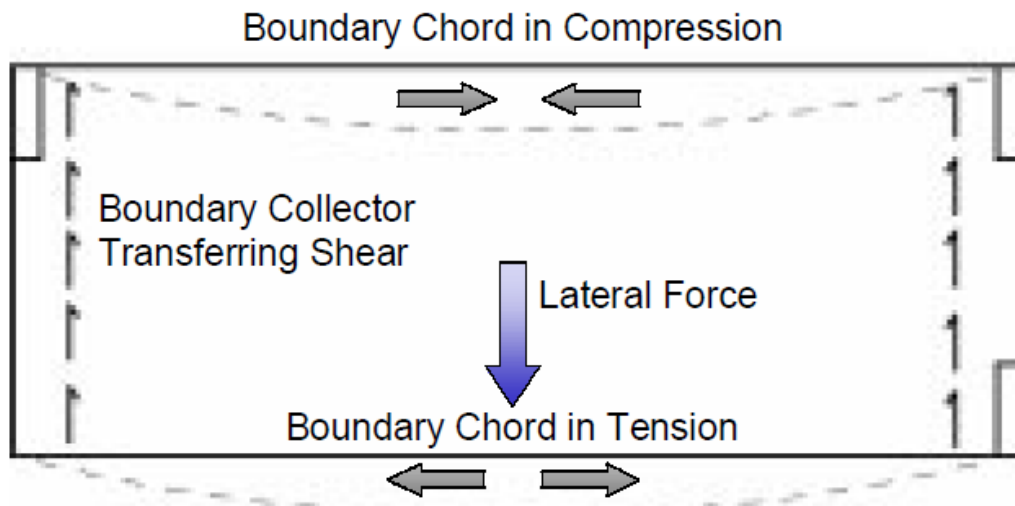

## 11. Diaphragms

Diaphragms in seismic design are the concrete floor and roof slabs. They are a critical element in the design of any building for seismic actions, as they tie the structure together and must be considered early in the design.

AS 1170 .4 makes passing reference to the deflection of diaphragms in Clause 5.2.5. AS 3600 in Clause 6.9.4, states that insitu concrete can be assumed to act as horizontal diaphragms. Unfortunately, there is no guidance in either Standard on the loads, the design of the diaphragm or the transfer of actions from diaphragms into the vertical elements.

Diaphragms have a number of roles in a building including carrying gravity loads and imposed vertical loads; to provide lateral support to vertical load bearing elements; to transfer the lateral earthquake actions applied at each floor level into the vertical elements. They also have a number of other functions such as redistribution of loads around openings, redistribution of forces due to torsion, and for resisting inclined or offset columns.

One method for the design of diaphragms has been to consider them as a horizontal deep beam where the flanges take the tension and compression as required as shown in Figure 3. Designers can also use a strut and tie approach. Diaphragms can also be rigid or elastic, regular or irregular, and have large penetrations, all of which can complicate their design.

***Figure 3. Floor as diaphragm after ATC/SEAOC briefing paper.***

Evaluating all the situations for the detailing of floor diaphragms requires experience and engineering judgement. For example, a building long and narrow in plan may be more flexible than thought, and the deformations may not be able to be accommodated by the walls at either end, resulting in separation of the walls from the diaphragm and possible failure.

Typically, edge beams form the edges of a diaphragm. They need to be continuously reinforced with the longitudinal bars fully lapped for tension and compression, restrained for compression and adequately anchored to the concrete walls and columns where they are attached.

Designers need to study how the forces from the diaphragm get into and out of the vertical elements, particularly shear walls and a good understanding of how these forces are transferred is necessary to ensure proper detailing.

Volume changes due to creep, shrinkage, thermal and post-tensioning also need to be considered with diaphragms. Where floors are temporally uncoupled from shear walls such as cores and lift shafts to allow for initial shrinkage, axial shortening, and post-tensioning effects, then correct detailing is required to ensure they will act as diaphragms in the final condition and are properly connected to the vertical elements.

Diaphragms will have a number of components depending on the design model adopted. Tension and compression members of the diaphragm are known as *collectors* or *collector bars* because they collect the shear forces and transmit them into the columns and walls. The earthquake forces must be transferred into the vertical element from the diaphragm, and these can be significant forces. The reinforcement used to transfer these forces is known as *drag bars*.

Failures of diaphragms in the recent high magnitude New Zealand Canterbury earthquakes were observed and a realisation that a more rigorous approach is required for the design of diaphragms. Designers need to consider these elements much more critically than they may have in the past (21, 22).

## 12. Conclusions

Australia is an area of moderate seismicity, of low probability but high consequence in comparison to areas such as California, Japan, and New Zealand. The provisions for both the design and detailing of reinforced concrete structures in Australia in accordance with the BCA and referenced Standards reflect this in the design and detailing required.

Many building structures in Australia will typically be designed and detailed in accordance with the main body of AS 3600 using the specific clauses for detailing in each section of the Standard. As a result, the detailing requirements are not that onerous and no more than would normally be required. Loose-bar detailing combined with efficient fabrication procedures and additional considerations, to provide the levels of ductility and continuity of reinforcement, will allow the structure to meet the anticipated earthquake loading satisfactorily in a life safety event.

With some additional design and detailing to Appendix C of AS 3600, the building can meet higher levels of earthquake resistance and minimise the damage requirements as required.

It is important to provide a minimum level of ductility in both beams and columns framing into a joint and to ensure adequate confinement of column reinforcement, regardless of the type of structural system employed.

With a limited additional quantity of appropriately detailed extra fitments and continuity reinforcement, plastic hinges can be induced to form at a given load. However, yielding will be ductile (gradual), even if the design earthquake load is exceeded (i.e. the hinge will act as a 'fuse' preventing transfer of the larger forces).

The choice for the designer is clear. A fully elastic response by the structure cannot be guaranteed, and a non-elastic response is allowed by the BCA and referenced Standards. Therefore, to prevent a catastrophic collapse and probable loss of life under a greater than design event, a ductile failure must be ensured. This minimum required level of ductility can be readily achieved by careful detailing and reducing the axial stresses in the columns and walls below the balance point on the interaction diagram

Precast and tilt-up concrete construction requires additional care in detailing to ensure connection detailing is satisfactory and that floors are adequately supported and will act as diaphragms in order to correctly transfer horizontal forces.

Comparable overseas experience has shown reinforced concrete, both in situ, precast and tilt-up concrete, is a simple, suitable and cost-effective solution for building structures in all seismic conditions. For low to medium seismic areas such as Australia reinforced concrete is eminently suitable. Designers and specifiers can remain confident of reinforced concrete's ability to function and to meet the needs of today's construction industry.

To further assist the client/building owner, designers and the builder/contractor specific seismic design checklists have been developed to provide a series of important questions for discussion and determination when conceptualising, designing and detailing reinforced concrete for structural performance under earthquake actions.

The new Guide will be a valuable resource for designers in Australia for the seismic design of reinforced concrete buildings.

<sup>3</sup>Senior Engineer, ARRB Group Pty Ltd, Australia

**Abstract:** Lynch's Bridge (inbound) over the Maribyrnong River was constructed in 1991/92, supported on six piers each of which consists of five columns and a crosshead. Two of the piers function as abutments and stand on dry land, whereas the other four piers are in the saline tidal river with a tidal range of about 0.4 to 0.7 m. The pier columns and crossheads were treated with an acrylic decorative/anticarbonation coating soon after construction in order to improve their appearance and protect them against aggressive environmental agents, including seawater and atmospheric carbon dioxide. Although the expected service life of the coating was in the order of 10 to 15 years, this coating has been in place for the past 24 years without renewal.

Monitoring investigations commenced in 1999 on one pile cap and two pier columns (Pier 2 from Melbourne Abutment), and have continued since then on a regular basis in order to assess the effectiveness of the acrylic surface coating in protecting the concrete against the aggressive agents, particularly chloride ion penetration, and the consequent chloride-induced corrosion damage. The present work was carried out in line with scheduled monitoring to provide additional information on the performance of the surface coating. The corrosion activity of the reinforcement has not changed significantly in the past 15 years. The reinforcing bars in the tidal and splash zones have shown higher corrosion activity compared to the drier atmospheric zone. The chloride content at the depth of reinforcement in the column has not yet reached the corrosion initiation threshold. This may be why the corrosion rate of the steel bar in the tidal/splash zone of columns remains low. Since 1999, the chloride profile of the concrete at tidal zone has not advanced, which may be attributed to the barrier effect of the acrylic coating applied on the columns.

**Keywords:** Coating, protection, performance, durability, testing, service life, corrosion.

## 1. Introduction

Lynch's bridge (inbound) was constructed shortly before the introduction in 1993 of major durability provisions into the VicRoads structural concrete specification Section 610 (1). As such the piers were constructed using a 50 MPa strength grade concrete containing cement only with a tricalcium aluminate (C<sub>3</sub>A) content of 2-5% and without the inclusion of supplementary cementitious materials (SCMs)(i.e. fly ash, slag or silica fume). A protective decorative/anticarbonation acrylic coating was applied on the pier columns and crossheads immediately after construction.

The decorative/anticarbonation acrylic coating was applied onto the Lynch's Bridge substructure (2) prior to the standardisation of the VicRoads concrete coating specification Section 686 (3), and only based on the material manufacturer's technical data sheet. As such the original coating was applied in two coats with a variable dry film thickness (DFT) of 100 to 140 micron, compared to the minimum total DFT of 150 micron required by Section 686. However, it is likely that other performance criteria, including equivalent air layer thickness, equivalent thickness of concrete and CO<sub>2</sub> diffusion, coefficient would have satisfied the current minimum requirements for a decorative/anticarbonation coating as stated in Section 686. It should be noted that this same acrylic coating although not marketed for aggressive environments was found to have performed very satisfactorily when subjected to significant exposure in a severe tidal marine environment as part of a coatings research project undertaken by VicRoads in 1995 (4).

The monitoring investigation of Pier 2 from the Melbourne abutment (Fig. 1) has been conducted on a frequent basis over a number of years since 1999 (5) in order to obtain information on the reinforcement corrosion in the pier, and the effectiveness of the coating applied on the concrete surface in protecting it from chloride ingress. This current monitoring work was carried out as a follow up some 4 years after the 2010 investigation (6) in line with the future performance requirements as flagged in that investigation, to identify any further potential deterioration changes, which may affect the structure or the surface coating over the intervening 4 year period.

Electrochemical measurements were conducted on selected elements, and 75 mm diameter concrete cores were extracted from the pile cap and the atmospheric and splash zones of the column and tested for chloride penetration (7, 8). In addition, pull-off testing was conducted on the two cores extracted from the atmospheric and splash zones of the column to determine the bond strength of the coating.

The corrosion activity of the reinforcement has not changed significantly in the past 15 years. The reinforcing bars in the tidal and splash zones have shown higher corrosion activity compared to the drier atmospheric zone. The chloride content at the depth of reinforcement in the column has not yet reached the corrosion initiation threshold. This may be why the corrosion rate of the steel bar in the tidal zone of columns remains low. Since 1999, the chloride profile of the concrete at the tidal zone has not advanced, which may be attributed to the barrier effect of the acrylic coating applied on the columns (8).

On the other hand, the chloride profile in the pile cap was much more advanced. This strongly supports the suggestion that prevention of chloride penetration was due to the effectiveness of the acrylic coating as a barrier to chloride penetration. The bond strength of the coating applied to the concrete surface was stronger than the tensile strength of the underlying concrete, and surprisingly the strength shown was greater than the typical range for this type of coating (acrylic) even after 24 years in service.

## **2. Scope of Investigation (7, 8)**

The current investigation was carried out in line with scheduled monitoring to provide additional information on the performance of the surface coating. The following on-site sampling and testing were carried out:

- Examination for any evidence of peeling of the acrylic coating and any visible corrosion or other defects on Pier No. 2 from the Melbourne side.
- Extraction of one 75 mm core from each of the atmospheric and splash zones on one bridge column (upstream) and one 75 mm core from the pile cap, i.e., a total of three cores.
- Determination of chloride content in the cover concrete of the three cores at four depth increments, i.e., analysis of 12 samples for chloride content.
- Pull-off testing on the two cores extracted from the atmospheric and splash zones of the column to determine bond strength of the coating.
- Half-cell potential mapping on two adjacent faces of the column to a height of 1.5 m and one location on pile cap on a 250-300 mm grid.
- Measurement of concrete resistivity on the two adjacent faces of the column, in the atmospheric and splash zones and on the top surface of the pile cap.
- Measurement of corrosion rate in the same areas as for the resistivity tests.
- Analysis and assessment of results and review of both the durability performance of the column and the effect of the existing acrylic coating on the concrete performance.

The acrylic coating required removal by grinding at the locations of half-cell potential, resistivity and corrosion current tests. The removed coating was subsequently reinstated. The site work was undertaken at low tide when the pile cap surface was above the water level.

## **3. Results of the Investigation and Testing (8)**

### **3.1 *Visual Inspection of the Columns and extraction of concrete cores***

The acrylic surface coating on the columns showed no sign of peeling, although crazing and very fine cracks could be seen when closely examining the surface, and small spots of impact damage could be seen on the lower part of column (Fig. 1) (8).

Corrosion staining could be seen at the construction joint, but this did not appear to be from structural reinforcement (Fig. 1 and Fig. 2). Concrete core drilling at tidal zone revealed that vertical reinforcing steel was not corroded (Fig. 2). No obvious defects were observed on the pile cap.

With respect to extraction of concrete cores, concrete Core 1 was extracted from the atmospheric zone and Core 2 from the tidal zone of the middle column (P2C3). Core 3 was extracted from the top of the pile cap to its west side (between P2C3 and P2C4). The holes of the three 75 mm diameter cores were backfilled with a suitable fast setting repair mortar with similar strength to the existing concrete.

Figure 2. (L) Coating removed for measurement, some corrosion stain visible at construction joint. (R) Reinforcing steel at tidal/splash zone with no sign of corrosion.

### 3.2 Half-cell Potentials

Half-cell potential mapping of columns was conducted on the south east face of the two upstream columns of the pier identified as P2C4 and P2C5. The column surface was mapped on a grid of 300 mm (horizontal) by 250 mm (vertical), starting from the top line of the column chamfer which is 150 mm from pile cap top. The half-cell potential survey was made in accordance with ASTM C876, and the final output presented in the form of potential maps as shown in Figure 3. The probability of reinforcing steel corrosion based on the measured copper-copper sulfate half-cell potential values (CSE) as presented by these potential maps is shown in Table 1. Figure 4 shows the average values of the potentials measured at the same height in the past four investigations on Column 4. The data shows that the half-cell potentials have not significantly changed in the past 15 years since monitoring commenced in 1999. This is further supported by the fact that vertical steel reinforcement exposed through a core hole in the tidal/splash zone area showed no sign of corrosion (Fig. 2).

Figure 3. Half-cell potential mapping of P2C4 and P2C5 (8).

Figure 4. Average value of half-cell potential mapping of P2C4 since 1999 (8).

Table 1. Concrete Surface Potential Criteria.

Potential (vs. Copper Sulphate Electrode (CSE))	Indication for reinforcing steel
More positive than -200 mV CSE	A greater than 90% probability that no corrosion is occurring
Between -200 to -350 mV CSE	Corrosion activity is uncertain
More negative than -350 mV CSE	A greater than 90% probability that corrosion is occurring

### 3.3 Corrosion Rate and Concrete Resistivity

The corrosion rate was measured by using the Gecor6 Corrosion Rate Meter, which measures the corrosion current in the steel area confined beneath the sensorised guard ring of the measuring device, as well as the corrosion potential of the reinforcement and concrete resistance. The measured corrosion current is divided by the surface area of the steel bar in the confined area to obtain the corrosion current density. The resistance was converted to resistivity as described by the equipment procedure. Corrosion rate measurement was undertaken on the south east face of the two upstream columns of Pier 2, identified as P2C4 and P2C5.

The locations of measurement represented concrete exposed to air, tidal zone and splash zone. As shown in Table 2 and Figure 5, the corrosion rate of the steel in the columns was low in all three exposure zones, and the corrosion rate of steel bars in the wet areas of the columns (splash and tidal zones) was comparatively higher than in the atmospheric zone. The corrosion potentials became more negative and concrete resistivity became lower with decreasing height above the pile cap. Considering that the steel bar exposed by core drilling below the high water mark had no sign of corrosion, these results indicate that corrosion activity is low in the columns.

The values of corrosion rate measured over the past years appeared to be consistent except for that measured in 2010 for P2C4, which was higher than the values obtained in other years. Compared to the columns, the corrosion rate of steel in the pile cap was higher, the corrosion potential was more negative and resistivity was lower. The measured values of the corrosion current density presented in Table 2 can be interpreted in terms of corrosion activity of the steel and categorised as shown in Table 3. The concrete resistivity results can be empirically interpreted as shown in Table 4.

**Table 2. Results of rebar corrosion and concrete resistivity (8).**

Position	Current Density and Corrosion Rate	$E_{corr}$ , CSE (mV)	Resistivity (k $\Omega$ -cm)
P2C4, h=1.2 m, Atmospheric zone	$i_{corr}$ = 0.14 $\mu$ A/cm <sup>2</sup> , rate =1.6 $\mu$ m/year	-210	18.9
P2C4, h=0.7 m, Splash zone	$i_{corr}$ = 0.12 $\mu$ A/cm <sup>2</sup> , rate =1.3 $\mu$ m/year	-408	10.1
P2C4, h=0.2 m, Tidal zone	$i_{corr}$ = 0.17 $\mu$ A/cm <sup>2</sup> , rate =2.0 $\mu$ m/year	-600	3.6
P2C5, h=1.1 m, Atmospheric zone	$i_{corr}$ = 0.13 $\mu$ A/cm <sup>2</sup> , rate =1.5 $\mu$ m/year	-181	17.2
P2C5, h=0.6 m, Splash zone	$i_{corr}$ = 0.28 $\mu$ A/cm <sup>2</sup> , rate =3.3 $\mu$ m/year	-431	8.0
P2C5, h=0.3 m, Tidal zone	$i_{corr}$ = 0.18 $\mu$ A/cm <sup>2</sup> , rate =2.1 $\mu$ m/year	-581	3.4
Pile cap, near P2C4	$i_{corr}$ = 1.32 $\mu$ A/cm <sup>2</sup> , rate =15.3 $\mu$ m/year	-719	1.5
Pile cap, near P2C5	$i_{corr}$ = 0.86 $\mu$ A/cm <sup>2</sup> , rate =10 $\mu$ m/year	-722	1.3

**Table 3. Corrosion current density and estimated corrosion rate for steel in concrete.**

Corrosion current density, $i_{corr}$ ( $\mu$ A/cm <sup>2</sup> )	Corrosion rate category
< 0.1	No corrosion expected
0.1 to 0.5	Low to moderate rate
0.5 to 1.0	Moderate to high rate
> 1.0	High rate

Note 1: Theoretically, for steel, a corrosion current density of 1.0  $\mu$ A/cm<sup>2</sup> is equivalent to a corrosion rate of 11.6  $\mu$ m/year.

**Figure 5. Corrosion current density of the columns measured in the past years (8).**

**Table 4. Empirical Interpretation of concrete resistivity.**

Resistivity	Empirical interpretation
100 k $\Omega$ -cm	The resistivity will effectively stop corrosion
50 - 100 k $\Omega$ -cm	Low corrosion rate
10 - 50 k $\Omega$ -cm	Moderate to high corrosion rate when steel is active
< 10 k $\Omega$ -cm	Resistivity is not the controlling factor

### 3.4 Performance of concrete surface coating

Pull off tests were performed on the acrylic coating at the exterior surface of the two cores drilled from the middle column of the pier, i.e., P2C3. The pull-off test results obtained on the same column in 2010 showed that the bond strength was higher than 3.7 MPa, which is the limit of the instrument when using 50 mm dollies (the maximum force is 7.5 kN). Therefore, the pull-off test area on the coated surface of the cores was reduced to about 30mm X 30mm by cutting through the coating and about 1 mm into concrete, and performed the pull-off test within that area.

The bond between the coating and the column surface was unusually high for this type of coating, and all pull-off failures occurred in the concrete. Table 5 presents the test results, and visual features of the cores and dollies after pull-off testing are shown in Figure 6. The dolly glued on Core 2 could not be pulled off at the maximum force. Therefore, two 20 mm dollies were then glued on the core surface for additional pull-off

tests. However, the results were inconsistent and may not be reliable. The pull-off strength for the two 30mm X 30mm dollies were 6.6 MPa and > 8.5 MPa, for the cores drilled from dry and wet surfaces, respectively. It is possible that the effects of the epoxy adhesive which was left in place with the dollies for the minimum curing period prior to testing may be reflected in these results. The bond strength onto the concrete substrate would nevertheless be in the range of 1.5 MPa to 4 MPa as shown in Table 5 which would be in the typical range of this type of coating even after 24 years in service.

It should be noted that the 2010 monitoring investigation (6) showed that the in-situ coating thickness, based on measurements off the pull-off dolly ranged between 30 and 100µm (compared to original DFT in the order of 100–140µm). However, it is considered that the in-situ use of a paint inspection gauge consisting of a microscope, typically of 50× magnification in accordance with the relevant standard would have resulted in more accurate DFT determinations.

Nevertheless, it is evident that although the coating exposed to the river water may be deteriorating to some degree, it still exhibits effectiveness and provides some protection. This is also supported by the visual observations in that the coating is still adhering well onto the concrete substrate. The coating thickness is possibly reducing as expected due to the long term exposure and consequent degradation of the polymeric structure of the coating thereby gradually reducing the ongoing effectiveness of the acrylic coating applied some 24 years earlier. However, both the 2010 and 2014 monitoring investigations show that the acrylic coating still maintains some effectiveness and they also validate the appropriateness of the early application of protective coatings onto new concrete bridges and other structures.

**Table 5. Results of the Pull-off test (8).**

Sample	Force (kN)	Area (mm <sup>2</sup> )	Strength (MPa)	Note
Core 1, P2C3, dry surface	5.0	760	6.6	Failure in concrete 1.5-3 mm
Core 2, P2C3, wet surface	7.4	870	> 8.5	Could not be pulled off
	1.4	360	4.0	20 mm dolly, failure in concrete
	0.5	310	1.5	20 mm dolly, failure in concrete

The strength obtained by using small dollies was much lower than that obtained on larger dollies and may be unreliable.

**Figure 6. Views of cores and dollies after pull-off test. Core 1 is from atmospheric zone and Core 2 from tidal/splash zone. The 50 mm dolly on Core 2 was sheared off in the testing machine (8).**

### 3.5 Chloride Profiles

Chloride content in the concrete was determined as shown in Table 6 and the detailed chloride ingress profiles for the three zones are shown in Figure 7. The chloride ingress values represent the combined effect in resisting ingress of the in-situ concrete and the acrylic coating applied immediately after construction.

The 75 mm diameter Core 1 and Core 2 were drilled to depths of a lateral bar and a vertical bar, which revealed the cover thickness to be 82 mm and 92 mm, respectively. Core 3 was drilled on the pile cap and touched a bar at a depth of 120 mm. The holes of the three 75 mm diameter cores extracted from the atmospheric and splash zones of the middle column (P2C3) and the pile cap between P2C3 and P2C4, were backfilled with a suitable fast setting repair mortar with similar strength to the existing concrete.

Figure 7 demonstrates that the chloride content in the atmospheric zone at 80 mm depth is still below the threshold value for initiation of corrosion. According to the Drawings, the cover to reinforcement in pile caps should be 70 mm. The core probably touched the bar of the second layer, not the first layer, and the chloride content at the first layer of bars is likely to be significantly above the threshold value for the pile cap.

Figure 7. Chloride profiles of the samples obtained in this investigation (8)

Table 6. Chloride content in concrete (8).

Sample	From (mm)	To (mm)	Cl-/Sample (%)
<b>Core1, Column, Atmospheric zone</b>	2.4	4.7	0.239
	8.5	13.6	0.098
	32.9	41.4	0.012
	69.7	79.5	0.011
<b>Core2, Column, Tidal zone</b>	0	3.9	0.473
	7.9	17.5	0.363
	34.1	40.1	0.126
	87.9	94.0	0.040
<b>Pile cap (Chloride threshold is taken as 0.07% by wt of concrete)</b>	0	3.4	1.539
	3.4	8.1	1.159
	16.8	25.7	0.695
	38.6	51.6	0.506
	79.6	87.0	0.306
<b>Chloride ingress and diffusion parameters represent the combined effect of the in-situ concrete and the acrylic coating applied immediately after construction.</b>			

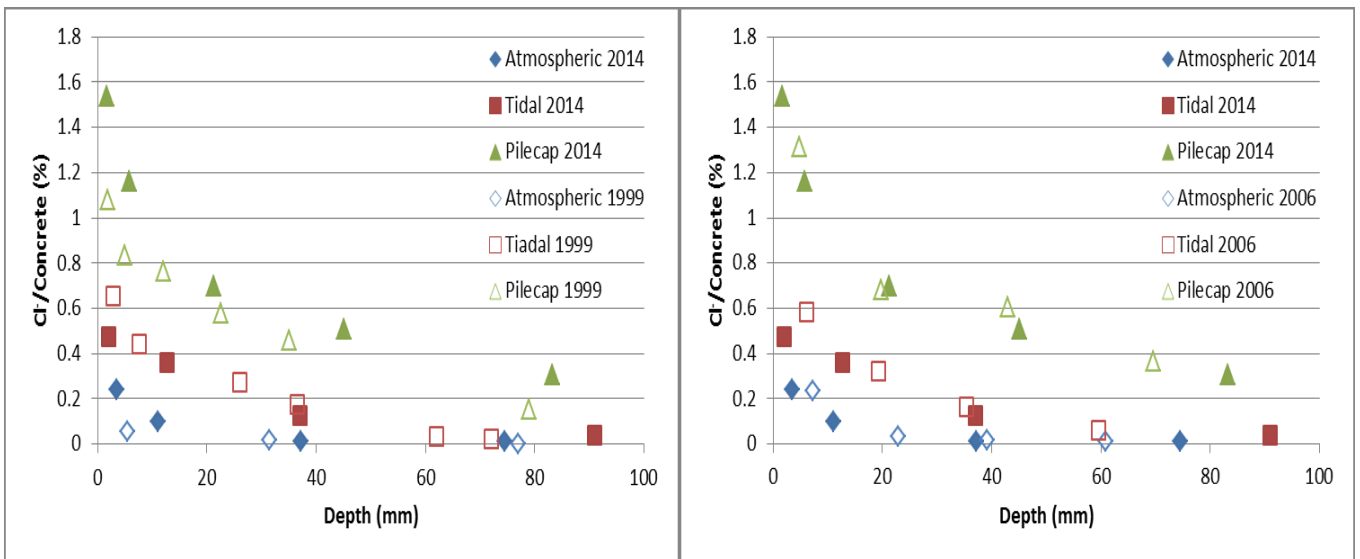

Compared with the chloride profiles obtained in 1999 and 2006 (9), in this 2014 investigation the chloride profile in the pile cap has gone slightly deeper. However, the chloride profiles obtained in 2014 are very similar, almost unchanged from the 2006 results in the tidal and atmospheric zones of the column (Figure 8). It appears that the acrylic coating has been effective in slowing down the chloride penetration in the tidal and atmospheric zones.

#### 4. Discussion

Two columns and the pile cap of Pier 2 of the 24 year old Lynch's bridge from the Melbourne side were investigated for reinforcing steel corrosion and chloride penetration. The acrylic surface coating on the pier columns was also tested for its bond strength.

It should be noted that the volume of permeable voids (VPV) of the pier concrete was determined at the initial investigation in 1999 at 15.5% which would represent the quality of the concrete after 8 years. The estimated corresponding 28 day estimate of VPV is in the order of 17.5% which represents the initial permeability condition and therefore microstructure performance of the original concrete. This would represent an in-situ

quality performance equivalent to a concrete grade of VR330/32 to VR400/40 as specified in Section 610 (1) instead of the required quality performance of a concrete grade VR450/50 which is essentially what was specified for use in the construction of the concrete piers for the bridge.

**Figure 8. Comparison of chloride profiles obtained in this investigation with those in 1999 & 2006 (8).**

The combined diffusion coefficient (D) determined in 2010 was  $2.9 \times 10^{-12} \text{ m}^2/\text{s}$  (atmospheric zone),  $1.3 \times 10^{-12} \text{ m}^2/\text{s}$  (tidal zone) and  $4.1 \times 10^{-12} \text{ m}^2/\text{s}$  (pile cap top face). Significantly, these diffusion coefficients (D) for the combination of acrylic coating and concrete is equivalent if not better than the specification requirements of RMS B80 - 50MPa of  $2 - 4 \times 10^{-12} \text{ m}^2/\text{sec}$  (durable concrete for Classification C, aggressive), and some 50% lower than RMS B80 - 40MPa of  $3.5 - 8 \times 10^{-12} \text{ m}^2/\text{sec}$  (for Classification B2) (10).

The relatively low chloride profiles obtained in the 2014 investigation which are similar to those determined in 1999 and 2006 as shown in Figure 8, and in conjunction with the low chloride diffusion coefficients determined in 2010, indicate that the combined effect of the average quality in-situ concrete (equivalent concrete grade of VR330/32 to VR400/40 instead of VR450/50) and the acrylic coating applied to the columns a short time after construction provide excellent protection to the steel reinforcement and enhanced performance in relation to the durability requirements. This outcome supports the fact that the acrylic surface coating applied to the columns during construction effectively slowed the chloride ingress in the tidal/splash and atmospheric zones of the columns.

The 2014 monitoring investigation showed that the corrosion activity of the reinforcement has not changed significantly in the past 15 years. Comparatively, the reinforcing bars in the tidal and splash zones have shown higher corrosion activity than in the drier atmospheric zone, in terms of steel corrosion rate and half-cell potentials and concrete resistivity.

The chloride profiles indicate that the chloride content at the depth of reinforcement in the column has not yet reached the corrosion initiation threshold. This may be one of the reasons why the corrosion rate of the steel bar in the tidal/splash and atmospheric zones of columns remains low. Since 1999, the chloride profile of the concrete at tidal/splash and atmospheric zones has not advanced, which may be attributed to the barrier effect of the acrylic coating applied on the columns after construction some 24 years ago.

On the other hand, the chloride profile in the pile cap was much more advanced, which strongly supports the suggestion that prevention of chloride penetration in the columns was due to the effectiveness of the acrylic coating as a barrier to chloride penetration.

## 5. Outcomes for Enhancing Structure Life

The ability of the acrylic surface coating applied to the columns of Lynch's bridge immediately after construction some 24 years ago to effectively slow down the chloride ingress in the tidal/splash and atmospheric zones of the columns, highlights the appropriateness of early application of protective coatings to bridges in all exposure conditions to enhance their ongoing performance.

It is considered that even if the protective coating which is initially applied to a new bridge is not re-applied as

part of ongoing maintenance, such initial application will protect the concrete for at least 15 to 20 years before the concrete structure is exposed to its in-service environment, thus providing the structure a valuable head start in its quest to achieve its required design life.

Furthermore, the monitoring investigations at Lynch's Bridge since 1999 revealed that even though the coating thickness may be reducing due to long term exposure and consequent degradation, coatings may still provide some protection to the concrete provided that they are still adhering well onto the concrete substrate.

The significance of the positive impact of early application of coatings is also demonstrated by the monitoring of the performance of an epoxy coating applied during construction on the columns of the Mordialloc Creek Bridge that are exposed to aggressive tidal marine conditions, some 8 years ago (11). The Mordialloc Creek Bridge epoxy coating investigation including the monitoring of other VicRoads bridges over the past 20 years demonstrated that early application of a protective coating provided enhanced performance, and contributed significantly to slowing down the ingress of chlorides into the columns concrete and lower the potential for earlier corrosion activity.

These evaluations further validate the case for the systematic application of protective coatings during construction of bridges and other structures in all types of exposure conditions, in combination with high quality concrete, to enhance their initial and long term durability performance even if such coatings are not re-applied during ongoing maintenance.

**Abstract:** This paper investigates the behaviour of short concrete filled steel tubular (CFST) columns during and after fire exposure. A total of 10 circular CFST columns were loaded with different load ratios and heated to various temperatures for a specified fire exposure period. During the fire exposure phase, the temperature versus time curves of specimens were measured, and the strain developments of the steel and concrete in fire were measured by using photogrammetry method. The interaction between the steel tube and concrete was analysed accordingly. After the fire exposure, the specimens were cooled naturally in the furnace to room temperature and then the columns were compressed concentrically until failure. In the post-fire loading phase, the failure modes, load-bearing capacity and axial load–axial strain relationships were recorded and presented. The effects of temperature, initial load and hold time period of heating on the post-fire residual strength were discussed. A non-linear finite element (FE) model was developed to simulate the tests by using existing material models included the effect of fire exposure. The predictions indicate that the FE model can capture the post-fire residual strength of CFST columns reasonably, but improvement is required in predicting the post-peak response of the load–deformation curves.

**Keywords:** concrete filled steel tubes, fire exposure, failure mode, post-fire behaviour.

## 1. Introduction

Concrete filled steel tubular (CFST) columns have been widely used in building structures due to their excellent fire performance compared with bare steel columns. With the increasing use of CFST columns in structures, the post-fire performance of the composite columns has attracted increasing research interest. Since 2002, Han et al. (1-3) has started to investigate the post-fire performance of CFST columns after exposure to ISO-834 standard fire. A series of tests on circular, square and rectangular short and slender CFST columns were conducted. The test results indicate that CFST columns demonstrate improved ductility after fire exposure, and the major influencing parameters on the post-fire residual strength were identified as fire protection thickness, fire duration time, section size and slenderness ratio. David et al. (4) recently reported test results of CFST columns after exposure to ISO 834 fire and Eurocode smouldering (slow-growth) fire. The test results showed that the influence of selected fire curves was minor. The possible reason explained by David et al. (4) was that similar maximum temperatures were experienced for the two types of fire curves.

It should be noted that no initial load was applied to the test specimens reported in (1-4) during fire exposure. This is different from the real fire scenario, and the presence of initial loading may have remarkable influence on the post-fire performance of columns. To identify the influence of initial load, Yang et al. (5) and Song et al. (6) established finite element (FE) models of CFST slender and short columns, which aimed to simulate the behaviour of CFST columns subjected to different phases including initial loading at ambient temperature, heating and cooling with constant load and post-fire loading. However, in these FE models, the influence of loading and temperature histories on the post-fire material properties models was not considered. Currently, only Huo et al. (7) reported 8 post-fire test results of CFST stub columns with initial loads. The investigated parameters included section size, maximum temperature, fire duration time and initial load level. Opposite trends were observed for the specimens exposed to temperatures of 400 °C and 600 °C. At a temperature of 400 °C, the presence of initial load enhanced the ductility of CFST columns, but at a temperature of 600 °C, the trend was opposite.

Set against this background, it is necessary to conduct more tests to clarify the influence of initial load on the post-fire performance of CFST columns. Therefore, this paper reports test results of 10 specimens for investigating the performance of CFST stub columns during and after fire exposure. To investigate the interaction between the steel tube and concrete during fire exposure, photogrammetry method was

employed to measure the axial and lateral deformations of the steel tube and core concrete in fire. Strength tests were conducted on the post-fire specimens after cooled to ambient temperature. A FE model is developed to simulate the test results and possible improvement to the FE model is discussed.

## 2. Experimental investigation

### 2.1 Specimen preparation

A total of 10 circular CFST columns were fabricated and tested. A summary of the specimens is shown in Table 1, in which  $D$  and  $t$  are the overall diameter and thickness of the steel tube, respectively. All the specimens have a same length of 800 mm. Specimen CFST-01 was reference specimen tested at room temperature, whilst the other 9 specimens were exposed to fire before strength testing.

**Table 1. Summary of test specimens.**

Specimen label	$D$ (mm)	$t$ (mm)	$T_t$ (°C)	$t_d$ (min)	$\Delta t$ (day)	$N_o$ (kN)	$n$	$f'_c$ (MPa)	$N_{uT}$ (KN)	$N_u$ (KN)	$RSI$
CFST-01	256	3	20	–	–	–	–	25.8	–	2103.2	–
CFST-02	256	3	400	45	42	650	0.25	32.1	2523.4	2601.4	0.970
CFST-03	256	3	600	45	8	650	0.22	37.6	2874.0	2901.5	0.991
CFST-04	256	3	700	45	132	650	0.22	38.8	2888.2	2918.7	0.990
CFST-05	256	3	800	45	60	650	0.20	43.7	2851.4	3220.6	0.885
CFST-06	256	3	800	0	60	650	0.20	43.7	2821.8	3220.6	0.877
CFST-07	256	3	800	90	56	650	0.20	43.4	2618.2	3219.8	0.813
CFST-08	256	3	800	135	92	650	0.20	42.8	1928.4	3193.8	0.604
CFST-09	256	3	800	90	61	0	0	29.2	2150.0	2488.1	0.864
CFST-10	256	3	800	0	55	1080	0.43	30.2	2555.7	2530.3	1.010

Photogrammetry method was used to measure strain developments of the CFST specimens in fire. Reference points were marked by using ceramic rods on the specimens during the fabrication stage. Ten holes with a diameter of 2 mm were drilled into the surface of the steel tube as shown in Figure 1. Then ceramic rods with two reference points were inserted into the  $\phi 2$  mm holes. The strain development of the steel tube in fire could be calculated based on the high pixel photos of these reference points. To measure the core concrete strains in fire, 4  $\phi 10$ mm holes were drilled through the steel tube to enable that the surface of the core concrete was exposed, and the ceramic rods with reference points were installed in the core concrete through the  $\phi 10$ mm holes.

**Figure 1. Location of ceramic rods and thermocouples (unit: mm).**

Three thermocouples were embedded into the CFST specimen to capture the temperature development in fire. Locations of the three thermocouples were shown in Figure 1, where point 1 is the centre of the

cross section, point 3 is located on the internal surface of the steel tube and point 2 is the midpoint between point 1 and point 3.

## 2.2 Material properties

The concrete used for specimens was made with ordinary Portland cement. The mix proportions of the concrete were: cement: 528 kg/m<sup>3</sup>; water: 210 kg/m<sup>3</sup>; sand: 664 kg/m<sup>3</sup>; coarse aggregate: 1027 kg/m<sup>3</sup>. Due to the availability of the furnace, the specimens were exposed to fire at a concrete age ranging from 53 days to 235 days. The compressive concrete strength ( $f_c'$ ) at the day of fire testing was measured from concrete cylinders. The obtained value of  $f_c'$  is presented in Table 1 for each specimen.

Steel coupons were cut from the same steel sheet which was used to fabricate the steel tubes of specimens. Tensile tests were conducted to obtain the steel material properties at room temperature. The yield strength ( $f_y$ ), tensile strength ( $f_u$ ), ultimate strain ( $\epsilon_u$ ) and modulus of elasticity ( $E_s$ ) of steel at room temperature are 330.4 MPa, 374.6 MPa, 0.154 and 206,500 MPa, respectively.

## 2.3 Test setup and procedure of the experiments

The following test procedure and setup were adopted:

- (1) Ambient temperature loading phase. Prior to the fire exposure, the column specimen was installed in the gas furnace located at the Structures Laboratory at the University of Western Sydney, Australia, as shown in Figure 2(a). Then the predetermined initial axial compression load ( $N_0$ ) was applied to the column specimen. The value of  $N_0$  corresponding to each specimen is shown in Table 1. The corresponding load ratio ( $n=N_0/N_u$ ) is given in Table 1, where  $N_u$  is the ultimate strength of the column at room temperature, which was determined based on FE prediction. The furnace chamber has a floor area of 640 mm in width and 630 mm in depth, and the height is 880 mm. The furnace is able to control the fire temperature following the specified temperature-time curve illustrated in Figure 3. Pin-pin end boundary condition was applied to the column specimen via two cylindrical hinges, and a loading jack with a capacity of 2,000 kN was used to apply load to the column.
- (2) Temperature rising phase. The applied load  $N_0$  was kept constant, and the furnace temperature was increased to the nominal target temperature ( $T_t$ ) with an average heating rate of 25 °C/min. The predetermined value of  $T_t$  for each specimen is shown in Table 1. During the test, there was some discrepancy between the actual maximum temperature and target temperature  $T_t$  due to the control accuracy. The difference was normally within 50°C. The temperature inside the furnace was controlled by four gas burners, and five thermocouples were used to monitor and record the furnace temperature. During the fire exposure, thermocouples in the specimen and a displacement transducer located at the top end of the specimen were used to measure the temperature and axial deformation of the column specimen. Two cameras, as shown in Figure 2(b), were installed outside the furnace to take photos of the reference points every 3 min until the end of cooling phase.
- (3) Constant temperature phase. After the furnace temperature reached the target temperature, the furnace temperature was kept constant until the predetermined hold time period of heating ( $t_h$ ) was reached. The value of  $t_h$  is shown in Table 1 for each specimen.
- (4) Cooling phase. After the hold time period of heating was reached, the heating was stopped and the specimen was cooled down to room temperature inside the furnace with the furnace door closed. In the cooling phase, the applied axial load was kept constant.
- (5) Post-fire loading phase. In the later stage of the cooling phase, the applied load to the specimen was removed. When the specimen cooled down to room temperature, the specimen was removed from the furnace and stored in the laboratory for a period ranging from 8 days to 132 days before conducting the residual strength testing. The stored period ( $\Delta t$ ) is presented in Table 1 for each specimen. The post-fire loading test was carried out using a testing machine with a loading capacity of 3,000 kN. All specimens were compressed under monotonic loading with a loading rate of 0.25 mm/min before the peak load and 0.75 mm/min after the peak load. The axial deformation of the column during the testing was measured by two displacement transducers as shown in Figure 2(c).

**Figure 2. Test setup.**

**Figure 3. Heating and cooling procedures.**

### 3. Temperature and strain developments in fire

#### 3.1 Temperature versus time curves

The average furnace temperature ( $T$ ) versus time ( $t$ ) curves of typical specimens CFST-03, CFST-04, CFST-06 and CFST-07 are shown in Figure 4. For specimens CFST-03, CFST-04 and CFST-07, the temperature rising, constant temperature and cooling phases described in Figure 3 can be clearly identified. But for specimen CFST-06, there was no constant temperature phase since the predetermined hold time period of heating ( $t_d$ ) was set to be zero. It should be noted that the furnace took more than 24 h to drop to room temperature. But after 200 mins, the furnace temperature generally dropped below 300 °C. Therefore, only the first 200 min was shown for the furnace temperature to clearly illustrate the heating stage.

Figure 5 illustrates the measured temperature ( $T$ ) versus time ( $t$ ) curves corresponding to points 1, 2 and 3 for a typical specimen CFST-07. As expected, the further the thermocouple location from the surface of the steel tube, the lower the measured temperature. Meanwhile, the measured  $T-t$  curves at points 1 and 2 had a platform at around 100°C owing to the fact that the water in the core concrete started to evaporate at that temperature, which consumes heat and slows down the temperature rise. Compared with the furnace and the steel tube, the concrete core cooled down more slowly due to the heat sink effect of concrete.

#### 3.2 Strain development

Specimens CFST-07 and CFST-09 have same test parameters except that an initial load of 650 kN was applied to CFST-07. Therefore, the two specimens are chosen to illustrate the influence of initial load on the strain developments of CFST columns. Using photogrammetry method, the steel axial strain, steel lateral strain and concrete lateral strain during the fire exposure were measured, and strain versus time curves are shown in Figure 6, in which positive and negative strains represent expansion and contraction, respectively. Different phases of fire exposure are indicated in this figure.

**Figure 4. Furnace temperature developments of typical specimens.**

**Figure 5. Temperature development of CFST-07.**

For specimen CFST-07 with an initial load, the steel developed a maximum axial expansion of 0.005 at the beginning of temperature rising phase because of the thermal expansion of the steel tube. With the degradation of material properties at high temperature, the axial expansion decreased and changed to contraction soon after entering into the constant temperature phase. At the end of the constant temperature phase, the steel axial contraction reached -0.01. In the beginning of the cooling phase, the steel axial deformation reduced slightly due to the thermal contraction. But soon the steel axial contraction demonstrated gradual increase due to the thermal creep of steel. The removal moment of the load in the cooling phase is marked in Figure 6(a), which indicates that its influence on the strain development was minor since the strength of the specimen had recovered before the load was removed. During the temperature rising and constant temperature phases, the lateral expansion of the steel tube increased significantly due to the combined effects of thermal expansion and Poisson's effect. At the end of the constant temperature phase, the steel lateral deformation stabilised at a value of 0.033, which is about three times the steel axial deformation at that moment. In the cooling phase, the steel lateral expansion decreased slightly due to the thermal contraction. For the concrete core, the lateral deformation increased almost linearly until the end of the constant temperature phase. Then the concrete lateral deformation decreased slightly during the cooling phase.

(a) CFST-07 with an initial load

(b) Unloaded CFST-09

**Figure 6. Axial and lateral deformations for typical specimens in fire.**

For the unloaded specimen CFST-09, all the strains measured during fire exposure were free thermal strains. Therefore, only expansion was observed for the steel and concrete in both the axial and lateral directions. Due to the delay in temperature rise within concrete, the concrete developed smaller value of

expansion than the steel in the heating phase. During the cooling phase, the expansion of the steel and concrete decreased gradually until reaching a very close constant value of about 0.0015. This is owing to the fact that residual dilation occurred for the unloaded concrete after heating up to above 400 °C.

The difference between the lateral strain developments of the steel tube and concrete shown in Figure 6 clearly indicates the interaction between the steel tube and concrete. During the heating phase, a gap was formed between the steel tube and concrete for both specimens CFST-07 and CFST-09, which indicates the loss of lateral interaction of the two components. It can be seen that the presence of an initial load significantly increased the gap size between the steel tube and concrete. Based on the measured lateral expansions of the steel and concrete, it is found that the maximum gap sizes during the fire exposure are 2.97 and 1.37 mm for CFST-07 and CFST-09, respectively. After the fire exposure, a reduced gap with a size of 1.83 mm was observed for specimen CFST-07, whilst the gap closed for the unloaded specimen CFST-09. Therefore, it can be concluded that the presence of an initial load during fire exposure has a detrimental influence on the interaction between the steel tube and concrete.

#### 4. Test results of specimens after fire exposure

##### 4.1 Failure modes

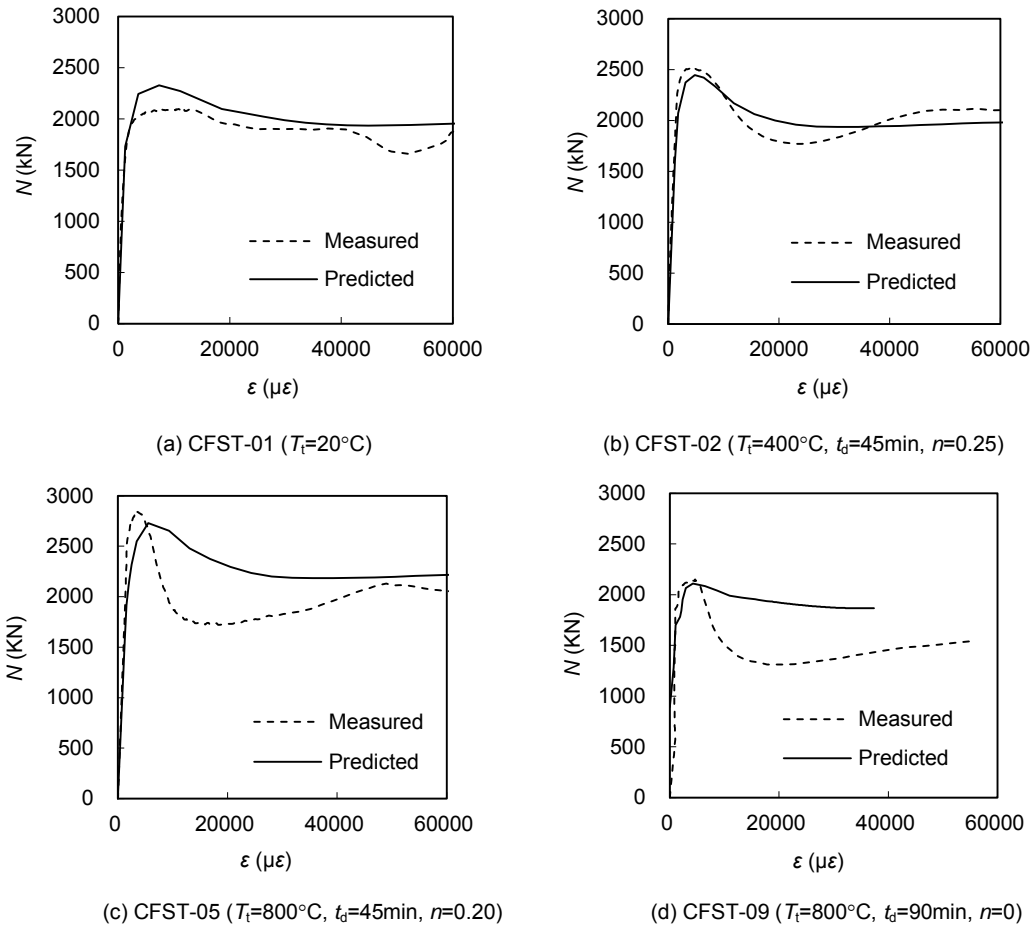

For specimens with an initial load, the steel tube buckled during the fire exposure. A typical specimen CFST-03 is chosen to demonstrate the local buckling of the steel tube, as shown in Figure 7(a). It is also found that oxide layer formed on the surface of the steel tube due to the fire exposure. In the post-fire loading phase, with the increase of the axial load, further deformation developed at the locations of initial local buckling until the column failed under axial compression, as shown in Figure 7(b).

**Figure 7. Failure mode of CFST-03.**

##### 4.2 Axial load versus axial strain curves

Figure 8 shows the measured axial load ( $N$ ) versus axial strain ( $\epsilon$ ) curves of typical specimens CFST-01, CFST-02, CFST-05 and CFST-09 tested in the post-fire loading phase. It can be seen that the  $N$ - $\epsilon$  curve of reference specimen CFST-01 without fire exposure exhibited good post-peak ductility as shown in Figure 8(a). But the  $N$ - $\epsilon$  curves of these fire-damaged specimens dropped sharply after the peak load compared with specimen CFST-01. At ambient temperature, the steel tube could provide effective confinement to the concrete core, thus improving the ductility of the concrete. Since there was a gap formed between the steel tube and concrete in fire-damaged CFST columns with initial loads, the interaction between the steel tube and concrete might be ignored. Due to the absence of proper confinement, the core concrete and steel tube worked independently, leading to the steep post-peak response of  $N$ - $\epsilon$  curves. Similar phenomenon was also observed for post-fire reinforced concrete columns reported by Huo et al. (8).

**Figure 8. Typical axial load ( $N$ ) versus average axial strain ( $\epsilon$ ) curves.**

### 4.3 Effect of different parameters on residual strength index

To quantify the influence of fire exposure on the ultimate strength  $N_{uT}$  of fire-damaged specimens, a residual strength index ( $RSI$ ) is defined, which is expressed as:

$$RSI = N_{uT} / N_u \quad (1)$$

in which  $N_u$  is the ultimate strength of corresponding column at room temperature determined based on FE prediction. The value of  $RSI$  corresponding to each specimen is given in Table 1. The effects of different parameters on  $RSI$  are described in the following.

#### 4.3.1 Effect of temperature

Figure 9(a) demonstrates the influences of temperature ( $T_i$ ) on  $RSI$  of CFST column specimens. The four specimens CFST-02 to CFST-05 were subjected to a same initial axial load (650 kN) during the fire exposure, and had a same hold time period of heating of 45 min. but they exposed to different target temperatures ( $T_i$ ) ranging from  $400^\circ\text{C}$  to  $800^\circ\text{C}$ . It can be found that when  $T_i$  is  $700^\circ\text{C}$  or less, the strength loss is generally less than 4%. But when  $T_i$  reaches  $800^\circ\text{C}$  for specimen CFST-5, a strength loss of 11.5% is obtained.

#### 4.3.2 Effect of hold time period of heating

The influences of hold time period of heating ( $t_d$ ) on  $RSI$  of CFST specimens is shown in Figure 9(b). The four specimens CFST-06, CFST-05, CFST-07 and CFST-08 were exposed to a same temperature of  $800^\circ\text{C}$ , but  $t_d$  of these specimens varied from 0 to 135 min. The influence of  $t_d$  on  $RSI$  is moderate when  $t_d$  is 45 min or less since  $RSI$  values of both specimens CFST-06 ( $t_d=0$ ) and CFST-05 ( $t_d=45$  min) are very close to 0.88. But when  $t_d$  is

greater than 45 min, a significant strength reduction is observed due to increased strength loss of the core concrete. When  $t_d$  increases from 45 to 135 min, the  $RSI$  value drops from 0.885 to 0.604.

#### 4.3.3 Effect of initial load

Figure 9(c) shows the influence of initial load on  $RSI$ . The two specimens CFST-09 and CFST-07 have the same test parameters except that an initial load of 650 kN was applied to CFST-07. But CFST-09 was unloaded during fire exposure.  $RSI$  for the unloaded specimen CFST-09 is 0.864, which is higher than the  $RSI$  value of 0.813 for loaded specimen CFST-07. This can be explained by the diminished confinement effect resulted from the presence of the initial load for specimen CFST-07. In contrast, Huo et al. (7) concluded that the influence of initial load on the post-fire strength of CFST stub columns is minor. Clearly, more tests need to be conducted in the future to reach a definite conclusion.

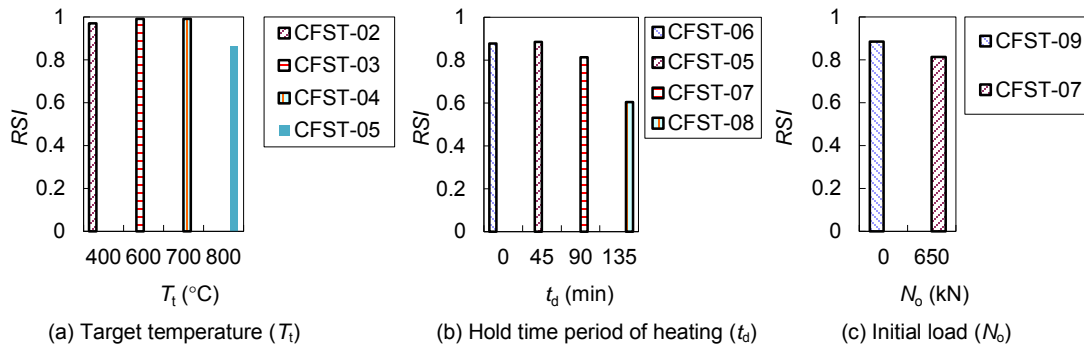

Figure 9. Influences of different test parameters on  $RSI$ .

## 5. Finite element (FE) analysis

### 5.1 FE model

Finite element analysis program ABAQUS (9) is used to simulate the behaviour of CFST stub columns during and after fire exposure. Heat transfer analysis model was established first to obtain the temperature distribution of CFST columns in fire, and then the predicted temperature field at the end of constant temperature phase was imported into the structural analysis model for conducting the post-fire analysis.

Extensive studies have been conducted by previous researchers to simulate the temperature distribution of CFST columns in fire. Tao and Ghannam (10) proposed refined thermal analysis models for CFST columns based on the analysis of extensive test data, and the proposed method can predict the temperature distributions of CFST columns with reasonable accuracy. Therefore, the FE model developed by Tao and Ghannam (10) was used in this paper to conduct the heat transfer analysis, in which the concrete was modelled using 8-node linear heat transfer brick elements (DC3D8), and 4-node heat transfer quadrilateral shell elements (DS4) were used for the steel tube.

For the structural analysis, the stress–strain models of steel at room temperature and after exposure to high temperature proposed by Tao et al. (11) were adopted. For concrete at ambient temperature, it expands laterally under axial compression, and the concrete will eventually be confined by the outer steel tube. This confinement is passive and should be considered in the concrete model (12). Concrete damaged plasticity model is a widely used concrete model, in which some key parameters, such as the dilation angle and strain hardening/softening rule, need to be determined very carefully to accurately simulate the behaviour of concrete in the steel tube. Tao et al. (12) recalibrated those important parameters in the concrete damaged plasticity model and proposed a FE model to simulate axially loaded CFST columns at room temperature. The FE model proposed by Tao et al. (12) was verified by a wide range of experimental data, and the accuracy of the proposed model is reasonable. Therefore, the FE model proposed by Tao et al. (12) is used in this paper to simulate CFST columns at room temperature. The concrete model after exposure to high temperature was determined according to Yang et al. (5). To simulate the interaction between the steel tube and concrete in the FE model, the Coulomb friction model

with a friction coefficient of 0.6 and 'hard contact' were employed in the tangential direction and normal direction, respectively. It should be noted that the initial gap between the steel tube and concrete was not considered in the FE modelling. The structural analysis model has the same mesh as heat transfer model, but different element types, i.e., 4-node shell elements (S4R) and 8-node linear brick elements (C3D8R) were used for the steel tube and concrete, respectively.

Based on the established FE models, the temperature versus time curves and axial load versus axial strain curves were predicted and the results will be discussed in the following subsection.

## 5.2 Discussion

Figure 5 shows the comparison between the predicted and measured temperature ( $T$ ) versus time ( $t$ ) curves. In general, the predictions agree well with the measured results. Although the predicted  $T-t$  curves cannot capture the platform stage at around 100 °C for points 1 and 2, it has very limited influence on the prediction accuracy at a later stage.

Figure 10 shows the comparison between the predicted and measured post-fire residual strengths. A mean ratio (predicted over measured strengths) of 0.965 is obtained with a coefficient of variation of 0.083. As can be seen, the predicted residual strengths are reasonable. The comparison of predicted and measured post-fire  $N-\epsilon$  curves is illustrated in Figure 8. Clearly, at a lower temperature ( $T_f \leq 400$  °C), the predicted  $N-\epsilon$  curves match well with the measured curves. But when  $T_f$  is higher than 400 °C, the predictions are reasonable for the initial stage of  $N-\epsilon$  curves and residual ultimate strengths. But the steep post-peak  $N-\epsilon$  curves are not captured very well in the FE predictions. The ductility of the fire-damaged CFST columns is overestimated. This can be explained by the fact that the initial gap was ignored in the current FE modelling, leading to the overestimation of the confinement effect. Further research is required for the FE modelling to accurately consider the influence of the initial load on the stress-strain model of concrete and interaction between the steel tube and concrete.

Figure 10. Comparison between predicted and measured post-fire residual strengths.

## 6. Conclusions

Based on the results of this study, the following conclusions can be drawn:

- (1) The measured steel and concrete lateral deformation versus time curves indicate that the presence of initial load can lead to the formation of a gap between the steel tube and concrete, which has a detrimental influence on the interaction of the two components.
- (2) The strength loss increases with the increase of temperature and hold time period of heating. A small load with a ratio of 0.2 has a detrimental effect on the residual strength in the current tests, but an increased load with a ratio of 0.43 increased the residual strength of the composite column.
- (3) Finite element models were established to simulate the test specimens. The accuracy of the predicted post-fire residual strengths is reasonable, but the predictions overestimate the post-peak ductility of fire-damaged CFST columns. For the FE modelling, further research is required to accurately consider the influence of the initial load on the stress-strain model of concrete and interaction between the steel tube and concrete.

## 7. Acknowledgments

This research was supported by the Australian Research Council (ARC) under its Discovery Projects scheme (Project No: DP120100971). The financial support is highly appreciated.

# Dynamic Performance Criteria for Suspended Courts at the National Tennis Centre

Mark Sheldon<sup>1</sup> and Benjamin Delaney<sup>2</sup>

<sup>1</sup>Technical Director, Aurecon

<sup>2</sup>Senior Project Manager, Major Projects Victoria

**Abstract:** The National Tennis Centre at Melbourne Park incorporates courts on the roof of a carpark building. As this has never been done at the home of a “Grand Slam” tournament, an appropriate structural design criterion for the suspended slabs was needed. A study was undertaken on how vibrations induced by the players and external sources would be perceived, and following testing on existing courts and undertaking real time studies on forces exerted by tennis players, a series of criteria for acceptable vibrations in the structure was developed. A bi-directionally banded post-tensioned concrete floor system was developed using FEA, and dynamically tested upon completion. The structure has now been successfully used during three Australian Open tournaments.

**Keywords:** Tennis court dynamic performance vibration

## 1. Introduction

The Eastern Plaza and National Tennis Centre are part of the Melbourne Park Redevelopment project which is being managed by Major Projects Victoria for Sport and Recreation Victoria, Melbourne & Olympic Parks, and Tennis Australia. The project, completed in late 2012, incorporates world-class tennis courts on the roof of the new carpark building. The new tennis courts are both indoor and outdoor, with the indoor courts covered by a metal and glass-clad architectural envelop as shown in the image below.

**The indoor tennis courts at the National Tennis Centre [1]**

Constructing international standard courts on top of a building is something not previously seen at the home of a “Grand Slam” tournament. This presented the design team with a new challenge – to determine an appropriate structural design criterion for the suspended slabs. The stiffness of the structure needed to be considered, in particular how vibrations induced by the players and external sources would be perceived. Following testing on existing courts and undertaking real time studies on forces exerted by tennis players, a design criterion for acceptable vibrations was developed for the suspended structure supporting the tennis courts.

Following completion of the design and construction, on-site testing was undertaken to compare the in-situ results to the theoretical predictions. The criteria was met, and the facility has now been successfully used by many of the world's top tennis players.

## **2. Background**

Most tennis courts suitable for international competition are located at ground level, on stable loadbearing layers supported by the ground. The structural design methodology for these courts is reasonably well understood within the structural engineering fraternity. However site constraints within the Melbourne Park complex dictated that for the new National Tennis Centre, opened just prior to the 2013 Australian Open, eight inside warm up courts and six outside courts needed to be located over the 1000 car carpark building. The National Tennis Centre also includes a player's gymnasium, a running track, and associated facilities which the design team identified could induce vibrations in the structure.

A study of major tennis venues around the world did not identify any design precedents for suspended "international standard" courts, so a design approach needed to be developed. The main concern was structure-borne vibrations, i.e. whether the movement of players or other external sources would cause unacceptable levels of vibration.

Structure-borne vibrations can be initiated from a number of sources. The simplest form of initiator is a single strike. Once struck, the structure will oscillate at its fundamental frequency or natural frequency. The length of time over which it will oscillate and the rate at which energy dissipates is a function of the inherent damping of the structure, which is influenced by the fixtures, services and furnishings attached to the structure, and the original form of the structure.

At the other end of the spectrum is the case where a cyclical load induces what could be considered a regular series of strikes on the structure. The effect of this type of loading is very dependent on the frequency of this cyclical load. If the load frequency does not match the natural frequency of the structure, then the resultant vibrations may not be significant. However when the load frequency matches the structure's natural frequency (or an integer multiple of the natural frequency), then significant vibrations can be induced.

In reality a tennis slab structure would be subjected to a wide range of forces, from single strikes generated by players jumping; a series of rhythmic strikes from players running; forces randomly generated from the movement of weights in the gymnasium; transient forces from cars moving around in the carpark or trains passing Melbourne Park on the nearby rail lines; and continuous forces from machinery in plantrooms. Each of these cases needed to be investigated.

Whilst the study of structure-borne vibrations can become quite technical, it was the desire of the client group (in particular Major Projects Victoria and Tennis Australia) that a quantifiable design approach be developed, so that this may be able to be used on similar future projects.

## **3. General Principles of Dynamics**

Under the influence of an applied load, or series of loads, a series of vibrations will be induced in the structure. As the structure will (typically) consist of slabs, beams, columns and foundations, these elements will all influence the frequency of the structure. Instead of having one natural frequency, a structure can have a number of resonant frequencies.

The main design parameter associated with an investigation into structure-borne vibration is usually the resultant acceleration. A person standing on the vibrating structure will feel this vibration. What they are actually sensing is the cycles of accelerations and decelerations. Interestingly, some people are more sensitive to the oscillating motion than others, and some people are more tolerant of this motion than others (and this may even change depending on the player's temperament).

Whilst the behaviour of the oscillation of a floor system can be quite complex, in simple terms under an applied striking force the following will occur:-

- The structure will vibrate at its “natural frequency” or one of its resonant frequencies
- The length of time over which it will oscillate is a function of the magnitude of the force and the damping in the building
- People will sense the acceleration of the slab caused by the vibration

There are various ways to measure and report accelerations, the relevance of which is dependent upon the type of floor and the predominant forcing loads. In this instance, it was determined that the as the frequency of forcing loads during play would be orders of magnitude above the frequency of the structure, then the most important structural response parameter is the peak acceleration. Immediately following the peak acceleration there will be a peak deceleration, both of which will contribute to the perceived vibration. It was therefore concluded that the average of these two peak figures would be used as the criterion.

A significant body of research has been undertaken over many years studying the perceptions of vibrations, particularly in North America based on work by Thomas Murray and David Allen. Much of this work has been published over a 30+ year period, and has formed the basis of the National Buildings Code of Canada’s design criteria [3] and the American Institute of Steel Construction’s Design Guide No 11 [4]. These studies have identified that humans are most susceptible to vibrations in the range of 4-8 Hz. It was also identified that people are more tolerant of vibrations in structures such as footbridges and shopping centres (where they only have limited exposure to the vibration) but are less tolerant of vibrations in an office environment and even less tolerant in their home. The following chart (Figure 1) is well known within the engineering fraternity as the basis for acceptable vibrations in different building types, based on the works of Murray and Allen.

**Figure 1: Acceleration Design Curves based on the works of Murray and Allen [2]**

A significant observation from these curves is that, above approximately 8 Hz the allowable accelerations can increase. This is due in part to the fact that people are less susceptible to higher frequency vibrations, but also recognizes that as the frequency increases, the displacement associated with the oscillation will be less (for a similar applied force).

In addition to the works by Murray and Allen, other structure-borne vibration studies have been undertaken in Australia and internationally over many years on buildings such as hospital wards, operating theatres and the like. These were referenced in the development of the criteria for the Eastern Plaza tennis courts.

Another critical factor in the development of the criteria for the tennis courts is the fact that a person using their own body weight to cause the load (by jumping, lunging, running etc) is generally not able to sense the resultant vibrations in a normal structure. This observation was central to the decision on where the accelerations should be measured in the structure, and is discussed in more detail below.

#### **4. Team Effort**

Developing a first-of-its-kind criterion that is practical and economical, yet still meets the “fitness for purpose” test requires buy-in from the whole team. Fortunately this occurred on this project. Similarly, it requires experienced people who are each able to contribute their inputs in their particular field of expertise, so that the important aspects of the whole issue can be identified and addressed. Again, this occurred on this project.

The client was concerned that if the courts were considered too bouncy by the world’s top players then the ensuing bad publicity would have significant impacts on the Australian Open. However they also had a budget to meet. The Eastern Plaza was tendered as a “Design and Construct” project by Major Projects Victoria. The three respondents to this tender each took different approaches to the issue of the dynamics of the tennis courts, proposing three different solutions. Each of the three proposals were based on a post-tensioned concrete structure, however the thicknesses and layout differed considerably as did their cost per square metre.

The contract was awarded to the team led by Watpac Construction, with Jackson Architecture, WSP as their structural engineer, and Marshall Day Acoustics providing vibration advice. After award, the final criterion was still to be resolved, and whilst different members of the team had different drivers, it was the professional approach by all parties that led to the successful conclusion.

#### **5. Pre-tender investigation**

At the pre-tender stage of the Eastern Plaza project Major Projects Victoria and Tennis Australia recognised that this was an unusual project requiring additional inputs, so Tennis Australia commissioned testing to examine the dynamic performance of selected existing tennis courts. One court tested was the existing Margaret Court Arena, which has been used for many years during previous Australian Open Grand Slam tournaments, and consists of a post-tensioned slab-on-grade. The second test was on a tennis court located on a carpark building associated with a major hotel development. In addition, to accumulate more data for comparison a third series of tests were undertaken on a tennis court located on a suspended slab at a tennis facility in Auckland New Zealand during the final design stage. Measurements of accelerations and frequencies were taken at each of the facilities during a tennis match. As was expected, the dynamic response measured from these three tennis courts differed greatly. It was determined that for the Melbourne Park facility, the new suspended courts needed to be stiffer than the two suspended courts tested.

In addition, Major Projects Victoria and Tennis Australia also commissioned some actual impact load tests, undertaken at the Victoria Institute of Sport (VIS) Sports Science Department. A competition player was put through a series of typical tennis manoeuvres over a load cell. The actual forces exerted on to the floor from these manoeuvres were measured against time. Selected graphical outputs of these tests follow. The testing showed that under a “jump smash” action, the force exerted on the floor was equivalent to approximately 12.5 times the player’s weight, but for a very short period of time. Under actions such as running and changing directions, the Gross Reaction Force (GRF) is approximately 2 times body weight, but occurs over a longer time and is obviously likely to occur much more frequently during a match. Under a serve motion, the maximum GRF was approximately 2.5 times the body weight, increasing to approximately 3.2 times under a volley motion.

**Figure 2: Gross Reaction Force diagram for Change in Direction**

**Figure 3: Gross Reaction Force diagram for Volley**

The results of the Volley tests were of particular interest, as this represents an activity that would occur relatively frequently during a match. It was noticed that this action produces a GRF plot with a peak similar to a “Heel Drop”. A Heel Drop test is a universally accepted (albeit crude) test to study vibrations in structures. It was identified that a Heel Drop test could be used to simulate the Volley design case, and could be reproduced with reasonable consistency.

## 6. Development of a criteria

To design a structure with “imperceptible” accelerations under all load conditions was virtually impossible and, at best, extremely cost-prohibitive. It was accepted that a design criteria had to be developed. Rather than try to adopt a single criterion for the design of the structure, it was decided that a rational approach coupling the probability of a load occurrence with an appropriate allowable acceleration was more logical. The Jump Smash action was identified as the most severe of the design cases, however this activity is expected to occur less frequently than serving, volleying and significantly less than running / changing directions. In addition to these forces caused by the players, we also needed to consider structure-borne vibrations caused by vehicles in the carpark, trains and trams passing the facilities, activities in the gymnasium, and machinery in the plantrooms of the facility.

Given that the professional players normally play on “on grade” courts that experience minimal accelerations under impacts, it was deemed necessary that a tight criterion for the suspended slabs was necessary. The starting point was to consider a criterion for the most common forms of activity – running and changing directions during a match. Australian Standard AS2670.1 – 2001 [5], which is based on ISO 2631-1:1997, indicates that approximately 25% of alert fit persons cannot detect a vertical vibration with a peak magnitude of 0.2%g. Similarly, the Department of Environment and Conservation NSW’s “Assessing Vibration: A Technical Guideline” [6] provides a maximum recommended acceleration from a vertical continuous vibration source in a hospital operating theatre which equates to a peak acceleration of approximately 0.14%g. Anecdotal evidence from the design team on the National Tennis Centre was that a figure of 0.2%g had recently been used as the design criterion for a large Australian hospital. It was therefore decided that the criterion where the peak accelerations is limited to less than 0.2% g (for structures in the range of 4-8 Hz) would be appropriate, as it was deemed that even the most temperamental tennis player would agree that if a surface was stiff enough to for a doctor to operate, it would be acceptable for a tennis match. Following the precedent of the curves as shown above, the allowable acceleration could increase if a stiffer structure (with a higher natural frequency) was provided.

The “background” vibrations from external sources (vehicles, trains, trams, activities in the gym, mechanical plant etc.) was the second criterion to be determined. As this vibration could be expected to occur for extended periods of time, an acceleration limit less than the running/ changing direction criterion was deemed appropriate. Following an assessment of what could be realistically and economically achieved in design, an acceleration curve at 80% of the running / changing direction criteria was adopted. This is nearing the level at which many people would consider is imperceptible.

The next criterion to be considered was for the serve action and volley action. As this activity would occur less frequently than the running and changing direction, a higher acceleration was considered acceptable. A peak acceleration of 0.5%g was adopted, increasing in line with the curves shown above for frequencies greater than 8Hz. This is similar to what would be deemed acceptable in an office or residential environment, as shown in figure 1. A convenient aspect of this criterion is that the Gross Reaction Force generated from the players is similar in magnitude and duration to a heel drop test, which is relatively easy to replicate by technicians.

Under the jump smash action a more lenient criteria was necessary, as a cost-prohibitive structure would otherwise be necessary. Through consultation with Marshall Day Acoustics, it was agreed that as the duration of the significant force was extremely short, an allowable acceleration of 2%g (increasing for structures above 8Hz) would be acceptable. The resultant design curves are presented in Figure 4 below.

Figure 4: Adopted design criteria

## 7. Location of Acceleration Measurements

The location of the acceleration measurements on the structure is another important feature of the adopted design criteria. For the bottom-most curve, (the background vibrations), these accelerations should not be exceeded anywhere on the slab. For the remainder of the criteria, however, two different practical factors were considered. As noted previously, it is known that the person performing the forcing action does not feel the resulting accelerations. In a tennis match environment it is therefore typically the umpire or a doubles partner that is likely to be located within about 4 metres of that player.

It was decided that to have requisite stiffness to accommodate the design criteria, and to accommodate the carparking layout and other constraints below, the structure would have columns on a grid of 8.1metres x 7.8metres. By undertaking a preliminary 3D Finite Element Analysis (FEA) and studying the modeshapes of the resonant frequencies of the likely structural system, it was known that maximum and minimum accelerations are likely to occur at multiples of grids and half-grids of the structure. The design methodology was therefore to place the forcing load at the most severe location on the structure as determined by the FEA analyses and check accelerations at half-grid spacings (4.05m in the north-south and 3.9m in the east-west directions). Due to the length of a tennis court (and the fact that the players may be both located beyond the baseline) it was considered necessary to continue the measurements for a distance of approximately 25-30 metres.

## 8. Pre-construction Dynamic Analysis

Significant analysis of the structure is required prior to construction, to determine the dimensions of structure to be constructed to meet the design criteria. A full 3D finite element analysis (FEA) with time history capability is necessary to model the characteristics of the load (from the GRF plots) and the response of the structure at multiple locations. To model the structure's response, an accurate assessment of the stiffness of the structural elements is essential. All flexural concrete members form fine cracks in the tensile zones which reduce its stiffness at these locations and increase deflections. These micro-cracks result in a varying effective Moment of Inertia across the structure. Similarly, under dynamic loads, publications such as the AISC Design Guide No 11 [4] recommend a dynamic modulus of elasticity

1.35 times higher for the concrete elements than what would normally be used for a static analysis. Whilst outside the scope of this paper, these parameters need to be carefully considered before a realistic dynamic FEA can be undertaken. It is wise to undertake a static analysis of the structure initially and compare moments, forces and deflections to results from a trusted flexural analysis program prior to embarking on the dynamic analysis. Modifications to the static design model may still be necessary, as the effect of the micro-cracking on the effective Moment of Inertia for very small amplitude deflections can be less prominent, especially in a post-tensioned structure.

The final design of the floor structure was undertaken by WSP using the ETABS software, and to test the accuracy of their model Aurecon produced our own Strand 7 FEA model. This reflected the edge conditions between the movement joints in the structure and the properties of the supporting columns below. The Aurecon model included the dynamic modulus of elasticity with a reduced effective Moment of Inertia in some elements. Based on the layout of the courts and the structural grids, it was identified that the maximum accelerations in the applicable portions of the building could be generated in the structure by locating the forcing load in the bay as shown in Figure 5. The structure was then designed and detailed based on this pre-construction dynamic analysis.

**Figure 5: Screen shot of the Aurecon Strand 7 model displacement under dynamic load (Load exerted at “P”)**

From the FEA analysis, a design evolved which essentially consisted of 450mm deep x 2400mm wide bandbeams in both the north-south and east-west directions, with 200mm infill slabs. Both the slabs and bandbeams are post-tensioned. This resultant structure is considerably stiffer than a “normal” slab that would otherwise be required for an office or retail development based on the same column grid.

## 9. Post-construction Dynamic Analysis

Once the structure had been completed, a series of tests were undertaken to measure the accelerations produced at the critical point located in figure 5. Tests were done whilst a player ran, changed direction, served, volleyed and hit jump smashes, with accelerometers at intervals up to 27metres away from the strike point. Tests were also performed using dropped loads, which were considered to more accurately reproduce the specified design GRF's in a repeatable manner. In addition, Heel Drop tests were undertaken to simulate the volley action. The results of the measured resonant frequencies of the structure were found to be around 20% lower than the theoretical figures. It is not unusual for there to be such a difference given the dependency of the results on numerous factors outside the control of the designer. This is accounted for in the performance criteria, as the allowable acceleration is a function of the actual frequency, as shown in figure 4. For the resonant frequency of the test bay the resulting accelerations were found to be within the criteria set for the project.

As the National Tennis Centre was opened prior to the end of 2012, it was used for the first time during the 2013 Australian Open, and again during both the 2014 and 2015 Australian Open. Feedback from the players and Tennis Australia was that the facility has performed well and met their expectations.

## 10. Summary

The National Tennis Centre at Melbourne Park incorporates courts on the roof of the new carpark building. Constructing international standard courts on top of a building is something not previously seen at the home of a “Grand Slam” tournament. This presented the design team with the challenge of how to determine an appropriate structural design criterion for the response of the structure to vibrations induced by the players and external sources.

Tests on existing courts were undertaken, as well as real time studies on forces exerted by tennis players. Based on a rational approach, relating how often an event may occur to an appropriate acceleration limit, a series of design curves was developed for acceptable vibrations in the suspended structure supporting the tennis courts. A criteria for the locations on the slab where the measurements should be taken was also determined. Using a Finite Element Analysis with a series of time history load inputs, a post-tensioned concrete structure was designed to satisfy the dynamic criteria.

This report provides guidance on the main parameters that should be considered, and the design approach that was applied for the dynamic performance of the suspended tennis courts at the Melbourne Park venue. The structure has now been constructed, and insitu testing has confirmed that it satisfies the design criteria. The structure was successfully used during the 2013, 2014 and 2015 Australian Open tournaments.

**Abstract:** This study investigated the flexural response of glass fibre reinforced polymer-reinforced geopolymer concrete (GFRP-RGC) beams using a four-point static bending test. Three full-scale beams were cast and reinforced with nearly same amount of longitudinal GFRP reinforcements but of varying diameters at the bottom (4-12.7 mm, 3-15.9 mm, and 2-19.0 mm), two 12.7 mm GFRP bars at the top, and 9.5 mm GFRP stirrups spaced at 100 mm on-centre. The average compressive strength of the geopolymer concrete was 38.2 MPa. Based on the experimental results, all the tested beams showed nearly similar crack pattern, load-deflection response, bending-moment and deflection capacities, and strain readings, suggesting that the flexural response of a GFRP-RGC beam was not significantly influenced by the bar diameter; instead, by the properties of the geopolymer concrete. The  $0.3M_u$  criterion suggested by Bischoff must be adapted in the serviceability design of a GFRP-RGC beam. The flexural capacities of the tested beams were generally higher than the predicted values from ACI 440.1R-06 and CSA S806-12 standards. Furthermore, the GFRP-RGC beams have higher strength compared with their GFRP-reinforced concrete counterparts. Thus, it can be concluded that the GFRP-RGC beams have structural properties that are suitable for civil infrastructure applications.

## 1. Introduction

Cement-based concrete is one of the oldest and most commonly used construction materials in the world. The demand for this material is expected to increase in the future owing to rise of infrastructure need by many developing countries and the growing number of old and deteriorated concrete structures needing urgent repair and rehabilitation. The production of cement, however, contributes billions of tons of waste materials and about 7% of the world's greenhouse gas yearly (1). In fact, several studies revealed that for every 1.0 tonne of cement produced, approximately 1.0 tonne of CO<sub>2</sub> are being released into the atmosphere (2). With the alarming increase of Earth's average surface temperature due to greenhouse gases, also known as global warming, the construction industry, specifically, are prompted to replace cement with a greener material like geopolymer. Geopolymer is a highly sustainable concrete binder as it can be manufactured using by-product materials, like fly ash and blast furnace slags. Davidovits (3) proposed the term "geopolymer" since the chemical reaction that takes place between the aluminum (Al) and silicon (Si) source material and the alkaline liquid activator is a polymerization process.

Many studies have shown that geopolymer concrete has physical and mechanical properties that are suitable for structural applications (4-6). In fact, the geopolymer concrete internally reinforced with steel bars has been successfully utilised in the construction of several civil infrastructures such as pavement, retaining walls, and bridges. However, in order to maximize its full potential for various structural applications especially in harsh environment, the corrosion of steel reinforcements must be avoided or must be eliminated, if possible, since this phenomenon results in geopolymer concrete cracking and spalling that can lead to early strength degradation and loss of serviceability of the structure before reaching its expected service life. Among the possible solutions that are being implemented to address this concern is to utilise fibre reinforced polymer (FRP) bars because, aside from being corrosion-resistant, these bars have high tensile strength, lightweight, high fatigue endurance, electromagnetic neutrality, and have low thermal and electrical conductivity (7).

With the advantageous properties of the geopolymer concrete and the FRP bars, their combination can be anticipated to yield a construction technology that is both more sustainable and more durable with adequate structural integrity. Limited studies, however, are available that deals with FRP-reinforced

geopolymer concrete and this has been the key motivation of this undertaking. This study presents an investigation of the flexural response of geopolymer concrete beams reinforced with sand-coated glass FRP (GFRP) bars subjected to four-point static bending test. Three full-scale beams with nearly same amount of bottom GFRP bars but with varying diameter were cast and tested. The crack patterns and failure modes, load versus deflection relationships, bending-moment and deflection capacities, and strains in the bars and geopolymer concrete are presented. Furthermore, the experimental flexural capacity of beams are compared with the predicted values using the current standards and with their GFRP-reinforced concrete (GFRP-RC) counterparts to verify the suitability of the proposed system for structural applications.

## 2. Experimental Program

### 2.1 Materials and test specimens

Three high modulus (HM) sand-coated GFRP bars with nominal diameters ( $d_b$ ) of 12.7 mm, 15.9 mm, and 19.0 mm were used to longitudinally reinforce the beams (Figure 1). The bars, as shown in Figure 1, were produced through the pultrusion process of E-Glass fibres impregnated in a thermosetting modified vinyl ester resin (Grade III, CSA S807-10 (8)). Table 1 summarises the physical and mechanical properties of the bars as provided by the manufacturer, including the guaranteed tensile strength ( $f_{tu}$ ) and elastic modulus ( $E_f$ ), computed based on the nominal area ( $A_f$ ), and the usable strain ( $\epsilon_{cu}$ ).

The geopolymer concrete used in the study was made up of fly ash and slag, fine and medium sands, 10 mm and 20 mm coarse aggregates, water, and alkaline liquid. Table 2 presents the mechanical properties of the geopolymer concrete. Based on the compression test of four 100 mm diameter by 200 mm high cylinders, the average 28-day compressive strength ( $f'_c$ ) and elastic modulus ( $E_c$ ) of the geopolymer concrete were 38 MPa and 38.5 GPa, respectively. Furthermore, the three-point static bending test of the three geopolymer concrete prisms (75 mm x 75 mm x 285 mm) yielded an average modulus of rupture ( $f_r$ ) of 3.86 MPa.

Three full-scale geopolymer concrete beams were cast and tested. The beams were longitudinally reinforced at the bottom with 4-12.7 mm, 3-15.9 mm, and 2-19.0 mm HM GFRP bars. Furthermore, each beam was provided with 2-12.7 top HM GFRP bars and 9.5 mm HM GFRP stirrups spaced at 100 mm on-center. The beams were 200 mm wide, 300 mm deep, and 3100 mm long and were designed as over-reinforced to achieve a concrete crushing failure mode. Figure 2 shows the beams' cross-sectional geometry and reinforcement details while Table 3 summarises the label and classification of each beam in accordance with their bottom longitudinal reinforcements. The actual and balanced reinforcement ratio ( $\rho_f$  and  $\rho_{fb}$ , respectively) were calculated using Equations 1 and 2. The terms  $\alpha_1$  and  $\beta_1$  were obtained from Equation 3 for ACI 440.1R-06 (9) and from Equation 4 for CSA S806-12 (10). These equations are summarised in Table 8. The maximum usable strain of the geopolymer concrete ( $\epsilon'_{cu}$ ) were assumed to be 0.003 and 0.0035 for ACI 440.1R-06 and CSA S806-12, respectively.

## 2.2 Test method and instrumentations

Figure 3 shows the schematic diagram of the four-point static bending test employed in the study. The beams were loaded at midspan with two concentrated loads spaced at 400 mm, yielding a shear span of 1100 mm on both sides. The load was applied using a 2000 kN capacity hydraulic jack at a rate of approximately 3 mm/min. The midspan deflection was measured using a Laser Optical Displacement (LOD) device. Furthermore, electrical strain gauges were attached to the top surface of the geopolymer concrete beam and in the top and bottom reinforcements to measure the longitudinal strains during loading. The loads and strain readings were captured using the System 5000 data logger.

**Figure 3. The four-point static bending test.**

### 3. Results and Discussion

#### 3.1 Experimental results

##### 3.1.1 Crack pattern and failure mode

All the tested beams were initially uncracked before loading. Then, several vertical cracks were formed along their constant bending-moment zone right after the applied load exceeded the geopolymer concrete tensile capacity. With further loading, these cracks became wider and propagated upward while new flexural cracks were developed on both shear spans of the beams. At higher loads, the vertical cracks within the pure bending zone further widen while the vertical cracks on both shear spans became more inclined due to the shear stresses. However, the rate of lengthening and widening of inclined cracks did not increase as the geopolymer concrete began to crush. At the final loading stage, few inclined cracks reached the crushed zone of the geopolymer concrete. Figure 4 shows the final crack patterns of the tested beams. Based on the figure, the cracks were almost uniformly distributed along the beam span with spacing of approximately 100 mm, similar to stirrups spacing. This observation demonstrated that a composite action existed between the GFRP bars and the geopolymer concrete, that is the stress is effectively transfer from geopolymer concrete to GFRP bars and vice versa, through the friction and mechanical interlock provided by sand-coats. No significant difference can be observed among the crack patterns of the beams.

Figure 5 depicts the typical failure mode of the tested beams. As expected, the over-reinforced beams failed in flexure through crushing of the geopolymer concrete in the compression zone. Gangarao et al. (7) reported that, generally, the preferred failure mode for any FRP reinforced concrete beam is the concrete crushing since this failure is more gradual, less brittle, and less catastrophic with higher deformability compared with the FRP tensile rupture. Thus, it can be concluded that the tested beams were designed satisfactorily and accordingly.

**Figure 6. Load-deflection response of the tested beams.**

### 3.1.2 Load-deflection response

Figure 6 shows the relationship between the applied load and the midspan deflection of the tested beams. Generally, their load-deflection curves can be divided into three segments. The first segment embodies the typical steep linear response of an uncracked beam, wherein the load increases linearly with midspan deflection. This section is similar for all beams no matter the amount and type of reinforcements, because at this stage, only the geopolymer concrete is sustaining all the applied loads. The second segment represents the cracked response of the beam. It is composed of a linear response with reduced slope, similar for all the tested beams, followed by a non-linear response up until the crushing failure of the geopolymer concrete in the compression zone. This non-linearity can be attributed to extensive cracking and crushing of the geopolymer concrete. Lastly, the third segment represents the post-failure response of the beam wherein the beam continued to sustain additional loads after the crushing failure of the geopolymer concrete, owed to the stirrup confinement effect that enhanced the ductility and strength of the beams. The slope of this segment is lower than the previous segment due to the initiation of failure in the GFRP bars.

The beams were loaded just before its final failure to avoid any mishaps during testing. The behaviour during load removal was also recorded. The unloading segment showed the inherent elastic characteristic of the beams at higher loads, even after exhibiting a nonlinear behaviour or even after the concrete crushing failure.

### 3.1.3 Bending-moment capacity

Table 4 summarises the experimental flexural capacity of the tested beams at geopolymer concrete cracking ( $M_{cr-exp}$ ), at service condition ( $M_{s-exp}$ ), at geopolymer concrete crushing failure ( $M_{u-exp}$ ), and at peak ( $M_{peak-exp}$ ). The  $M_{cr-exp}$  was determined based on the recorded load when the first flexural crack appeared and was verified from load-deflection and moment-strain plots of beams. The GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0 beams yielded nearly similar  $M_{cr-exp}$  values of 10.4 kN-m, 11.5 kN-m, and 11.9 kN-m, respectively. This can be expected since the  $M_{cr-exp}$  is mainly dependent on the geopolymer concrete properties. The marginal difference can be attributed to the nonhomogeneous and anisotropic properties of the geopolymer concrete. The average cracking moment and the corresponding modulus of rupture ( $f_r$ ) were 11.3 kN-m and 3.76 MPa, respectively. This value of  $f_r$  was comparable to that obtained from the bending test of geopolymer concrete prisms.

In this study, the suggested criteria by ISIS-06 (11) and Bischoff et al. (12) were used to identify the  $M_{s-exp}$  of the beams. The first benchmark defines the  $M_{s-exp}$  as the bending-moment value that

corresponds to a tensile-strain reading of 2000  $\mu\epsilon$  in the reinforcement, the specific strain value that limits the crack width to 0.7 mm and 0.5 mm for interior and exterior exposures, respectively, in any FRP-RC components. The second benchmark, on the other hand, approximates  $M_{s-exp}$  as 30% of a beam's ultimate capacity ( $0.3M_{u-exp}$ ). Based on these criteria, all the tested beams yielded comparable  $M_{s-exp}$  values except that of GFRP-RGC-3-15.9 beams at 2000  $\mu\epsilon$ .

The  $M_{u-exp}$  of GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0 were 96.1 kN-m, 104.8 kN-m, and 91.4 kN-m, respectively. These values were relatively comparable to each other, suggesting that the nominal diameter does not influence the beams' bending-moment capacity, mainly because the failure of these beams was governed by geopolymer concrete crushing failure and not by tensile rupture of the GFRP bars. The slight variation can be attributed to, again, the intrinsic composite characteristic of the geopolymer concrete. All the tested beams, however, continued to sustain further loads even after the crushing failure and yielded another peak bending-moment, owed to the confinement effect provided by GFRP stirrups located in the constant bending-moment zone. The  $M_{peak-exp}$  were 109.3 kN-m, 104.7 kN-m, and 110.1 kN-m for GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0, respectively. The 25 mm gap, between the beam and the load applicator, prior to load application resulted in a relatively lower  $M_{peak-exp}$  of GFRP-RGC-3-15.9 compared with the other beams. Thus, it can be further concluded that the nominal bar diameter have no significant effect on beam strength even after crushing failure.

**Table 4. Flexural capacity and failure mode of the tested beams.**

Beam	$M_{cr-exp}$ (kN-m)	$M_{s-exp}$ (kN-m)		$M_{u-exp}$ (kN-m)	$M_{u-theo}$ (kN-m) <sup>†</sup>		$M_{peak-exp}$ (kN-m)	Failure Mode
		2000 $\mu\epsilon$	0.30 $M_{u-exp}$		ACI 440.1R-06	CSA S806-12		
GFRP-RGC-4-12.7	10.4	27.2	28.8	96.1	71.5 [74%]	77.2 [80%]	109.3	Concrete crushing
GFRP-RGC-3-15.9	11.5	21.3	31.4	104.8	73.9 [71%]	79.7 [76%]	104.7	concrete crushing
GFRP-RGC-2-19.0	11.9	27.0	27.4	91.4	72.3 [79%]	78.0 [85%]	110.1	concrete crushing

<sup>†</sup> The number inside [ ] represents the ratio between  $M_{u-theo}$  and  $M_{u-exp}$

### 3.1.4 Midspan deflection

Table 5 shows the midspan deflection at service load level ( $\Delta_{s-exp}$ ), at geopolymer concrete crushing failure ( $\Delta_{u-exp}$ ), and at unloaded phase or residual deflection ( $\Delta_{res-exp}$ ) of tested beams. As discussed earlier, the serviceability performance of the beams was described based on ISIS-07 and Bischoff et al.'s suggestions. The recorded  $\Delta_{s-exp}$  based on ISIS (Bischoff) criterion were 10.6 mm (11.5 mm), 7.1 mm (12.3 mm), and 8.7 mm (8.8 mm) for GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0, respectively. It was evident from these results that the nominal bar diameter have no significant correlation on the serviceability performance of the beams since the measured  $\Delta_{s-exp}$  for each criterion was comparable to each other. Generally, all the tested beams satisfy the deflection limit set by the ACI 440.1R-06, which is equivalent to L/240 or 10.8 mm. However, the results showed that the serviceability design of a GFRP-RGC beam should be based on 0.3 $M_{u-exp}$  criterion since the estimated deflections based on this criterion were higher than that of ISIS. El-Nemr et al. (13) also adapted the same criterion for the serviceability design of FRP-RC beams.

The  $\Delta_{u-exp}$  of GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0 were 53.2 mm, 52.5 mm, and 43.4 mm, respectively. From these results, it can be concluded that the deflection behaviour of GFRP-RGC beam is not dependent on the bar diameter. All the tested beams yielded similar  $\Delta_{res-exp}$  values, having an average of 14.3 mm. This magnitude of residual deflection shows the inherent elastic behaviour of the GFRP-RGC beams at higher loads, even after the crushing failure of the geopolymer concrete.

**Table 5. Midspan deflection of the tested beams.**

Beam	$\Delta_{s-exp}$ (mm)		$\Delta_{s-theo}$ (mm) <sup>†</sup>		$\Delta_{u-exp}$ (mm)	$\Delta_{u-exp}$ (mm) <sup>†</sup>		$\Delta_{res-exp}$ (mm)
	2000 $\mu\epsilon$	0.30 $M_{u-exp}$	2000 $\mu\epsilon$	0.30 $M_{u-exp}$		ACI 440.1R-06	CSA S806-12	
GFRP-RGC-4-12.7	10.6	11.5	7.4	8.2	53.2	36.3	35.3	15
GFRP-RGC-3-15.9	7.1	12.3	3.6	8.3	52.5	36.3	35.7	14
GFRP-RGC-2-19.0	8.7	8.8	6.6	6.8	43.4	32.9	32.9	14

<sup>†</sup>Based on ACI 440.1R-06

**3.1.5 Strain in the longitudinal reinforcement and geopolymer concrete**

Figure 7 shows the moment-strain relationships of the tested beams. Analogous moment-strain curvatures occurred among top bars (TB), bottom bars (BB), and geopolymer concrete (GC). Furthermore, the top and bottom reinforcements yielded trilinear curves, similar to the load-deflection curve, while the geopolymer concrete only yielded a bilinear curve because the strain gauge attached on geopolymer concrete’s top surface did not provide further readings after its crushing failure. These observations tend to show that no slippage occurred during the test, thereby demonstrating the effectiveness of anchoring the GFRP bars in geopolymer concrete using sand-coatings.

Table 6 shows the strain readings at service condition based on 0.3  $M_{u-exp}$ , at geopolymer concrete crushing failure, and at peak. The strains at bottom bars were all greater than 2000  $\mu\epsilon$ , showing the appropriateness of using Bischoff’s criterion for the GFRP-RGC beam serviceability design. On other hand, the maximum usable strain in the geopolymer concrete reached a magnitude of 4831  $\mu\epsilon$  that is higher than those normally assumed in ACI 440.1R06 and CSA S806-12 standards. The peak tensile strain at the bottom bars were just 79 %, 79 %, and 86 % of the bars’ tensile capacity for GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0, respectively. All the tested beams yielded nearly comparable strains at different load stages that further verified that bar diameter have no significant effect on the flexural performance of the GFRP-RGC beam.

**Figure 7. Moment-strain relationships of the tested beams.**

**Table 6. Strains in geopolymer concrete (GC), top bars (TB), and bottom bars (BB).**

Beam	At service condition ( $\mu\epsilon$ )			At failure ( $\mu\epsilon$ )			At peak ( $\mu\epsilon$ )	
	GC	TB	BB	GC	TB	BB	TB	BB
GFRP-RGC-4-12.7	348	247	2147	4831	2327	11547	9271	15746
GFRP-RGC-3-15.9	698	156	3508	2934	2115	12244	11083	14956
GFRP-RGC-2-19.0	502	203	2028	4226	2086	10855	11186	14963

<sup>†</sup>Based on ACI 440.1R-06

### 3.2 Theoretical Prediction

Table 7 shows the summary of the equations, suggested by ACI 440.1R-06 and CSA S806-12 standards, used in the study. The theoretical flexural capacities of the beams at geopolymer concrete crushing failure ( $M_{u-theo}$ ) were computed using Equation 5 and were summarized in Table 4. The stress in the bar ( $f_f$ ) was calculated from Equation 6 for ACI 440.1R-06 and from Equation 7 for CSA S806-12, where the neutral axis  $c$  was determined from Equation 8. The  $M_{u-theo}$  based on ACI 440.1R-06 were 71.5 kN-m, 73.9 kN-m, and 72.3 kN-m for GFRP-RGC-4-12.7, GFRP-RGC-3-15.9, and GFRP-RGC-2-19.0, respectively, while CSA S806-12 yielded 77.2 kN-m, 79.7 kN-m, and 78.0 kN-m, respectively. Generally, the prediction equations underestimated the flexural capacity of the tested beams due to several factors. First, the  $\varepsilon'_c$  used in the prediction, such as 3000  $\mu\varepsilon$  for ACI 440.1R-06 and 3500  $\mu\varepsilon$  for CSA S806-12, were lower compared with the actual strain that can reach a value of 4831  $\mu\varepsilon$ . Second, the flexural contribution of top GFRP bars was neglected in both equations. Finally, the confinement effect due to later ties provided in the pure bending-moment zone were not considered. By comparing the two standards, the CSA S806-12 yielded more accurate results than the ACI 440.1R-06.

The predicted midspan deflection at service condition ( $\Delta_{s-theo}$ ) and at geopolymer concrete crushing failure ( $\Delta_{u-theo}$ ) were shown in Table 5. These values were calculated from Equations 9, 10, and 11 for ACI 440.1R-06 and from Equations 12 and 13 for CSA S806-12. The computed  $\Delta_{s-theo}$  and  $\Delta_{u-theo}$  were lower than their actual deflection counterparts. The underestimation, however, was more evident at higher applied loads, owing to the overestimation of the tension stiffening parameter.

**Table 7. Summary of equations used for theoretical predictions.**

ACI 440.1R-06	CSA S806-12
$\rho_f = A_f/bd$	(1)
$\rho_f = \alpha_1 \beta_1 \frac{f'_c}{f_{fu}} \frac{E_f \varepsilon'_c}{E_f \varepsilon'_c + f_{fu}}$	(2)
$\alpha_1 = 0.85$ (3a)	$\alpha_1 = 0.85 - 0.0015 f'_c \geq 0.67$ (4a)
$\beta_1 = 0.85 - \frac{0.05(f'_c - 27.6)}{6.9}$ (3b)	$\beta_1 = 0.85 - 0.0025 f'_c \geq 0.67$ (4b)
$M_{u-theo} = \rho_f f_f b d^2 \left( 1 - \frac{\rho_f f_f}{2\alpha_1 f'_c} \right)$	(5)
$f_f = \sqrt{\frac{(E_f \varepsilon'_{cu})^2}{4} + \frac{0.85 \beta_1 f'_c}{\rho_f} E_f \varepsilon'_{cu}} - 0.5 E_f \varepsilon'_{cu} < f_{fu}$ (6)	$f_f = A_f E_f \frac{\varepsilon'_{cu} (d-c)}{c} < f_{fu}$ (7)
	$\alpha_1 \beta_1 f'_c b c - A_f E_f \frac{\varepsilon'_{cu} (d-c)}{c} = 0$ (8)
$\Delta = \frac{(Pa/2)}{24E_c I_e} [3L^2 - 4a^2]$ (9)	$\Delta = \frac{(P/2)L^3}{24E_c I_{cr}} \left[ 3\frac{a}{L} - 4\left(\frac{a}{L}\right)^3 - 8\eta \left(\frac{L_g}{L}\right)^3 \right]$ (12)
$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 \beta_d I_g + \left[ 1 - \left(\frac{M_{cr}}{M_a}\right)^3 \right] I_{cr} \leq I_g$ (10)	$\eta = 1 - \frac{I_{cr}}{I_g}$ (13)
$\beta_d = 0.2 \left( \frac{\rho_f}{\rho_{fb}} \right) \leq 1.0$ (11)	

### 3.3 Comparison between GFRP-RGC and GFRP-RC beams

Table 8 shows the comparison between the normalized flexural capacity of GFRP-RGC and GFRP-RC beams. The GFRP-RC beams that were considered in the study have nearly similar dimensions, concrete strengths, and amount and type of reinforcements. In general, the bending-moment capacities of the tested beams (GFRP-RGC beams) were higher than the GFRP-RC beams owing to the enhanced mechanical properties of the geopolymer concrete compared with normal concrete, the provision of lateral ties within the constant bending-moment zone that provided confinement, and the higher tensile properties of GFRP bars used in this study compared with the previous ones.

**Table 8. Flexural capacity of GFRP-RGC and GFRP-RC beams.**

Reference	Beam	$\rho_f$ (%)	$M_u / f_c b d^2$
Current Study	GFRP-RGC-4-12.7	1.13	47.7
	GFRP-RGC-3-15.9	1.18	54.3
	GFRP-RGC-2-19.0	1.00	49.6
Toutanji and Saafi (14)	GB3-1	1.10	44.6
	GB3-2	1.10	47.3
Benmokrane et al. (15)	ISO1	1.10	35.1
	ISO2	1.10	36.7
Benmokrane et al. (16)	ISO30-2	1.01	35.9

## 4. Conclusions

The flexural response of geopolymer concrete beams reinforced with GFRP bars (GFRP-RGC beams) was investigated using a four-point static bending test. Based on the experimental results, the following conclusions were made:

- Nearly similar cracking pattern, load-deflection response, bending-moment and deflection capacities, and strain readings were obtained from all the tested beams. These results tend to show that the flexural performance of a GFRP-RGC beam is not dependent on the nominal diameter of the bottom longitudinal reinforcements.
- The uncracked and cracked response of the beams were relatively comparable since the strength of the beam mainly depends on the geopolymer concrete strength.
- The serviceability design criterion suggested by Bischoff et al. ( $0.3MU_{-exp}$ ) is more appropriate in designing a GFRP-RGC beam.
- The prediction equations recommended by ACI 440.1R-06 and CSA S806-12 underestimated the flexural and deflection capacities of the tested beams, suggesting that new prediction must be developed for a GFRP-RGC beam.
- The strength of GFRP-RGC beam is generally higher than that of GFRP-RC beam, indicating that the GFRP-RGC can be adapted for different structural applications; however, additional studies must be conducted to increase the approval of the proposed technology in the construction industry.

**Abstract:** The behaviour at service conditions of a reinforced concrete member is highly dependent on the deformational properties of the materials, the extent of cracking, the creep and shrinkage deformations in the concrete and the magnitude and distribution of the applied loads. This paper presents initial measurements of an experimental study carried out on two simply-supported and three continuous reinforced concrete slabs aimed at evaluating the variation over time of the instantaneous flexural stiffness induced by time-dependent cracking. For this purpose, a particular loading device has been set-up based on the use of water tanks to provide different levels of sustained loads and to load/unload the sample in a short time (to simulate instantaneous loads). The long-term measurements have been recorded to provide insight into the influence of creep and shrinkage effects on the time-dependent response of the slab. Relative humidities have been measured through the thickness of the concrete samples to gain more insight into the development of drying shrinkage. It is envisaged that this experimental data represents valuable information for the calibration and validation of numerical and design models incorporating shrinkage effects for reinforced concrete slabs.

**Keywords:** Concrete, Creep, Instantaneous stiffness, Relative humidity, Shrinkage, Slabs.

## 1. Introduction

Reinforced concrete construction is widely used for building applications. Typical floor systems consist of statically indeterminate continuous reinforced concrete slabs. In the case of building floors, their design is usually governed by serviceability limit state requirements and their behaviour depends on the deformational properties of the materials, the extent of cracking, the creep and shrinkage deformations in the concrete, and the magnitude and distribution of the applied loads at service conditions. Typical slab systems used in Australia are lightly reinforced and their service loads induce maximum moments close to their cracking moments, therefore inducing cracking to develop over time (1, 2). Under these conditions, the flexural stiffness might reduce over time as highlighted from experimental measurements performed on reinforced concrete beams (3).

In this context, this paper presents initial measurements recorded as part of an experimental study aimed at investigating the time-dependent behaviour of lightly reinforced concrete slabs. In particular, two simply-supported and three continuous reinforced concrete slabs were prepared and tested subjected to different levels of instantaneous and sustained loads. A particular loading arrangement was devised to load the specimens by means of water pumped in and out from tanks placed on the samples, and its details are outlined in the following. All slab specimens were instrumented to monitor the instantaneous stiffness and time-dependent deformations. Separate concrete samples were prepared to measure the occurrence of shrinkage through the thickness of the slab considering different drying conditions for the slab surfaces. Relative humidity measurements were carried out on both reinforced and plain concrete samples to gain insight into the development and profile of drying shrinkage.

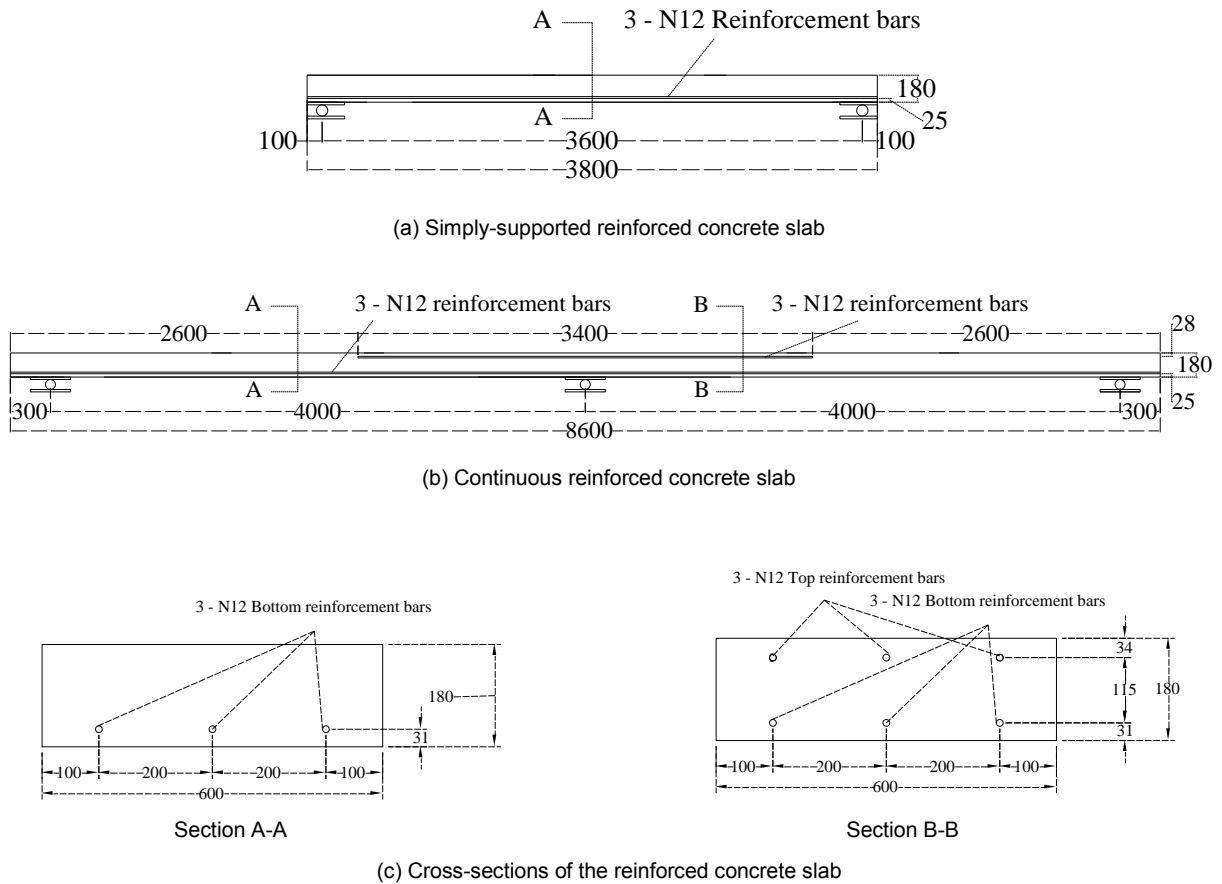

## 2. Experimental Program

### 2.1 Preparation of specimens

Two simply-supported and three continuous reinforced concrete slabs were prepared as part of this experimental program.

The simply-supported specimens had an overall length of 3800 mm and cross-sectional dimensions of 600 mm × 180 mm, as illustrated in Figure 1(a). Three N12 reinforcement bars were placed in a single layer at the bottom of the slab at a spacing of 200 mm. The continuous samples possessed identical geometric properties, with overall length of 8600 mm and rectangular cross-section of 600 mm × 180 mm. Samples were continuous over two equal spans of 4000 mm with an end outstand of 300 mm. Three N12 reinforcing bars were specified at the bottom of the slab and three N12 reinforcing bars were placed at the top of the slab over interior supports in the longitudinal direction with a transverse spacing of 200 mm, as shown in Figure 1(b). The tensile reinforcement ratio was about 0.4% for both simply-supported and continuous slabs.

The geometric characteristics and loading conditions adopted in the experiments are summarised in Table 1. All slab samples were wet cured for 7 days from the day of casting and then subjected to drying.

**Figure 1. Dimensions and reinforcement details for all specimens (all units in mm).**

**Table 1. Different geometric characteristics and loading conditions for reinforced concrete slabs.**

Type of Sample	Sample ID	Dimensions (mm) (Length × width × thickness)	Distance between supports (mm)	Instantaneous Load/Span (kN)	Sustained Load/Span (kN)
Simply-supported reinforced concrete slab	SS1	3800 × 600 × 180	3600	5	0
	SS2			5	5
Continuous reinforced concrete slab	CS1	8600 × 600 × 180	4000	5 followed by 10	10
	CS2			5 followed by 10	0
	CS3			5	0

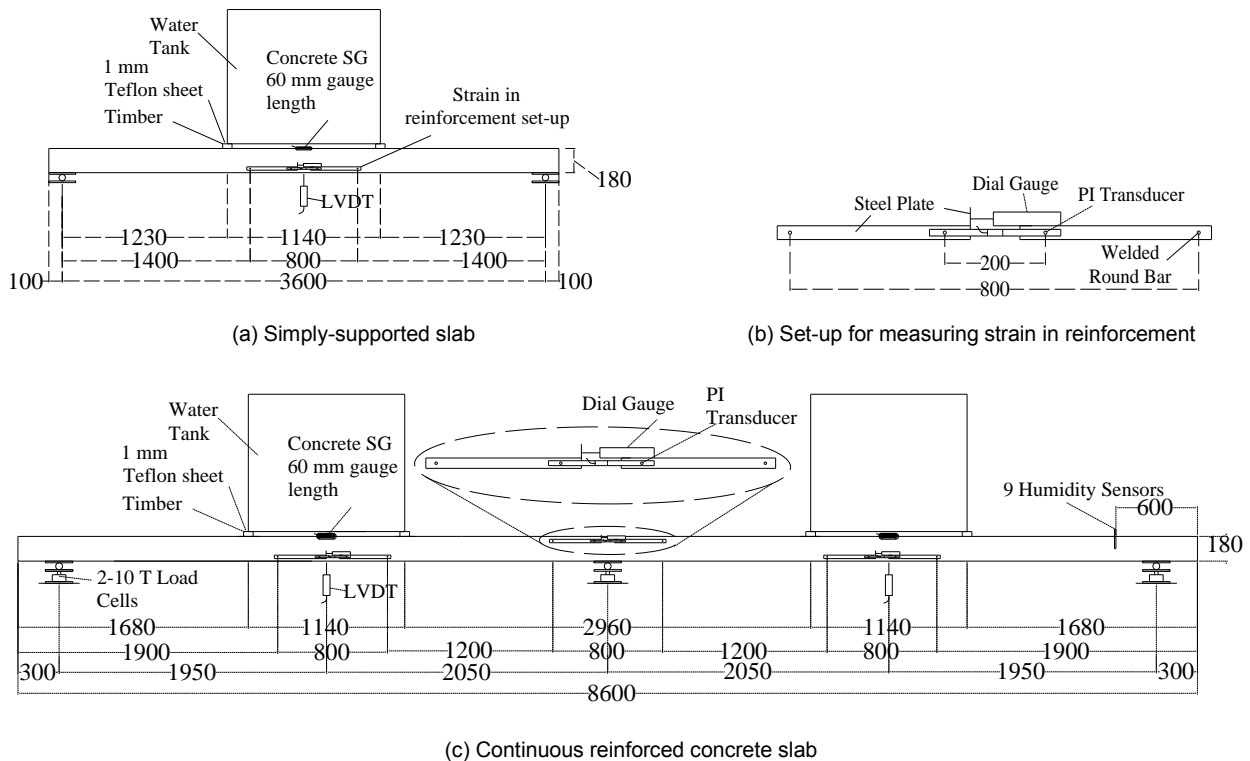

Material properties related to shrinkage were collected from four square plain concrete slabs cast with the same concrete mix of the reinforced concrete samples. These plain concrete slabs had dimensions of 600 mm × 600 mm × 180 mm to match the width and thickness of the reinforced concrete slab samples. Similar to the reinforced concrete slabs, shrinkage slabs were also wet cured for 7 days after the day of casting and then air dried. After curing, two shrinkage slabs, namely SH1 and SH2, were covered on their edges with moisture barrier paint to reproduce the continuity which the slab would have in a real floor system. Bottom surface and all four edges of other two shrinkage slabs, denoted as SH3 and SH4, were also covered with moisture barrier paint to obtain the non-uniform shrinkage distributions that would develop in a slab when its underside is sealed, as it would be the case in a composite floor. Exposure conditions specified for the shrinkage slabs are presented in Table 2.

**Table 2. Shrinkage slabs with different exposure conditions.**

Type of Sample	Sample ID	Dimensions (mm) (Length × width × thickness)	Exposure conditions: Top/Bottom Surface
Shrinkage slab	SH1	600 × 600 × 180	Exposed/Exposed
	SH2		
	SH3		Exposed/Covered with moisture barrier paint
	SH4		

## 2.2 Instrumentation

All samples were instrumented to measure deflections, strains in the concrete and reinforcement, and reactions during the experiment as shown in Figure 2. Mid-span deflections of the reinforced concrete slabs were measured by means of LVDTs. Concrete strain gauges were attached at mid-span to the top surfaces of the slabs while load cells were placed at support locations to monitor the reactions of the continuous reinforced concrete slabs over time. Average strains in the reinforcement bars were monitored with an 800 mm gauge length at mid-span for both continuous and simply-supported slabs, and over interior support locations for the continuous samples. These measurements were carried out using both dial gauges and PI transducers as shown in Figure 2.

**Figure 2. Schematic diagram of instrumentation for all samples (all units in mm).**

Changes in relative humidity over the thickness of the slabs were measured over the time. Relative humidities were measured at 3, 5, 10, 15, 25, 35, 50, 70 and 90 mm depths from the top surface of each reinforced concrete slab and of two shrinkage slabs with top and bottom surfaces exposed to drying (SH1 and SH2). Relative humidities were measured at 3, 5, 10, 15, 25, 35, 50, 70, 90, 110, 130, 145, 155, 165, 170, 175 and 177 mm depths from the top of surface of other two shrinkage slabs (SH3 and SH4). Perspex tubes with cut at desired depths were held at position before casting to form holes inside the concrete as shown in Figure 3. Aluminum round bar with diameter slightly less than the inner diameter of Perspex tube was inserted to the Perspex tube to prevent the concrete flowing into the tube during casting. After few hours from casting, the aluminum bars were removed from the tube and the top of the tube was then sealed. All humidity sensors were inserted into the Perspex tubes after the end of curing and the tubes were then sealed with a silicon tape.

(a) Before casting

(b) After casting

**Figure 3. Set-up for the relative humidity measurements.**

### **2.3 Loading Arrangement**

The devise used for the loading and unloading of the slabs is outlined in this section. At the beginning of the tests, empty tanks were placed on top of the slabs. Double layers of 1 mm Teflon sheets were used between the water tank and timber supports to minimise the restraint during deformations, therefore avoiding the possible longitudinal restraint to the slab provided by the water tank frame. Details of the positions and dimensions of the water tanks are illustrated in Figure 2.

The loading and unloading was performed by pumping water into the loading tanks placed on top of the slab from the storage tank and vice-versa, respectively, as shown in Figure 4. With the adopted pump arrangement, the loading/unloading rate was about 4 kN/minute for each tank which was considered acceptable to represent typical instantaneous loads. The same arrangement was implemented to apply the sustained loads on the slab.

Figure 4. Loading/unloading arrangement using water tanks.

## 2.4 Testing Procedure

After curing, all continuous slab samples were unpropped and simply-supported slabs were placed in their simply-supported configuration and, therefore, were subjected to their self-weight and to shrinkage effects (Figure 5). After six weeks from casting, all samples were subjected to instantaneous loads to develop different level of cracking and to determine the stiffness of the slabs at that instant of time as shown in Figure 6. During the instantaneous tests, three loading/unloading cycles were applied for each sample. The levels of instantaneous loads applied during the tests are summarised in Table 1.

For the long-term tests, the slabs were monitored to evaluate the long-term deformations produced by different levels of sustained load and due to shrinkage. Different levels of sustained load for each sample are summarised in Table 1.

## 3 Material Properties and Environmental Conditions

### 3.1 Instantaneous Material Properties

All samples were cast from the same batch of ready-mixed concrete. Standard compressive strength tests and indirect tensile strength tests were carried out by testing standard cylinders of 150 mm diameter and 300 mm height. Average compressive and tensile strengths of concrete were 41.0 and 3.1 MPa, respectively, at 29 days from the day of casting. Average compressive and tensile strengths of concrete during the first application of external loading were 45.1 and 3.2 MPa, respectively, at the seventh week from casting. The measured yield and tensile ultimate strengths for the steel reinforcement were 590 MPa and 659 MPa, respectively.

### 3.2 Shrinkage and Relative Humidity Measurements

Free drying shrinkage was measured from the shrinkage slabs. Demec targets with 200 mm gauge length were attached on the top and bottom surfaces of the shrinkage slabs. To facilitate measuring the shrinkage strains at the top and bottom surfaces, all shrinkage slabs were placed in vertical position supported on three rollers (shown in Figure 7) after being cast horizontally.

The shrinkage strains of shrinkage slabs SH1 and SH2 (with top and bottom surfaces exposed to drying), and SH3 and SH4 (only top surfaces exposed to drying) are shown in Figure 8(a) and (b), respectively.

Figure 5. Reinforced concrete slabs subjected to only self-weight.

(a)

(b)

Figure 6. Reinforced concrete slabs with applied loading.

Figure 7. Shrinkage slabs in vertical position.

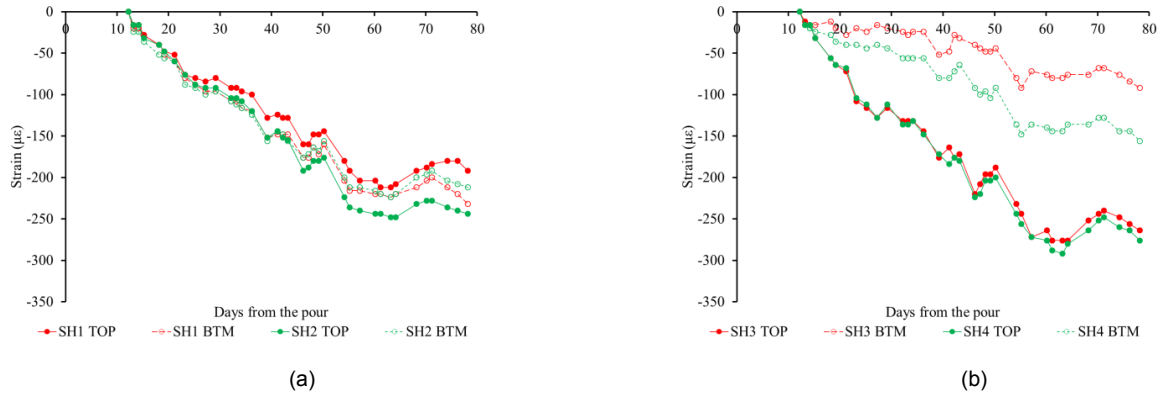

Figure 8. Shrinkage strains measured over time on shrinkage slab samples.

Over time, samples SH1 and SH2 experienced similar shrinkage values at the top and bottom surfaces, while samples SH3 and SH4 exhibited higher shrinkage strains at the top surface than that of the bottom surface because of the presence of moisture barrier paint at the bottom surface. This is consistent with previous work carried out on composite slabs by the authors (4, 5, 6, 7) and with the relative humidity profiles measured in the samples, highlighting the significance of the drying shrinkage component. Typical relative humidity profiles measured through the slab depths at different instants in time for the reinforced concrete slab and shrinkage slab samples are depicted in Figure 9.

### 3.3 Environmental Conditions

The samples were kept in a laboratory environment where the relative humidity and temperature were not controlled, and their variations are presented in Figure 10.

Figure 9. Representative measurements showing the variations in relative humidity over the cross-section taking place over time.

Figure 10. Ambient relative humidity and temperature over time.

#### 4. Test Results

The instantaneous and total deflections at mid-span for the two simply-supported slabs are shown in Figure 11(a) and (b), respectively.

Deflections measured at mid-span of all continuous slabs during instantaneous tests are plotted in Figure 12. During the tests, deformations at both adjacent spans were similar reflecting the symmetric behaviour of the geometry and loading conditions of the samples.

The loading/unloading cycles applied during the instantaneous tests for both simply-supported and continuous slabs exhibited an overall constant stiffness following an initial softening effect attributed to the formation of cracking. From Figure 11(a), comparing the slope of the load-deflection curves of the two simply-supported slabs, it can be observed that both specimens had similar stiffness at that time. Similarly, Figure 12(a) also confirms that all continuous slabs possessed similar stiffness at the time of the instantaneous tests.

In Figure 13, comparison between the total mid-span deflections of all continuous slabs is presented. Both instantaneous and long-term components of deflection are included in Figure 13. All samples exhibited similar deflections over time until the application of the instantaneous load. After that point of time, sample CS2 exhibited a similar incremental deflection as CS3 despite its higher instantaneous loading. After the application of the sustained load, sample CS1 showed higher deflection than that of other two samples due to creep produced by the application of the external sustained load.

Figure 11. Mid-span (a) instantaneous and (b) total deflections for simply-supported slabs.

Figure 12. Mid-span load-deflection curves up to (a) 5 kN and (b) 10 kN for continuous slabs.

Figure 13. Mid-span deflections over time including both instantaneous and long-term components for continuous slabs.

## 5. Conclusions

This paper presented preliminary results of a series of tests carried out on two simply-supported and three continuous reinforced concrete slabs aimed at evaluating the change in flexural stiffness over time induced by cracking due to the effect of shrinkage and different levels of loads. A particular loading arrangement was set-up for applying different levels of sustained loads on the slabs and also to load/unload the specimens to investigate the stiffness of the slab at different instants of time.

Two different levels of instantaneous loadings were applied on the slabs before applying sustained loads by using the loading arrangement based on water tanks. From these tests, it was observed that all the slab samples showed an initial softening effect attributed to cracking followed by an overall constant stiffness during the instantaneous loading/unloading cycles. The load-deflection curves confirmed that both simply-supported and continuous slabs had similar instantaneous stiffness at that instant of time.

After the instantaneous tests, two continuous and one simply-supported slab samples were maintained unloaded and subjected to only their self-weight, while one simply-supported slab and one continuous sample were loaded with external sustained load (applied with water). These samples are currently being monitored to observe their long-term behaviour. First three months of readings were presented in the paper which showed that all three continuous slab samples exhibited similar deformations over time until the application of external loading and, after that, the sample with the sustained load exhibited higher deformations than the other two continuous samples because of the additional sustained load and its associated creep.

The development of shrinkage deformations taking place through the slab thickness was monitored considering different drying conditions applied to the slab surfaces. A qualitative overview of the variation of the drying shrinkage component over time was observed from the relative humidities measurements collected through the thickness of the slabs.

The long-term experiments presented in this paper are expected to continue in coming months and it is envisaged that these results will provide valuable benchmark data for the calibration and validation of numerical and design models.

**Abstract:** The fatigue resistance of concrete declines in saturated conditions, such as in water, more quickly than it does under air-drying conditions. In addition, the compressive strength of concrete increases under low-temperature conditions. However, little research has been conducted on the influence of moisture conditions and environmental temperature on the fatigue resistance of concrete in low-temperature conditions. In this study, the fatigue resistance of concrete cylindrical samples under compression is investigated by means of a static loading test and a fatigue test. The experimental results show that the statically compressive strength decreases in normal temperature while the moisture content increases. On the other hand, the statically compressive strength increases in low temperatures. The test results show that the fatigue resistance of concrete decreases under wet conditions in normal temperatures and in low temperatures.

**Keywords:** fatigue resistance, environmental temperature, moisture content, compressive stress.

## 1. Introduction

The fatigue resistance of reinforced concrete members is influenced by both the fatigue strength of the steel reinforcing bars and the concrete. Concrete fatigue resistance is greatly dependent on the prevailing moisture conditions, for example, fatigue resistance decreases underwater more than in dry conditions especially (1). In addition, the compressive strength of concrete increases in low-temperature conditions, meaning that it is influenced by the environmental temperature (2). However, there have been few investigations into the influence of low temperatures and moisture conditions on the fatigue resistance of concrete. In this study, the fatigue resistance of concrete cylindrical samples is investigated by means of fatigue tests.

## 2. Experimental procedures

### 2.1 Mixture proportion

The water–cement (W/C) ratio of the test samples was 0.69. Thus, the water content of the mix ratio was 170 kg/m<sup>3</sup>. The target compressive strength of the concrete at the age of starting the load test was 24 MPa. Table 1 shows the mix proportions of concrete.

### 2.2 Test procedure

In this study, loading test types, environmental temperature, and moisture conditions were investigated as test variables. The following parameters were recorded: type of loading test carried out, static (S) and fatigue (F); environmental temperature, normal temperature (N) and low temperature (L, -20°C); and moisture conditions, dry and saturation. Table 2 lists the experimental conditions.

**Table 1. Mix proportions of concrete.**

G <sub>max</sub> (mm)	W/C	Air content	s/a (%)	Unit content (kg/m <sup>3</sup> )					
				W	C	S	G	Additives	
								Ad	AE
20	0.69	0.045	0.48	170	246	899	1000	3.696	0.004

Each specimen is 75 mm in diameter and 150 mm in length. Concrete samples were cured in water for 7 days.

In the loading tests, a static test and a fatigue test were conducted on specimens of the same age under identical environmental temperature and moisture conditions.

The cyclic range of fatigue load applied to the specimens determined 70% and 10% of the maximum compression stress from the static compressive strength test. The load, compressive strain, and number of load cycles were measured during the load test.

The saturated condition (S) defined the convergence of increase of mass by water absorption. The dry condition (d2) reduced the amount of water content to 0.75 from the saturated condition; and the dry condition (d1) was an air-drying condition with a water content of about 0.5. The moisture contained in the concrete was prevented from evaporating by sealing the surfaces of the samples with a layer of wax. Figure 1 shows the experimental setup used in this study.

**Table 2. Experimental conditions.**

Figure 1. Experimental setup for low temperatures.

### 3. Results and discussion

#### 3.1 Compressive strength

Figure 2 shows the results of the compressive strength for different specimens. In normal temperature cases (N), the compressive strength for conditions d1, d2, and s are 28.6 MPa, 22.3 MPa, and 23.2 MPa, respectively. The compressive strength is seen to weaken as the water content increases. On the other hand, in low-temperature cases (L), the compressive strength for conditions d1, d2, and s are 27.3 MPa, 36.7 MPa, and 42.3 MPa, respectively. The compressive strength of s is 1.5 times higher than that of d1. This trend of increasing compressive strength under low-temperature conditions has been noted in past studies (2).

Figure 2. Results of compressive strength.

### 3.2 Fatigue resistance

Figure 3 shows the number of load cycles as the result of fatigue tests. The number of load cycles varied widely. In full consideration of this wide variation, the fatigue failure point is 16,150 for N-d1, 17,300 to 118,520 for N-d2, and 100 to 2,780 for N-s. In comparison with N-d1, it is not seen that the number of load cycles is less for N-d2 than for N-d1. For L-d1, the fatigue life was 17,000. Therefore, N-d1 and L-d1 were almost equivalent in terms of the number of cycles to fatigue failure. However, L-d2 endured 2,700 load cycles, and L-s underwent an average of 3,750 load cycles. This fatigue at low temperature indicates that concrete with a high water content has a reduced fatigue failure point compared with N-d1. In the experiments, the lowest fatigue durability was recorded for L-s, which had a remarkably higher static compressive strength than N-s. Thus, in terms of fatigue load under low temperature, it is possible that the fatigue failure process has a different mechanism than for normal temperature or underwater.

Figure 3. Number of load cycles to fatigue failure.

Figure 4 shows the relation between maximum compressive strain and the number of load cycles for (a) normal temperature and (b) low temperature. The compressive strain for the initial fatigue load was dispersion. The compressive strain showed a similar trend between L-d1 and N-d1. Thus, the results obtained show that the d1 case was not influenced very much by environmental temperature. In the d2 and s cases, the compressive strain was approximately 700  $\mu$  for normal-temperature conditions, and approximately 1000  $\mu$  for low-temperature conditions. The strains were basically classified by environmental temperature conditions such as the same maximum stress ratio. This tendency of compressive strain under normal-temperature conditions gradually increased toward fatigue failure with an increase in the number of load cycles. On the other hand, compressive strain under low-temperature conditions indicates that it increases rapidly just before fatigue failure. The results show that the stiffness of concrete was improved due to a freezing effect when moisture is present in concrete. However, this fatigue indicates that frozen concrete has a reduced fatigue durability compared with ordinary concrete without moisture.

(a) Results under normal temperature

(b) Results under low temperature

Figure 4. Relation between maximum compressive strain and number of load cycles.

#### **4. Conclusions**

The following conclusions were reached in this study.

- 1) The experimental results indicated that static compressive strength is reduced when the moisture content is increased under normal-temperature conditions. However, it increased under low-temperature conditions.
- 2) The fatigue durability of concrete by compressive stress was reduced when the moisture conditions are saturation at normal temperature and high moisture content at low temperature.

# An Approach for the Quantification of Ductility and Robustness of Reinforced Concrete Beams and Slabs

R. Ian Gilbert<sup>1</sup>, Stephen Foster<sup>2</sup> and Ankit Agarwal<sup>2</sup>  
<sup>1</sup>Emeritus Professor, <sup>2</sup>Professor and <sup>3</sup>Research Associate  
Centre for Infrastructure Engineering and Safety,  
School of Civil and Environmental Engineering, UNSW Australia

**Abstract:** Ductility is the ability of a structure or structural member to undergo large plastic deformations without significant loss of load carrying capacity. AS3600-2009 states that structures should be designed to be robust, but qualitative statements rather than quantitative recommendations are made. To design a concrete structure for robustness, a quantitative measure of ductility is required. In this paper, design guidance is given for the design and detailing of robust structures and a method is proposed whereby ductility and robustness of reinforced and prestressed concrete beams and slabs are quantified based on the ratio of internal energy absorbed by the structure before and after the formation of the first plastic hinge. Guidance is also provided on how to calculate the rotation at a plastic hinge and how much rotation is required to provide ductile and robust behaviour in a given situation.

**Keywords:** beams, ductility, elastic energy, plastic energy, plastic hinge, reinforced concrete, robustness, slabs.

## 1. Introduction

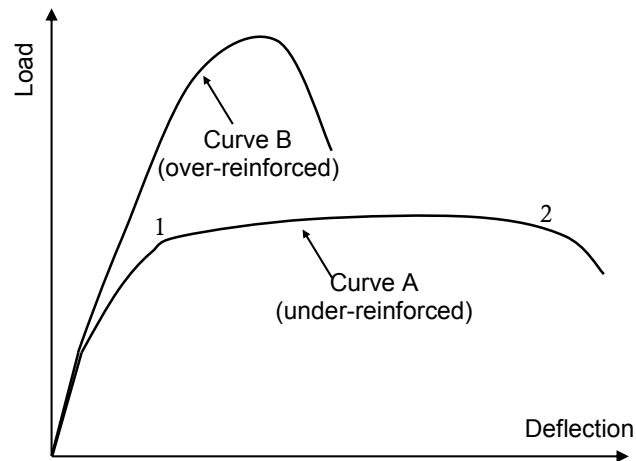

Ductility is the ability of a structure or structural member to undergo large plastic deformations without significant loss of load carrying capacity. Ductility is important for many reasons. It provides indeterminate structures with alternative load paths and the ability to redistribute internal actions as the collapse load is approached. Ductility is the reason why elastic analysis can be used to determine the internal actions in a statically indeterminate concrete structure. After the on-set of cracking, concrete structures are non-linear and inelastic. The stiffness varies from location to location depending on the extent of cracking and the reinforcement/tendon layout. In addition, the stiffness of a particular cross-section or region is time-dependent, with the distribution of internal actions changing under service loads due to creep and shrinkage, as well as other imposed deformations such as support settlements and temperature changes and gradients. All these factors cause the actual distribution of internal actions in an indeterminate structure to deviate from that assumed in an elastic analysis based on uniform stiffness.

Despite these difficulties, codes of practice, including AS3600-2009 (1), permit the use of elastic analysis based on uniform stiffness for the design of concrete structures at the strength limit state. This is quite reasonable provided the critical regions possess sufficient ductility (plastic rotational capacity) to enable the actions to redistribute towards the calculated elastic distribution as the collapse load is approached. If critical regions have little ductility (such as in over-reinforced elements) the member may not be able to undergo the necessary plastic deformation and the safety of the structure could be compromised.

Ductility is also important to resist impact and cyclic loading, and to provide robustness. With proper detailing, ductile structures can absorb the energy associated with sudden impact (as may occur in an accident or a blast) or cyclic loading (such as a seismic event) without collapse of the structure. With proper detailing, ductile structures can also be designed to resist progressive collapse.

Figure 1 shows the load-deflection curves for two reinforced concrete beams, one under-reinforced (Curve A) and one over-reinforced (Curve B). Curve A indicates ductile behaviour with large plastic deformations developing as the peak load is approached. The relatively flat post-yield plateau (1-2) in Curve A, where the structure deforms while maintaining its full load carrying capacity (or close to it) is characteristic of ductile behaviour. Curve B indicates non-ductile or brittle behaviour, with relatively little plastic deformation before the peak load. There is little or no evidence of a flat *plastic plateau* as the peak load is approached and the beam immediately begins to unload when the peak load is reached.

Structures with load-deflection relationships similar to Curve B in Figure 1 are simply too brittle to perform adequately under significant impact or seismic loading and they cannot resist progressive collapse. Reinforced and prestressed concrete beams can be designed to be robust and not to suddenly collapse when overloaded, but ductility is the key and a ductile load-displacement relationship such as that shown

**Figure 1. Ductile and non-ductile load-deflection curves.**

as Curve A in Figure 1 is an essential requirement. AS3600-2009 (1) states that structures should be designed to be robust, but qualitative statements rather than quantitative recommendations are made. To design a concrete structure for robustness, some quantitative measure of ductility/robustness is required.

## 2. Designing and Detailing for Robustness

The past twenty years, or so, has seen increasing emphasis on extreme event scenarios, such as blast loading, impact, fire and so forth. Earthquakes, tsunamis, and cyclonic events have placed increasing emphasis on the resistance of structures to withstand such hazards and of the reserve of strength available in Australia's infrastructure to withstand these events. In the case of building structures, the global response of the structure caused by the local event is of primary interest. For example, in the bombing of Murrah Federal Building in downtown Oklahoma in 1995, the effect of a local (blast) event was to cause the complete collapse of almost half the structure resulting in 168 deaths (2). It was not the blast loading that caused the majority of deaths but rather the progressive collapse of the structure. More recently, the Christchurch earthquake saw collapse and near collapse of many reinforced concrete framed structures, with perhaps the most notable being the 26 storey, 85 metre tall, Grand Chancellor Hotel built in 1985 and to the earthquake standards of the day. In 2012, an earthquake of magnitude 8.9 occurred off the coast of Japan, with devastating consequences. Such events highlight the need of a comprehensive understanding of structures and structural behaviour for extreme events.

For the above reasons, Standards bodies require engineers and designers to design robust structures. AS1170.0–2002 (3) defines structural robustness as:

*“Ability of a structure to withstand events like fire, explosion, impact or consequences of human errors, without being damaged to an extent disproportionate to the original cause.”*

and mandates that:

*“The design of the structure shall provide load paths to the foundations for forces generated by all types of actions from all parts of the structure, including structural and non-structural components.”*

Engineers generally tend to struggle with questions such as ‘What are the units of robustness?’, ‘How are these ‘load paths’ carried through a structure?’, ‘What are the design forces that must be guarded against?’. Little guidance is found in AS3600-2009, where the term ‘robustness’ is mentioned just twice, once in a two line Clause 2.1.3 mandating the designer to meet the requirements stipulated in AS1170, and the other noting that action effects can be determined using common methods of analysis.

For design purposes, AS/NZS1170.0 (3) requires that structures be designed and detailed such that adjacent parts of the structure are tied together in both the horizontal and vertical planes so that the structure can withstand an event without being damaged to an extent disproportionate to that event. In addition, structures should be able to resist lateral loads applied simultaneously at each floor level not less than  $0.01 (G + \frac{1}{6}Q)$  for each level of a structure taller than 15 m above the ground and  $0.015 (G + \frac{1}{6}Q)$  for each level

of all other structures, where  $G$  is the permanent gravity load and  $\frac{1}{6}Q$  is the factored imposed action on a particular floor level. In addition, AS/NZS1170.0 (3) requires that all parts of the structures be interconnected, with each connection able to transmit at least  $0.05 \times (G + \frac{1}{6}Q)$  for that connection.

Other general ways to increase robustness of the structure are to: (i) provide redundant load paths in the vertical load carrying systems; (ii) include additional ties as described below; (iii) increase the ductility of the structural frame; (iv) provide adequate shear strength of beams, such that it always exceeds the flexural capacity, in order to encourage a ductile response; (v) and provide capacity for resisting load reversals.

The inclusion of additional tie members in the structural frames provides improved protection against progressive collapse. Key elements of a structure must be tied together so that redistribution of the forces happens if a local failure occurs. Ties in a structural frame may consist of peripheral ties, internal ties, horizontal ties to columns and walls, and vertical ties, as shown in Figure 2.

Some general guidelines for providing ties in a RC structural frame are provided in (5) and include: (i) reinforcement provided to resist normal design loads may also be used to meet the requirement for structural integrity; (ii) if the bars extend (for an effective anchorage length) beyond all the bars of another tie, it may be anchored to that tie at right angles; (iii) where there is interruption in the continuity of the ties, the ties must be adequately anchored; (iv) internal ties must be continuous throughout their length, and should be anchored to the peripheral ties; (v) internal ties at each floor and roof level should be in two perpendicular directions (in walls, the ties should be relatively close to the top or bottom of the floor slabs); (vi) continuous peripheral ties should be provided at each floor and roof level; and (vii) all vertical load bearing elements should be tied continuously, including the corner columns, which should be tied into the structure in each of the two perpendicular directions.

To enhance the resistance of concrete building frames to progressive collapse and increase their robustness, the following factors need to be considered in design (5):

For the beams:

- (i) ensure flexural failure (ductile) rather than shear failure (brittle) and use ductile reinforcement (Class N or better);
- (ii) maintain continuous positive and negative moment reinforcement throughout. The non-seismic and seismic detailing of a beam according to AS 3600-2009 is shown in Figure 3;
- (iii) do not splice reinforcement near joint regions or near mid-spans;
- (iv) provide closely spaced confining steel to improve ductility and increase shear and torsional strength;
- (v) use 135 degree hooks at the anchorage of all stirrups; and
- (vi) consider the maximum plastic rotation after formation of plastic hinges. For plastic analysis, ensure that shear failure does not occur prior to developing the full plastic moment capacity.

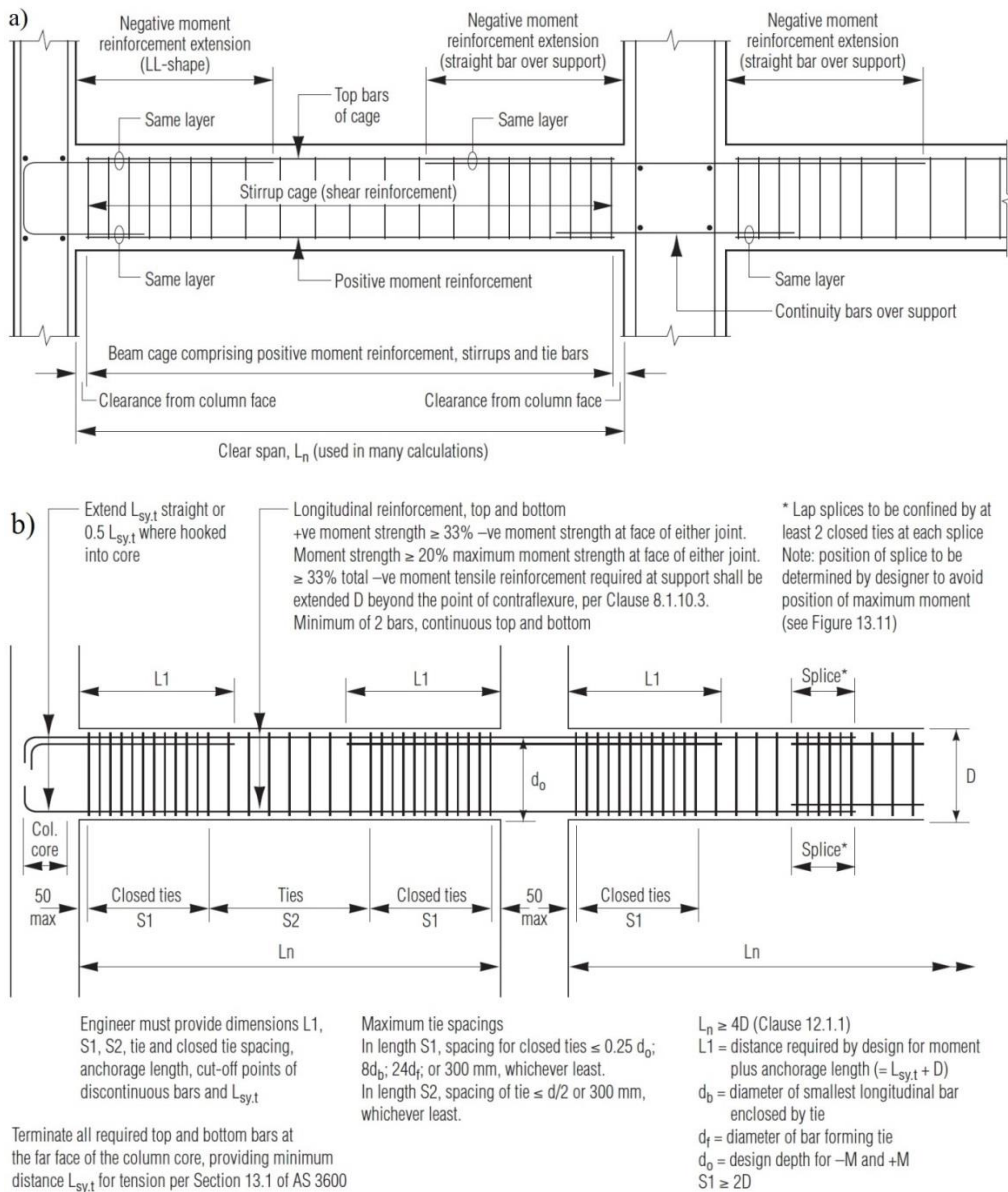

Figure 2. Ties in a structural frame for structural integrity (6).

**Figure 3. (a) Non-seismic and (b) seismic detailing of the beam (7).**

For the columns:

- (i) ensure flexural failure (ductile) rather than shear failure (brittle) and use ductile reinforcement;
- (ii) ensure plastic hinging in beams can occur by designing columns for larger moment than the beam can deliver (expected strength) (in AS 3600 this is included in the adoption of more conservative capacity reduction factors for less ductile members (eg. columns and walls compared to more ductile beams and slabs reinforced with N Class steel);
- (iii) Detail columns to have good confinement (Figure 4a and b show examples of good confinement, while Figure 4c shows potentially poor confinement because Class L ties may fracture at overloads and should be avoided in progressive collapse design scenarios);
- (iv) Splice column reinforcement at third-points along a column and not at the ends or at mid-span;
- (v) Continue confining ties through the joint region, as shown in Figure 5;
- (vi) For loss of a corner column, consider possible large moments and axial loads in adjacent columns.
- (vii) Identify critical elements where failure (or removal) could lead to large regions of damage and have high consequences on progressive collapse, and reinforce to resist such a possibility.

For the slabs:

- (i) use normal weight concrete floor slabs to enhance the blast resistance performance even though lightweight concrete will reduce the load;
- (ii) use of additional reinforcing steel to help tie-back adjacent beams to share load in event of column loss under a beam.
- (iii) provide continuous top and bottom reinforcement in both directions, and do not splice at mid-span or at the ends;
- (iv) cast slabs monolithically with beams and girders to provide better continuity and improve load redistribution;
- (v) the addition of a perimeter frame to a flat plate systems;
- (vi) consider reversals of load in design;
- (vii) provide sufficient tying of slabs into supporting walls;
- (viii) use N Class reinforcing steel for strength in flexure and, where needed, in column heads for punching shear.

**Figure 4. Tie configurations for confinement in columns (7).**

**Figure 5. Column-joint shear reinforcement (7).**

### 3. Beeby's approach for quantifying ductility and robustness

In his classic paper on the topic of robustness, Beeby (4) stated that

*“The problem with robustness is that, while we all have some intuitive idea what we mean by the term, it has never satisfactorily been put on a quantitative basis which would permit mathematical modelling or risk analysis to be carried out”.*

He further stated that a structure is robust if it is able to absorb damage resulting from unforeseen events without collapse. He also argued that this could form the basis of a design approach to quantify robustness. Explosions or impacts are clearly inputs of energy. Beeby (4) suggested that accidents or

even design mistakes could also be considered as inputs of energy and that robustness requirements could be quantified in terms of a structure's ability to absorb energy.

The area under the load deflection response of a member or structure is a measure of the energy absorbed by the structure in undergoing that deformation. Consider the load deflection response of a simply-supported under-reinforced beam shown in Figure 6. The area under the curve up to point 1 (before the tensile steel yields) is  $W_1$  and represents the elastic energy. The area under the curve between points 1 and 2 (when the plastic hinge develops and the peak load is reached) is  $W_2$ , which represents the plastic energy. A minimum value of the ratio  $W_2/W_1$  could be specified to ensure an acceptable level of ductility and, if all members and connections were similarly ductile and appropriately detailed, then an acceptable level of robustness (or resistance to collapse) could be achieved.

A ductile simply-supported member is one for which  $W_2/W_1$  exceeds about 0.5, but for statically indeterminate structures where significant redistribution of internal actions may be required as the peak load is approach, satisfaction of the following is recommended:

$$W_2 / W_1 \geq 1.0 \quad (1)$$

**Hinge rotation:** A typical moment curvature relationship for an under-reinforced concrete cross-section is shown as the dashed line in Figure 7 and an idealised elastic-plastic moment-curvature curve is also shown as the solid line. A plastic hinge is assumed to develop at a point along the span of a beam or slab when the peak (ultimate) moment is reached at a curvature of  $\kappa_y$  and rotation of the plastic hinge occurs as the curvature increases from  $\kappa_y$  to  $\kappa_u$ . The rotation at the plastic hinge  $\theta_h$  is the change in curvature

Figure 6. Typical load-deflection curve of an under-reinforced member.

Figure 7. Idealised elastic-plastic moment-curvature relationship.

multiplied by the length of the plastic hinge  $\ell_h$  in the direction of the member axis. For under-reinforced cross-sections with ductile tensile reinforcement and tendons, the length of the plastic hinge  $\ell_h$  is usually taken to be equal to the effective depth of the beam or slab  $d$ . The maximum rotation available at a plastic hinge may therefore be approximated by:

$$\theta_h = \ell_h (\kappa_u - \kappa_y) \approx d (\kappa_u - \kappa_y) \quad (2)$$

**Ductility:** To investigate the ductility of reinforced concrete beam, it is convenient to idealise the load-deflection curve as elastic perfectly plastic. As an example, consider the idealised load-deflection response shown in Figure 8 of a simply-supported reinforced concrete beam of span  $L$  and subjected to a point load  $P$  applied at mid-span. A plastic hinge develops at mid-span when the applied load first reaches  $P_u$  and the mid-span deflection is  $\Delta_y$ . The moment at the plastic hinge is  $M_u = P_u L/4$ . After the formation of the plastic hinge, it is assumed that the deflection at mid-span increased from  $\Delta_y$  to  $\Delta_u$  by rotation of the plastic hinge through an angle  $\theta_h$  and this can be described as follows:

$$(\Delta_u - \Delta_y) = \frac{L\theta_h}{4} \quad (3)$$

**Figure 8. Idealised load-deflection curve.**

As an example, consider a singly-reinforced simply-supported beam of span  $L$  carrying a single point load  $P$  at mid-span. Let us assume that the reinforcement ratio is  $p = A_{st}/bd = 0.01$ , with  $f'_c = 32$  MPa,  $E_c = 28,600$  MPa and  $f_{sy} = 500$  MPa. Using the rectangular stress block specified in AS3600-2009 (1), the ultimate moment at the plastic hinge  $M_u$  and the corresponding ultimate curvature are given by:

$$M_u = f_{sy} A_{st} \left( d - \frac{\gamma d_n}{2} \right) \approx \beta b d^2 \quad \text{and} \quad \kappa_u = \frac{0.003}{d_n} \quad (4a, 4b)$$

where  $b$  is the section width and  $d$  is the effective depth to the tensile reinforcement and  $d_n$  is the depth to the neutral axis at the ultimate moment. The term  $\beta$  depends on the area, position and strength of the reinforcement and tendons. In our example,  $\beta$  is 4.54 and  $d_n = 0.223d$ .

For the centrally loaded simply-supported beam, the deflection  $\Delta_y$  may be approximated as:

$$\Delta_y = \frac{P_u L^3}{48 E_c I_{cr}} = \frac{M_u L^2}{12 E_c I_{cr}} \quad (5)$$

and, for the stated material properties and steel quantities, the cracked moment of inertia of the cross-section is approximated by:

$$I_{cr} = 0.0432 b d^3 \quad (6)$$

From Figure 7, the curvature  $\kappa_y$  is given by

$$\kappa_y = \frac{M_u}{E_c I_{cr}} = \frac{4.54bd^2}{28600 \times 0.0432bd^3} = \frac{3.67 \times 10^{-3}}{d} \quad (7)$$

Substituting Eqs. (4a) and (6) into Eq. (5) gives:

$$\Delta_y = \frac{L^2}{3266d} \quad (8)$$

If we assume that satisfaction of Eq. (1) is required for robustness, the minimum required plastic energy  $W_2$  must be 1.0 times the elastic energy  $W_1$  and, from the geometry of Figure 8,  $(\Delta_u)_{min} = 1.5\Delta_y$ . The elastic energy  $W_1$  (shown in Figure 8) may be approximated as:

$$W_1 = \frac{P_u \Delta_y}{2} = 0.5 \times \frac{4 \times 4.54bd^2}{L} \times \frac{L^2}{3266d} = 0.00278bdL \quad (9)$$

The minimum internal value for plastic energy  $W_2$  that must be absorbed during the hinge rotation is  $1.5W_1 = 0.00417bdL$  and this must equal the external work:

$$P_u (\Delta_u - \Delta_y) = W_2 = 0.00417bdL \quad (10)$$

Substituting Eqs. (3) and (4a) into Eq. (10), we get the minimum rotation required at the plastic hinge, as follows:

$$(4M_u / L)(L\theta_h / 4) = 4.54bd^2\theta_h = 0.00417bdL$$

$$\therefore \theta_h = 0.919 \times 10^{-3} \frac{L}{d} \quad (11)$$

It is evident that the plastic rotation required at the hinge at mid-span depends on the span to effective depth ratio. To achieve a ductility corresponding to  $W_2/W_1 = 1.5$ , the rotation required at the hinge at mid-span and the span to final deflection ratio ( $L/\Delta_u$ ) are determined from Eqs. (10), (3) and (5) and are given in the table below.

$L/d$	10	14	18	22	26	30
$\theta_h$ (radians)	0.0092	0.0129	0.0165	0.0202	0.0239	0.0275
$(L/\Delta_u)$	290	207	161	132	112	97

The maximum rotation available (given by Eq. 4 and using Eq. 4b and 7) depends on the reinforcement quantity and the effective depth. For this cross-section, Eq. (4b) gives  $\kappa_u = 0.0135/d$ , Eq. (7) gives  $\kappa_y = 0.00367/d$  and, from Eq. (2), the rotation available at the plastic hinge is  $\theta_h = 0.00983$ . For a singly-reinforced beam cross-section containing 1% reinforcement, the required ductility is only available for span-to-depth ratios less than about 11.

The rotation  $\theta_h$  required for ductility (according to the requirement of Eq. 1) and the rotation available at the plastic hinge for a singly reinforced simply-supported beam carrying a point load at mid-span are given in Table 1 for different reinforcement ratios and different span-to-depth ratios. The shaded cells in the Table represent those combinations of reinforcement ratio and span-to-depth for which the ductility requirement specified in Eq. 1 is satisfied. It is noted that cross-sections with any of the reinforcement ratios considered in Table 1 are classified as ductile in AS3600-2009, with  $d_n \leq 0.36d$  in all cases. When the reinforcement ratio is less than about 0.009,  $d_n < 0.2d$  and, according to AS3600-2009, up to 30% redistribution of moments is permissible irrespective of the span-to-depth ratio.

#### 4. Conclusions

Guidance is provided on the design and detailing requirements for robust structures. A method is proposed whereby ductility and robustness may be quantified based on the ratio of internal energy absorbed by the structure before and after the formation of the first plastic hinge. Guidance is provided on how to calculate the rotation at a plastic hinge and how much rotation is required to provide ductile and behaviour in a given situation.

**Abstract:** This paper presents the results of 24 full-scale shear-critical (partially) prestressed and reinforced concrete members subjected to a four-point bending test with monotonically increasing load until failure. The main investigated parameters were the amount of prestressing, the amount of longitudinal and shear reinforcement and the shear span-to-effective depth ratio respectively. During the experiments, a vast amount of displacement and deformation data was gathered using two advanced optical measurement methods (i.e. 3D CCD-LED Coordinate Measurement Machine and Stereo-vision Digital Image Correlation). The experimentally observed failure load and failure mode are compared to analytical predictions using current shear design equations found in Eurocode 2.

A very poor correlation was found between the experimental results and analytical predictions (average experimental-to-predicted failure load ratio equal to 1.66, coefficient of variation equal to 36.8%). Based on the experimental data, it was found that direct strut action plays an important role in the overall structural behavior of the vast majority of the experimental test beams. This improved insight can be used to develop more suitable analytical modeling procedures.

## 1. Introduction

Despite more than a century of continuous research effort [1], shear remains one of a few areas into fundamentals of the behaviour of concrete structures where dispute remains amongst researchers about the mechanisms that enable the force flow through a concrete member and across cracks. The main reason for this contention can be attributed to the complexity of the shear phenomenon in structural concrete members. Firstly, various interrelated shear transfer mechanisms contribute to the overall shear capacity after the occurrence of cracking. Secondly, many parameters influence each shear transfer mechanism separately. Due to the complexity of the shear phenomenon, a generally accepted theoretical basis to model shear in structural concrete members is still absent within the research community.

Therefore, a multitude of analytical models dealing with shear in structural concrete members can be found in literature. Based on the cracking pattern typically observed during beam tests, Ritter [2] idealized the flow of forces by means of a parallel chord truss consisting of compressive diagonals inclined at 45°. This approach has ever since been referred to as the truss model approach. The necessary amount of shear reinforcement per unit length follows from the calculation of the axial force in the vertical tension ties.

The truss analogy is on one hand easy to understand and highly didactic but on the other hand a very simple representation of the actual structural behaviour. Moreover, in the case of structural concrete members without shear reinforcement, design engineers still mainly rely on empirical equations to estimate the shear strength. It is thus clear that more refined models are needed in order to optimize and economize the overall structural design of reinforced and prestressed concrete beams. An excellent overview of recent approaches to shear in structural concrete is given in references [3] and [4]. However, up until now, none of the existing theoretical approaches for shear in structural concrete elements has been able to fully explain the mechanics behind shear failure.

The ongoing debate in the literature on how to deal with shear in concrete members is also reflected by the code provisions. Current codes of practice [5-8] all recommend very different design approaches resulting in different design shear capacities and take parameters affecting the shear capacity into account in a different way. Due to our incomplete understanding and the brittle failure modes typically associated with shear, current codes of practice tend to propose highly conservative design equations, specifically in the case of prestressed concrete beams [9].

This paper therefore reports on the investigation of the mechanical behaviour of 24 full-scale shear-critical prestressed and reinforced concrete beams subjected to a combination of bending moment and shear force. In the first section, the experimental program is elaborated. Secondly, the experimental results are presented and compared to analytical predictions using current shear design equations found in Eurocode 2 [5, 6]. Finally, based on the experimentally observed deformation data, the mechanical behaviour is identified.

## **2. Experimental research**

### **2.1 Test specimens**

Each test specimen was labelled with the descriptive letter B followed by a number ranging from 1 to 12 or a number ranging from 101 to 112. The first set of beams, i.e. B1-B12, had a rectangular cross section, were 6000 mm long and 240 mm wide. The height of the aforementioned specimens varied between 400 mm, 500 mm and 600 mm. Specimens B101-B112 were characterized by an I-shaped cross section, were 7000 mm long, 630 mm high and had a flange width equal to 240 mm. The web width was equal to 70 mm. Specimens B2, B5, B7, B9, B12 and B101-B106 were provided with 8 low-relaxation seven-wire strands at the bottom (nominal diameter 12.5 mm) whereas beams B1, B4, B8, B10-B11 and B107-B109 were prestressed using 4 low-relaxation seven-wire strands at the bottom. All aforementioned beams were provided with two low-relaxation seven-wire strands (nominal diameter 9.3 mm) at the top. Specimens B8 and B10-B11 were additionally provided with two hot-rolled bars at the bottom (nominal diameter 25 mm). The same amount and diameter of reinforcement was used for the conventionally reinforced specimens (B3, B6 and B110-B112).

Shear reinforcement was provided in beams B7, B11-B12 consisting of closed double-legged stirrups (nominal diameter 6 mm, centre-to-centre distance equal to 300 mm). Shear reinforcement in beams B101-B102, B104-B105, B107-B108 and B110-B111 consisted of single-legged stirrups (nominal diameter 6 mm, centre-to-centre distance equal to 150 mm). Splitting reinforcement (nominal diameter 8 mm, centre-to-centre distance equal to 50 mm) was provided at both ends of all specimens. The geometry and reinforcement layout of all specimens are shown in Fig. 1-2.

### **2.2 Materials**

The self-compacting concrete mixture, used for both rectangular and I-shaped beams, was designed to have a characteristic cylindrical compressive strength  $f_{ck}$  equal to 50 MPa. Cement was specified as CEM I 52.5 R whereas the coarse aggregate consisted of 12 mm maximum size limestone gravel. Limestone filler and a high range water reducer were also used. The expected density of this mixture was 2378 kg/m<sup>3</sup>. The concrete mixture composition is listed in Table 1. The measured concrete material properties are reported in Tables 2-3. Tensile tests were performed on shear, splitting and passive reinforcement types to determine the modulus of elasticity  $E_s$ , the yield and ultimate stress,  $f_{ym}$  respectively  $f_{tm}$ , and the strain at failure  $\varepsilon_{su}$ . The characteristics of the prestressing strands were taken from the manufacturer. The results are summarized in Table 4.

### **2.3 Experimental setup**

All specimens were subjected to a four-point bending test as shown in Fig. 3. The tests were carried out in load control using a hydraulic press (Instron, maximum capacity 2.5 MN). The distance between the support points is equal to 4000 mm for the rectangular specimens and 5000 mm for I-shaped specimens. The distance outside the support points was equal to 1000 mm. The shear span  $a$  is equal to 1200 mm (specimens B1-B7 and B10), 1800 mm (specimens B8-B9 and B11-B12), 1600 mm (specimens B101, B104, B107 and B110) or 2000 mm (specimens B102-B103, B105-B106, B108-B109 and B111-B112). An overview of the investigated parameters is given in Table 5.

Discrete displacements and deformations of rectangular specimens were measured using analogue displacement gauges and demountable mechanical strain gauge points (DEMEC). Continuous displacements were measured during the tests on I-shaped beams using LVDTs. Additionally, advanced optical(-numerical) measurement techniques, i.e. *3D CCD-LED Coordinate Measurement Machines* and *Stereo-vision digital image correlation (DIC)*, were employed to investigate both zones where a shear force occurs in the case of I-shaped beams. The corresponding experimental setup and measurement precision are elsewhere described and reported in [10] and [11].

### 3. Experimental results

In this section, the experimentally observed structural behaviour is reported. Fig. 4 (a-f) show the experimentally observed load-displacement response curves for all investigated specimens apart from B3 and B7. During testing of B3, a sudden stage of unloading occurred. After increasing the load, the beam suddenly failed. The results of this specimen will therefore not be considered. Specimen B7 did not yield

any useful load-displacement data due to measurement errors. The onset of bending ( $\circ$ ) and diagonal ( $\triangle$ ) cracking is also indicated in the aforementioned Fig. 4 (a-f). Typical observed cracking patterns prior to failure are shown in Fig. 5(a-b) for both rectangular and I-shaped specimens.

**Figure 4: Load-displacement response curves for (a-c) rectangular beams (measured at mid-span) and (d-f) I-shaped beams (measured at 1200 mm from the support point)**

(a) B4 (b) B102  
**Figure 5. Typical cracking pattern prior to failure for (a) rectangular specimens and (b) I-shaped specimens**

Despite being designed to fail in shear, all rectangular specimens apart from beam B6 and B10, exhibited a bending failure mode due to severe yielding of the longitudinal reinforcement followed by brittle crushing of the compressive zone between the load points. Specimens B6 and B10 failed due to the loss of anchorage of the longitudinal reinforcement. All I-shaped beams but specimens B107 and B108 failed due to shear in a very brittle manner. The aforementioned specimens exhibited severe web cracking leading to excessive yielding and rupture of the shear reinforcement bars. Crushing of the diagonal struts was not observed. Table 6 summarizes the experimentally observed failure load and failure mode of each considered test beam. The experimental results can be compared to analytical strength calculations according to current Eurocode 2 (EC2) [5, 6] design guidelines. To better estimate the actual failure load, average material strength properties rather than characteristic values are to be used and all partial safety factors should be omitted. The results of the aforementioned calculation procedure are also incorporated in Table 6. Based on the results presented in Table 6, following observations and preliminary conclusions can be made.

1. For the vast majority of the reported test specimens, a poor correlation is found between the experimentally observed and analytically calculated failure load according to EC2 for both rectangular and I-shaped beams. A relatively good correlation was found between experimental and analytically predicted failure load in the case of reinforced I-shaped specimens with shear reinforcement (B110-B111) and prestressed I-shaped beams without shear reinforcement (B103, B106, B109 and B112), refer to Table 6. Even if all partial safety factors were omitted and average material strength properties were used rather than characteristic values, a mean experimental-to-predicted failure load ratio equal to 1.66 is found (coefficient of variation (COV) equal to 36.8%).
2. Although all considered rectangular specimens were characterized by a lower shear strength in comparison to their respective predicted bending capacity, no shear failure mode was observed. It can be noted that the experimentally observed failure load correlates well with the analytically calculated load necessary to obtain the bending capacity  $V_{u,bend}$ . All I-shaped beams were

characterized by a lower theoretical shear capacity compared to their respective bending strength. A shear failure mode was indeed encountered for all I-shaped beams except beams for B107 and B108 which failed due to bending. Table 6 clearly indicates that the experimental failure load is marginally higher than  $V_{u,bend}$  for the aforementioned beams.

**Table 6: Experimentally observed and analytically predicted failure load and failure mode**

Specimen	Experiment		Eurocode 2 [5, 6]

#### 4. Discussion

To further investigate the discrepancy between the experimentally observed and analytically predicted failure load, the measured (full-field) deformations are investigated. Fig. 6(a-c) show the typical horizontal and vertical strains for rectangular specimens as a function of the distance from the support point and applied load level. Fig. 7(a-c) show the same results observed for I-shaped specimens. From Fig. 6(a-c) and Fig. 7(a-c), it can be clearly seen that, near the support point, the horizontal strain  $\varepsilon_x$  at the top of both rectangular and I-shaped specimens rapidly decreases to low strains and thus also low stresses. Moreover, the vertical strains in the web of rectangular specimens remained relatively small in comparison to the vertical deformation in the web of I-shaped beams, refer to Fig. 6(b) and Fig. 7(b) respectively. For high load levels applied to I-shaped beams,  $\varepsilon_y$  rapidly increases and near failure, the strain in the web is nearly equal to the ultimate strain of the shear reinforcement bars as determined from uni-axial tensile tests, refer to Table 4.

Fig. 8(a) depicts the experimentally measured full-field direction and magnitude of the principal compressive strain  $\varepsilon_3$  near failure of specimen B104 whereas Fig. 8(b) shows the measured angle  $|\theta_{\varepsilon_3}|$  between the principal compressive strains with respect to the horizontal as a function of the distance from the support point. Fig 8(a) indicates that, after the occurrence of inclined cracking in I-shaped beams, an inclined strut is formed which partly resists the applied shear force in the case of prestressed I-shaped beams. Apart from the direct compression strut, which develops through cracked concrete, refer to Fig. 5(b) two fan regions are developed which deviate the inclined web cracks and resist the remaining part of the applied shear force.

(b)

(c)

**Figure 7. Horizontal (a,c) and vertical (b) strain profiles of B101 at various load levels (○ 25%, □ 50%, △ 80%, ● 95%, ■ 99% of  $V_{u,exp}$ )**

The identified structural behavior of the above mentioned specimens corresponds to the observed parabolic course of the direction of the principal compressive strain  $|\theta_{z3}|$  along the axis of the member, as presented in Fig. 8(b). In view of the mechanical behavior described above, the experimentally observed failure mode can be understood as a splitting failure mode due to the spreading out of the compressive force in the web of the beam. Similarly, it can be assumed that direct strut action is the main bearing mechanism for the presented rectangular beams. However, different from I-shaped beams, the area where the direct compression strut can be developed remains uncracked, refer to Fig. 5(a). Hence, there is no reason for a fan region to be developed which deviates cracked zones.

(a)

(b)

**Figure 8. (a) Direction and magnitude of the principal compressive strain of specimen B104 at 95% of the experimental failure load; (b) Angle between the principal compressive strain and the horizontal for specimen B104 at 95% of the experimental failure load**

The identified structural behavior, as described above, provides a plausible explanation for the following experimentally observed phenomena:

1. The possibility of carrying the applied shear force by means of direct strut action significantly increases the shear carrying capacity in comparison to the shear capacity obtained using the variable angle truss model as proposed by Eurocode 2. This provides a possible explanation why the current sectional shear design provisions found in EC2 performed poorly in predicting the shear capacity of the reported (partially) prestressed concrete beams.

2. The direct strut action poses high demands on the anchorage of the longitudinal tensile reinforcement near the support point. This explains the anchorage failure of the partially prestressed specimen B10 which failed at the highest shear force in comparison to the other reported partially prestressed rectangular specimens.
3. In the case of rectangular (partially) prestressed concrete beams, no inclined cracks crossed the path between the support point and loading point. If the vast majority of the applied load is carried by means of direct strut action, then it is indeed expected that providing shear reinforcement does not contribute significantly to the overall structural behavior. This explains why a relatively small difference in failure load was observed for specimen sets (B5, B7), (B8, B11) and (B9, B12), refer to Table 6 and Fig. 4(c). The aforementioned specimen sets are identical apart from the provided amount of shear reinforcement.
4. In Fig. 6(a) and Fig. 7(a), the typically observed profile of the horizontal strain  $\varepsilon_x$  was presented at the top of rectangular respectively I-shaped beams. It was shown that the horizontal strain at the top of the presented beams rapidly decreases to relatively low strains, and thus relatively low stresses, away from the loading point. Due to the inclined strut action, it is indeed expected that low strain values occur at the top of the specimen near the support point.

## 5. Conclusions

This paper presented extensive experimental results obtained from 23 full-scale structural tests on prestressed and reinforced concrete members subjected to a four-point bending test until failure. The presented experimental results can be used in further research for model validation and model calibration. The main investigated parameters were the amount of prestressing, the amount of shear and prestressing reinforcement and the shear span-to-effective depth ratio respectively. Using either traditional mechanical measurement techniques or advanced optical(-numerical) measurement methods, a vast amount of displacement data was gathered from which deformations can be easily derived. All specimens were designed to fail in shear. However, 11 specimens exhibited a bending failure mode, 2 specimens failed due to the loss of anchorage and the remaining 10 specimens failed due to excessive yielding leading to sudden rupture of the shear reinforcement bars. The experimental results were compared to analytical calculations using the current design procedures as proposed by Eurocode 2 (EC 2). Based on the work presented in this paper, it can be firstly stated that, EC 2, using the variable angle truss model, in general significantly underestimates the load capacity of the presented test beams. Omitting all partial safety factors and using average material strength properties rather than characteristic values, an average experimental-to-predicted failure load ratio equal to 1.66 was found (coefficient of variation 36.8%). Moreover, the failure mode is wrongly predicted for 13 test specimens using current EC 2 design procedures. Secondly, direct strut action was found to be an important bearing mechanism for the presented rectangular beams and prestressed I-shaped beams with shear reinforcement. This mechanism, although generally believed to be only important for members with a shear span-to-effective depth ratio less than or equal to 2.5, significantly increases the failure load of the reported test specimens and form a plausible explanation for the experimental observations.

**Abstract:** Partially grouted masonry walls subjected to in-plane shear exhibit a complex behaviour because of the influence of the aspect ratio, the pre-compression, the grouting pattern, the ratios of the horizontal and the vertical reinforcements, the boundary conditions and the characteristics of the constituent materials. The existing in-plane shear expressions for the partially grouted masonry are formulated as sum of strength of three parameters, namely, the masonry, the reinforcement and the axial force. The parameter 'masonry' includes the wall aspect ratio and the masonry compressive strength; the aspect ratio of the unreinforced panel inscribed into the grouted cores and bond beams are not considered, although failure is often dominated by these unreinforced masonry panels. This paper describes the dominance of these panels, particularly those that are squat, to the shear capacity of whole of shear walls. Further, the current design formulae are shown highly un-conservative by many researchers; this paper provides a potential reason for this un-conservativeness. It is shown that by including an additional term of the unreinforced panel aspect ratio a rational design formula could be established. This new expression is validated with independent test results reported in the literature – both Australian and overseas; the predictions are shown to be conservative.

**Keywords:** partially grout, in-plane shear, concrete masonry, design formulae.

## 1. Introduction

The existing in-plane shear design expressions in various national standards are based on additive approach. This method adds the capacity of masonry, the contributions of the pre-compression and the reinforcement. The masonry terms is accounted as a function of masonry strength and the wall aspect ratio. A fraction of the applied pre-compression and the steel reinforcement yield strength are also accounted. However, there are additional factors that influence the in-plane shear capacity of the partially grouted masonry shear walls, such as the boundary condition and the grout spacing / panel aspect ratio (Dhanasekar and Haider 2011; Haach et al. 2011; Janaraj et al. 2011). In the absence of these parameters, the current design formulae are often criticised as being highly un-conservative/ unsafe (Shrive et al. 2009; Nolph and ElGawady 2012; Janaraj 2014; Janaraj and Dhanasekar 2014).

The existing design expressions in the Australian, New Zealand and the USA standards ( AS 3700 (2011), NZS 4230 (2004) and MSJC (2008), respectively) are considered in this paper. These expressions attracted criticism of providing un-conservative predictions. This un-conservatism may be attributed to the complexity and to some extent, the lack of understanding of the in-plane shear behaviour of the walls. AS 3700 (2011) contains only masonry and reinforcement terms; although very simple, also is shown very highly non-conservative. The masonry term is expressed in wall aspect ratio while completely disregarding masonry strength. The exclusion of masonry strength might well be a problem. Further this formula completely neglects the effect of pre-compression and boundary conditions effects. AS 3700 (2011) in-plane shear expression is shown in Eq. (1).

$$V = (1.5 - 0.5\lambda_w)A_s + 0.8f_yA_s \quad (1)$$

Where  $\lambda_w$  is the aspect ratio of the whole wall  $\left(\frac{H}{L}\right)$ , in which  $H$  is height and  $L$  is length of the wall.

Walls of aspect ratio less than unity, low vertical and the horizontal reinforcement areas are particularly prone to provide highly non-conservative predictions; for example, a wall of 1.6 m high, 5.0 m long reinforced with N12 bars at 1.2 m c/c are shown to predict 234 % higher capacity compared to laboratory experiment, where care is taken on the quality of specimens. Therefore, using this expression for real world designs require urgent attention – this paper attempts to provide a rational base for making the predictions conservative.

The NZS 4230 (2004) expression is shown in Eq. (2).

$$V_n = \left[ (C_1 + C_2)v_{bm} + \frac{0.9P}{b_w d} \tan \alpha \right] b_w d + 0.8 \frac{f_{yh} A_{sh} d}{s_h} \quad (2)$$

Where  $C_1 = 33 \frac{A_{sv} f_{yv}}{300 b_w d}$

$$\frac{H_e}{L} < 0.25 \rightarrow C_2 = 1.5$$

$$0.25 \leq \frac{H_e}{L} \leq 1 \rightarrow C_2 = 0.42 \left[ 4 - 1.75 \frac{H_e}{L} \right]$$

$H_e$ ,  $A_{sh}$ ,  $A_{sv}$ ,  $b_w$ ,  $d$ ,  $f_{yh}$ ,  $f_{yv}$ ,  $L$ ,  $s_h$  and  $P$  stands for effective height of the wall, area of the horizontal steel, area of the vertical steel, effective wall width, design length of wall, yield strength of the horizontal steel, yield strength of the vertical steel, wall length, vertical spacing of the horizontal bars and pre-compression load, respectively.  $v_{bm}$  is the basic shear strength of masonry and  $\alpha$  is the angle of diagonal strut to vertical. The term  $(b_w d)$  accounts for the face shell area and does not include the area of grout. This assumption considers the shear flow continuity requirements and to avoid any potential for shear failures in the un-grouted shells. The design length ( $d$ ) of the wall is limited to 80% of the actual wall length.

The in-plane shear expression of the Masonry Standard Joint Committee (MSJC 2008) is shown in Eq. (3). This equation includes wall aspect ratio and the strength to masonry terms. The pre-compression load and the horizontal reinforcement terms are also included.

$$V = \left[ 0.166 \left( 2 - 0.875 \frac{M_f}{V_f d_v} \right) \sqrt{f'_m} \right] A_n + 0.25P + 0.5 f_{yh} \frac{A_{sh}}{s_h} d_v \quad (3)$$

In which the maximum in-plane load is limited to,

$$a) \frac{M_f}{V_f d_v} \leq 0.25 \rightarrow V_n \leq 0.083(6A_n \sqrt{f'_m})$$

$$b) \frac{M_f}{V_f d_v} \geq 1 \rightarrow V_n \leq 0.083(4A_n \sqrt{f'_m})$$

$\frac{M_f}{V_f d_v}$  is moment to shear arm length ratio of the wall and  $f'_m$  is compressive strength of the masonry.

The net area ( $A_n$ ) accounts the facially bedded area and the grouted area.

Partially grouted masonry walls were shown to exhibit panel failures while the grouted cores remain intact (Janaraj et al. 2011; Nolph and ElGawady 2012; Minaie et al. 2014). This panel failure is critical in determining the in-plane shear capacity of the wall. Therefore, this paper examines the significance of the panel aspect ratio and the factors influencing the wall failure and panel only failure. Further, an in-plane shear expression is developed based on the panel only failure walls which predict the in-plane shear

capacity conservatively. The panel aspect ratio ( $\lambda_p$ ) is defined in Eq. (4). Where  $h$  is panel height and  $l$  is panel length as shown in Figure 1.

$$\lambda_p = \frac{h}{l} \quad (4)$$

The in-plane shear capacity of the wall is non-dimensionalised as in Eq. (6).

$$\ddot{X} = \frac{V}{A_n \times f'_m} \times 100 \quad (6)$$

Where  $\ddot{X}$  is non-dimensional shear strength and  $V$  is in-plane load capacity of the wall. The wall containing several panels is denoted as  $W_{x,y}$  where  $x$  indicated number of panels along the wall horizontal in-plane loaded direction and  $y$  indicates number of panel along the wall height direction. Number of panels along the height direction of the wall is also called as storey. Two storey wall defines a wall which has two panels along its height direction.

## 2. Experiment and Numerical validation.

Diagonal compression tests reflect the behaviour of laterally loaded shear walls, although the boundary condition and aspect ratio of walls could not be replicated in these tests; however, they are simpler and can provide reliable estimate of the shear strength of masonry (ASTM 2002; Petersen et al. 2012; Janaraj and Dhanasekar 2014). It is therefore prudent to develop finite element models to replicate the diagonal compression tests and then use the same FE model for various geometry of shear walls. The shear wall behaviour output from the FE models can be validated using other independent tests. This approach is followed in this paper.

The transmission of the diagonal compression test into the in-plane horizontal load is shown in Figure 1 where the diagonal strut formation of load resisting mechanism exists. This diagonal load test is widely used to examine the effectiveness of strengthening mechanism of the masonry with FE model development. This diagonal load test was conducted and tested in accordance with provisions of ASTM (2002). As large size wall cannot be tested under this method, half scale specimens were constructed to accommodate higher number of mortar joints within the panel.

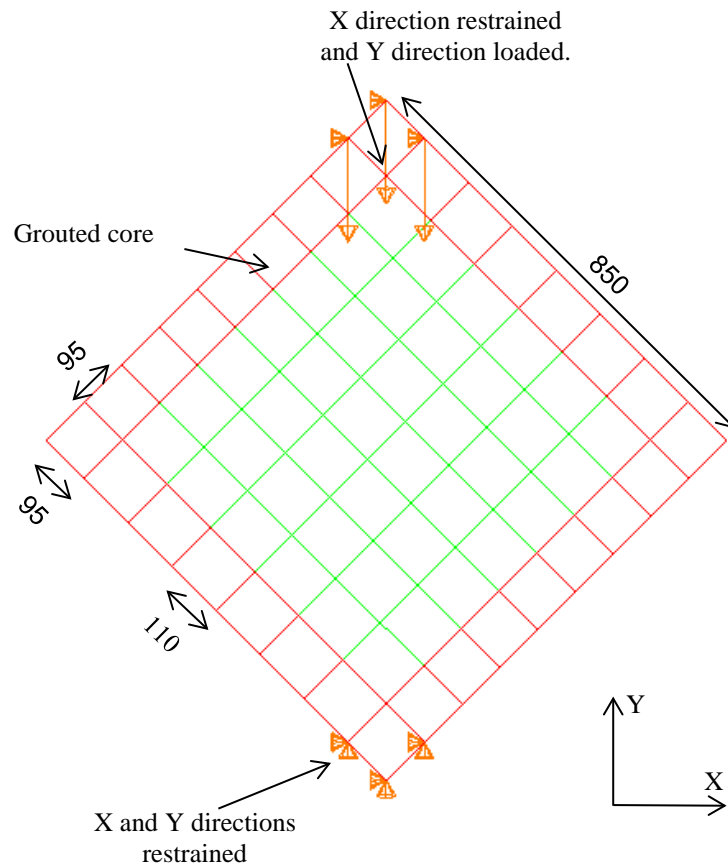

**Figure 1. Conversion of diagonal load test to partially grouted masonry walls.**

Four experimental walls were constructed and tested under diagonal load test; a) two un-grouted masonry walls and b) two grouted masonry walls. The wall dimension is 850 mm square as shown in the figure with the thickness of 90.5 mm. The face shell thickness is 15.75 mm. The grouted masonry wall has grout in its

edge recesses with a 12 mm diameter reinforcing bar placed at the centre. The diagonal load versus diagonal displacement was obtained and used for FE model validation. A non-linear FE modelling based on the homogenized macro element characteristics in explicit formulation was adopted as it predicting the masonry shear wall behaviours well (Dhanasekar and Haider 2008). A macro modelling strategy was deployed using ABAQUS Explicit formulation reported in Dhanasekar and Haider (2008) was adopted and reported in Janaraj and Dhanasekar (2014). The masonry mesh height was selected to represent one block height (90 mm) and one mortar thickness (5 mm). The length of the masonry mesh was selected by compromising the optimum mesh size from the mesh sensitive study which can sufficiently represent block and mortar. The FE model arrangement and the selected mesh sizes are shown in Figure 2.

Multi surface plasticity model was adopted to represent the masonry behaviours (Lourenço 1996). As the grouted cores are governed by similar masonry anisotropic behaviour, same masonry multisurface material model was selected to represent the grouted cores with different parameters. These masonry and the grouted cores parameters were determined from the conducted material testing of compression test, four point bending tests and triplet tests. The test results and the parameters can be found elsewhere Janaraj and Dhanasekar (2014).

The reinforcement was represented by two node truss elements with the limited compression as the reinforcement was placed without any shear ties. From the conducted tensile coupon test, the yield strength and the elastic modulus was found as 500 MPa and 200 GPa, respectively. The stress strain curve was input as material parameters.

**Figure 2. Finite element model**

The predicted diagonal load versus diagonal displacement response of the diagonally loaded wall was compared with that of the tested panels and is shown in Figure 3. The un-grouted panel is denoted as (UG) and the partially grouted panel is denoted as (PG). Two walls of the each configuration are denoted by "1" and "2". It can be seen in the figure that the PG FE model FEM(PG) well predicts the average peak load of the tested panels (59 kN) and the failure displacement of 5.3 mm. Similarly the FEM(UG) predicts both experimental curves acceptable. Therefore, this model enables to study the behaviour of the partially

grouted masonry shear walls in-plane shear analysis. Further details of other validated parameters such as reinforcement strains, strains at centre of the panel, crack pattern can be found in Janaraj and Dhanasekar (2014), Janaraj and Dhanasekar (2015a) and Janaraj and Dhanasekar (2015b). This validated model is used for the further studies reported in the following sections.

**Figure 3. Diagonal load versus diagonal displacement**

### 3. Influencing parameters

#### 3.1 Panel failure

It was found that the panel failure is determined by the aspect ratio of the panel. The study outlined such findings is reported in this section. For this purpose a wall with a wall aspect ratio of 0.68 walls containing  $\lambda_p = 1.9$  panels was selected as shown in Figure 4.a. The same wall was introduced with horizontal reinforced grout at the middle to form  $\lambda_p = 1.0$  panels as shown in Figure 4.b. The wall with three panels  $W_{3,1}$  is technically converted into six panels' wall  $W_{3,2}$  without changing its overall dimensions. The principal logarithmic strains are shown in Figure 4 where red shows tensile strains corresponding to failure of the wall. It can be clearly seen that the failure was obtained along the wall diagonal in Figure 4.a where  $\lambda_p = 1.9$ . The partition of wall using horizontal grout has arrested the diagonal failure within the panels. In this scenario, considering the wall aspect ratio to determine the in-plane shear capacity does not represent the actual resisting mechanism. Therefore, the sensitivity of the panel is analysed in the following sections.

#### 3.2 Effect of horizontal reinforcement

It is widely reported in the literature the horizontal reinforcements have limited contribution to the shear capacity of the masonry shear walls (for example Shing et al. (1990)). It has been found that the horizontal reinforcement activates in the post peak region of the wall hence no in-plane shear capacity will be attained. To examine this nature, the wall reported in Figure 4.b is considered.

(a) Wall failure.

(b) Panel failure.

**Figure 4. Effect of horizontal reinforced grout**

(a) Tensile stress in the reinforcement.

(b) Tensile stresses at two loading

(c) Location definition

**Figure 5. Tensile stresses on the reinforcement**

Location A was selected at the heel side of the wall where higher tensile stress on the reinforcement exists and location B was selected in the horizontal reinforcement as shown in Figure 5.a. The graphs in Figure 5.b are denoted by the location followed by the net area of the reinforcements stated in percentage of net area of the wall. The amount of horizontal reinforcement was changed and its corresponding tensile stresses are shown in Figure 5.b. It can be seen from Figure 5.a that the reinforcement did not yield and reached only 25% of its yield capacity of 500 MPa. The increase on amount of horizontal reinforcement merely reduces the tensile stresses indicate it was in elastic region. As these A and B points were selected in two locations it was decided to study the tensile stress variation

along the length of the horizontal reinforcement. The tensile stress of the reinforcement at the peak load capacity of the wall and the ultimate capacity of the walls were selected as shown in Figure 5.c. The yield stress of the reinforcement had shown no significant difference for the ultimate and the peak load capacity of the wall. Therefore, it was decided the horizontal reinforcements do not contribute to enhance the in-plane shear capacity of the wall.

### 3.3 Panel efficiency

The panel efficiency measures the increase of the in-plane shear capacity of the wall than its individual arithmetic sum of individual panel in-plane shear capacity of the panels. This increase is achieved due to effective confinement induced in between panels. The panel efficiency is measured using Eq. (7).

$$\xi = \left( \frac{\ddot{X}_{x,y} - \ddot{X}_{1,1}}{\ddot{X}_{1,1}} \right) \times 100\% \quad (7)$$

Where  $\ddot{X}_{1,1}$  is shear strength parameter of single panel and  $\ddot{X}_{x,y}$  is the shear strength parameter of the wall containing  $x$  and  $y$  numbers of panels. Any value of shear strength parameter above zero indicates the increase of shear strength of the wall through effective confinement. The panel efficiency of the walls which has four different aspect ratios of the panels is shown in Figure 6.

Figure 6. Panel efficiency of  $W_{x,1}$  walls.

For the walls containing  $\lambda_p=1.00$  panels along its wall loaded direction/ wall length, the increase of wall length from 1 to 3 did not increase any shear strength through confinement. However, the further increase of panels substantially increased the panels walls hear strength. For example, individual panel located in the nine panel wall produces 22% higher in-plane shear load than its individual capacity as confinement increased substantially. However, further increase of the panels within the wall does not increase the efficiency indicating saturation was occurred at 9 panel wall. It is also found that reduce in panel aspect ratio merely reduces the panel efficiency. This study was conducted on a single panel height wall or single storey height wall. When the panel height was increased, it was found that the efficiency reduces. This efficiency is implemented in the following sections of the equation development.

#### 4. In-plane shear expressions development

The in-plane shear expressions are formulated based on the capacity of the single panel. Then this single panel capacity is converted to wall in-plane shear capacity using panel efficiency factor. As these panel efficiencies were formed for single storey panel, the effect of multi storey was analysed and its correlation was found as below (Eq. (8)).

$$\ddot{X}_{1,y} = 0.9^{y-1} \ddot{X}_{1,1} \quad (8)$$

The in-plane shear capacity expressions of the partially grouted masonry wall are formulated by analysing masonry panel properties, Pre-compression load and boundary conditions. As horizontal reinforcement shows no effect on the in-plane shear capacity, it is completely disregarded in the equation formation.

##### 4.1 Masonry

A masonry panel was considered for the analyses. The panel was loaded in horizontal direction with fixed boundary conditions at the top while completely arresting bottom wall movements in both directions. The strength of masonry and the panel aspect ratio were considered as major variables. Initially, the panel aspect ratio was kept as constant and the in-plane shear capacity was correlated with  $\sqrt{f_m}$ . This correlation was performed separately for  $\lambda_p$  of 1.0, 0.80, 0.65 and 0.55 panels. An established linear correlation for the  $\lambda_p = 0.80$  panel can be seen in Figure 7. Similar linear correlation was observed in other aspect ratio panels.

Figure 7. In-plane shear strength versus  $\sqrt{f_m}$ .

As the in-plane shear stress of the panel ( $\tau$ ) is linearly correlated with  $\sqrt{f_m}$ , further studies have been conducted by considering  $\tau / \sqrt{f_m}$  varies with panel aspect ratio ( $\lambda_p$ ) linearly as shown in Eq. (9).

$$\frac{\tau}{\sqrt{f_m}} = a(\lambda_p) + b \quad (9)$$

For this study, a compressive strength of masonry 6 MPa, 9 MPa, 12MPa, 15 MPa, and 18 MPa were considered. Curves were plotted in the  $\tau / \sqrt{f_m}$  versus  $\lambda_p$  space and 95% confidence line was obtained as shown in Eq. (10).

$$\frac{\tau}{\sqrt{f_m}} = 0.17(2 - 0.9 \times \lambda_p)$$

#### 4.2 Pre-Compression and boundary condition

A single panel was subjected to different levels of pre-compression changing from 0% of its compressive strength of the masonry to 50% of the compressive strength of the masonry. It was found that an inclusion of 25% pre compression load would conservatively measures the enhancement of the in-plane shear capacity of the panel through pre-compression. Further, any load exceeds 13% of the compressive strength of the masonry cause more brittle type failure of the wall. Similar limitation is enforced in 4230 (2004). It is also noticed that a transition of fixed boundary wall to cantilever type free boundary wall cause reduction in in-plane shear capacity of the wall. It was found that the release of boundary condition reduces the in-plane shear capacity by 50%. This effect is included through boundary condition factor  $\gamma$  in the equation which is 1.0 for fixed boundary wall and 0.5 for free boundary cantilever wall. Other factors are outlined in Table 1.

**Table 1. Design criteria for fixed boundary walls**

Wall height	Wall length	$\lambda_p$	$\xi$
Single panel	Less than 4 panels*	$\lambda_p=1-0.55$	1.00
	More than 10 panels	$1.0 \geq \lambda_p \geq 0.8$	1.22
		$0.8 > \lambda_p \geq 0.6$	1.00
		$0.6 > \lambda_p$	0.93
2-3 panels	All panels	$1.0 \geq \lambda_p$	1.00
4 panels	Less than 5 panels	$1.0 \geq \lambda_p$	1.00
	above 10 panels	$\lambda_p = 1.0$	1.00
		$1.0 > \lambda_p \geq 0.55$	0.94

\* Linear interpolation is permitted in between 4 to 10 panels.

For released boundary wall the factor need to be multiplied by 0.4.

After considering all the factors the final in-plane shear expressions is shown in Eq. (11).

$$V = \left\{ 0.17(2 - 0.9\lambda_p) \sqrt{f_m'} A_n + 0.25P \right\} \times (0.9)^{y-1} \times \xi \times x \times \gamma \quad (11)$$

Where  $V$ ,  $P$ ,  $x$  and  $\gamma$  are In-plane load capacity of the wall, pre-compression load, number of panel along wall length and boundary condition factor, respectively.

#### 4.3 Independent validation of the model

To examine the reliability of the model, nine independently tested walls published in Nolph and ElGawady (2011), Minaie et al. (2010), Shrive et al. (2009), Schultz (1996) and Ghanem et al. (1993) were considered as it contained  $\lambda_p \leq 1$  panels. Its prediction is shown in Figure 8, where  $V/V_{EXP}$  greater than 1.0 is un-conservative prediction. The prediction of AS 3700 is far away from the actual wall in-plane shear capacity whereas the propose expression average is 0.93 which is 7% conservative.

Figure 8. Prediction of the expressions.

## 5. Conclusions

The proposed model that accounts the effect of panel aspect ratio, pre-compression and boundary condition conservatively predicts the wall within acceptable safety margin. As 3700(2011) un-conservative prediction is quiet visible in the figure, hance it needs an urgent review.

**Abstract:** Transient heat transfer analyses of concrete structures can provide useful insight into their structural response when subjected to thermal effects, as for example in the case of exposure to elevated temperatures or when simulating the development of early-age thermal shrinkage. In these situations, the occurrence of concrete cracking can influence the temperature field and this effect needs to be included in the analysis. In early finite element formulations, the development of discrete cracks was based on progressive remeshing strategies to adapt the topology of the mesh and accommodate propagating cracks. It was a computationally demanding strategy, often leading to distorted meshes and inaccurate results. Recent nodal enrichment strategies (XFEM, GFEM) have overcome this drawback. However, in these simulations, the size of the problem increases dramatically with both number and size of cracks, i.e. with the increasing structural damage. In this context, this paper proposes an alternative element enrichment approach that can be efficiently used for transient heat transfer problems in cracked concrete members.

**Keywords:** Finite Elements, Element Enrichment Technique, Fracture Analysis, Transient Heat Transfer.

## 1. Introduction

The need for transient heat transfer analyses of concrete structures can arise in many different situations. For instance, in the case of concrete dams, predicting the heat distribution, and corresponding evolution, is critical for the optimisation of the construction procedure. Assessing the behaviour of a structure when exposed to elevated temperatures, or even predicting the impact of early-age thermal shrinkage on the serviceability behaviour of concrete members, are other examples in which transient heat transfer analyses can be very beneficial. In these situations, the development of accurate models has to take into account the coupling between mechanical behaviour, including possible fracture, and heat transfer analysis.

There are currently different numerical techniques for transient heat transfer problems, either formulated in the time domain (1-4), or in transformed domains (5-7). These procedures have been validated using different numerical discretisations, including finite differences, finite elements, boundary elements and meshless methods (8-11). Among all, the finite element method (FEM) is the most widely used since it easily caters for media with varying properties and different nonlinear features. In its standard form, the finite element model has to accommodate all discontinuities within the underlying mesh, hence thus it requires remeshing algorithms to progressively adapt the topology as cracks propagate or intersect (12). This, however, can lead to severely distorted meshes and inaccurate results without special approaches (13). Nodal enrichment techniques, such as XFEM or GFEM (14-16), entirely avoid this drawback by using additional nodal degrees of freedom directly placed on top of existing nodes and in the neighbourhood of all the cracks. The latter method was successfully applied to heat transfer analyses (17-19), even with heterogeneous domains (20-21). Nevertheless, these algorithms are computationally demanding, particularly when dealing with numerous discontinuities (i.e. when the additional degrees of freedom grow significantly).

This paper presents a preliminary study towards the development of an innovative and more efficient finite element enrichment strategy. The formulation is developed within the scope of the discrete crack approach (22-24) and uses the same variational framework for both mechanical and heat transfer analyses. Cracked finite elements are enriched with additional “rigid body” movements of the displacement field (in the case of the mechanical problem) and temperature field (in the case of the transient heat transfer problem) to account for the presence of strong discontinuities. The compatibility between mechanical and heat transfer formulations creates the possibility of evolving towards the proposal of a thermo-mechanical coupled model for concrete structures, based entirely on element embedded discontinuities.

## 2. Formulation

In this section, the element enrichment approach for simulating the mechanical behaviour of a fractured body is firstly presented. The framework is then extended for transient heat transfer problem.

### 2.1 Mechanical problem

The body  $\Omega$  shown in Fig. 1a is delimited by the external boundary,  $\Gamma$ , and contains an internal discontinuity,  $\Gamma_d$ , which defines two subregions,  $\Omega^+$  and  $\Omega^-$ . Loading is applied slowly, such that the response remains quasi-static, and is composed of body forces,  $\bar{\mathbf{b}}$ , and natural boundary conditions,  $\bar{\mathbf{t}}$ , the latter distributed on part of the external boundary,  $\Gamma_t$ . The essential boundary conditions,  $\bar{\mathbf{u}}$ , are applied on the remaining part,  $\Gamma_u$ , being  $\Gamma = \Gamma_t \cup \Gamma_u$  and  $\emptyset = \Gamma_t \cap \Gamma_u$ . Vector  $\mathbf{n}$  is orthogonal to the boundary surface, pointing outwards, whereas  $\mathbf{n}^+$  is orthogonal to the internal discontinuity and pointing inwards.

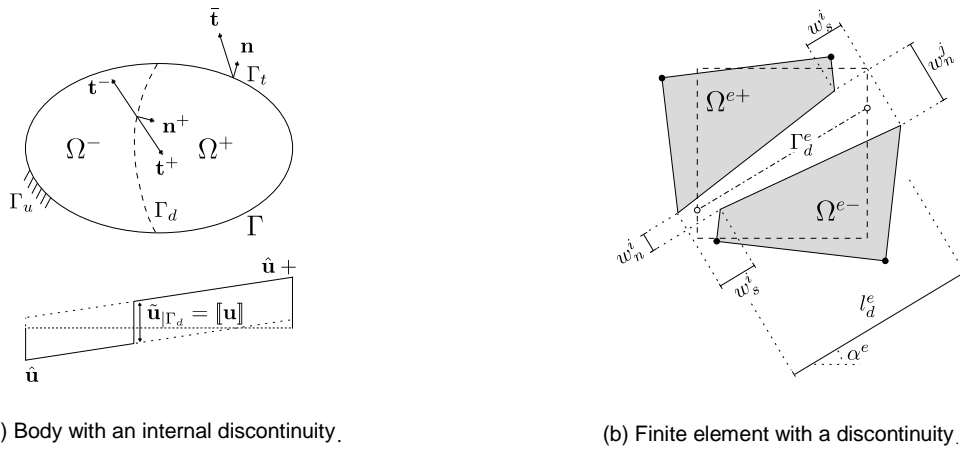

Figure 1. Adopted definitions.

The total displacement at any material point within the body is given by (22-24):

$$\mathbf{u} = \hat{\mathbf{u}} + \mathcal{H}_{\Gamma_d} \tilde{\mathbf{u}}(\mathbf{x}), \quad (1)$$

where  $\hat{\mathbf{u}}$  is the regular displacement field,  $\tilde{\mathbf{u}}$  is the enhanced displacement field solely due to the internal discontinuity, and  $\mathcal{H}_{\Gamma_d}$  is the Heaviside function taking the value 1 in  $\Omega^+$  and 0 otherwise.

The opening of discontinuity  $\mathbf{u}^{+/-}$ , or jump in the displacement field, across the discontinuity is calculated by applying Eq. (1) to both sides of the discontinuity and then equating the difference, which can be expressed as:

$$\mathbf{u}^{+/-} = \mathbf{u}^+ - \mathbf{u}^- = \tilde{\mathbf{u}}(\mathbf{x}_{\Gamma_d}). \quad (2)$$

The equations that govern this mechanical problem are as follows:

$$\nabla \cdot \boldsymbol{\sigma} + \bar{\mathbf{b}} = \mathbf{0} \quad \text{in } \Omega \setminus \Gamma_d, \quad (3)$$

$$\boldsymbol{\varepsilon} = \nabla^s \mathbf{u} \quad \text{in } \Omega \setminus \Gamma_d, \quad (4)$$

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}(\boldsymbol{\varepsilon}) \quad \text{in } \Omega \setminus \Gamma_d, \quad (5)$$

$$\mathbf{u} = \bar{\mathbf{u}} \quad \text{at } \Gamma_u, \quad (6)$$

$$\boldsymbol{\sigma} \cdot \mathbf{n} = \bar{\mathbf{t}} \quad \text{at } \Gamma_t, \quad (7)$$

$$\boldsymbol{\sigma}^+ \cdot \mathbf{n}^+ = \mathbf{t}^- \quad \text{at } \Gamma_d, \quad (8)$$

$$-\boldsymbol{\sigma}^- \cdot \mathbf{n}^+ = \mathbf{t}^- \quad \text{at } \Gamma_d, \quad (9)$$

$$\mathbf{t}^+ = \mathbf{t}(\mathbf{u}^{+-}) \quad \text{at } \Gamma_d, \quad (10)$$

$$\mathbf{t}^+ = \mathbf{t}^- \quad \text{at } \Gamma_d, \quad (11)$$

being  $\mathbf{t}^+$  and  $\mathbf{t}^-$  the traction vectors at the discontinuity, respectively, on each side of the domain. The internal equilibrium is imposed by Eq. (3), whereas external and internal equilibrium are enforced by Eqs. (6), (7) and (11). The kinematic compatibility and constitutive laws are represented by Eqs. (4), and Eqs. (5) and (10).

The principle of virtual work for the cracked body can be seen as a particular case of the Hu and Washizu principle (25-27), where the independent unknown fields are  $\mathbf{u}$  and  $\mathbf{u}^{+-}$ . In this case the following variational equation applies:

$$-\int_{\Omega \setminus \Gamma_d} \delta \mathbf{u} \cdot (\nabla \cdot \boldsymbol{\sigma} + \bar{\mathbf{b}}) d\Omega + \int_{\Gamma_t} \delta \mathbf{u} \cdot (\boldsymbol{\sigma} \cdot \mathbf{n} - \bar{\mathbf{t}}) d\Gamma - \int_{\Gamma_d} \delta \mathbf{u}^{+-} \cdot (\boldsymbol{\sigma}^+ \cdot \mathbf{n}^+ - \mathbf{t}^+) d\Gamma = 0. \quad (12)$$

The first term of Eq. (12) can be expanded and integrated by parts, and after applying the Gauss theorem, the following equation is written:

$$-\int_{\Omega \setminus \Gamma_d} \nabla^s \delta \mathbf{u} : \boldsymbol{\sigma} d\Omega - \int_{\Gamma_d} \delta \mathbf{u}^{+-} \cdot \mathbf{t}^+ d\Gamma + \int_{\Omega \setminus \Gamma_d} \delta \mathbf{u} \cdot \bar{\mathbf{b}} d\Omega + \int_{\Gamma_t} \delta \mathbf{u} \cdot \bar{\mathbf{t}} d\Gamma = 0, \quad (13)$$

which is the classic virtual work principle for a medium with a discontinuity (28).

If the body is now discretised into a certain number of finite elements (as illustrated in Fig. 1b), the displacement field within each element is interpolated by (24):

$$\mathbf{u}^e = \mathbf{N}^e(\mathbf{x}) \left[ \mathbf{a}^e + \left( \mathcal{H}_{\Gamma_d} \mathbf{I} - \mathbf{H}_{\Gamma_d}^e \right) \tilde{\mathbf{a}}^e \right] \quad \text{in } \Omega^e \setminus \Gamma_d^e, \quad (14)$$

where  $\mathbf{a}^e$  are the total nodal displacements,  $\tilde{\mathbf{a}}^e$  are the nodal displacements due to the discontinuity,  $\mathbf{I}$  is the identity matrix,  $\mathbf{N}^e$  are the shape functions of the element, and  $\mathbf{H}_{\Gamma_d}^e$  is a diagonal matrix containing the Heaviside function evaluated at each regular degree of freedom of the element.

The enhanced nodal displacements result directly from assuming that the movement of  $\Omega^{e+}$  over  $\Omega^{e-}$  is a rigid body motion (22, 24). According to this:

$$\tilde{\mathbf{a}}^e = \mathbf{M}_w^{ek} \mathbf{w}^e, \quad (15)$$

where  $\mathbf{w}^e$  is a vector containing the jumps at additional nodes placed at both extremities of the discontinuity ('i' and 'j' in Fig. 1b), and  $\mathbf{M}_w^{ek}$  is the matrix transmitting the displacement due to the opening of the discontinuity, being calculated by evaluating  $\mathbf{M}_w^e$  at each node and then stacking it into rows:

$$\mathbf{M}_w^e(\mathbf{x}) = \begin{bmatrix} 1 - \frac{(x_2 - x_2^i) \sin \alpha^e}{l_d^e} & \frac{(x_2 - x_2^i) \cos \alpha^e}{l_d^e} & \frac{(x_2 - x_2^i) \sin \alpha^e}{l_d^e} & \frac{(x_2 - x_2^i) \cos \alpha^e}{l_d^e} \\ \frac{(x_1 - x_1^i) \sin \alpha^e}{l_d^e} & 1 - \frac{(x_1 - x_1^i) \cos \alpha^e}{l_d^e} & -\frac{(x_1 - x_1^i) \sin \alpha^e}{l_d^e} & \frac{(x_1 - x_1^i) \cos \alpha^e}{l_d^e} \end{bmatrix}. \quad (16)$$

The opening of the discontinuity is calculated by either using Eqs. (14) and (15), or by direct interpolation of the nodal jumps:

$$\mathbf{u}^{e+/-} = \mathbf{N}^e \mathbf{M}_w^{ek} \mathbf{w}^e = \mathbf{N}_w^e \mathbf{w}^e \quad \text{at } \Gamma_d^e, \quad (17)$$

where  $\mathbf{N}_w^e$  are the interpolation shape functions defined using the two additional nodes.

The stress within the element is incrementally given by:

$$d\boldsymbol{\sigma}^e = \mathbf{D}^e \mathbf{B}^e (d\mathbf{a}^e - \mathbf{H}_{\Gamma_d^e}^e \mathbf{M}_w^{ek} d\mathbf{w}^e) \quad \text{in } \Omega^e \setminus \Gamma_d^e, \quad (18)$$

$$d\mathbf{t}^{e+} = \mathbf{T}^e d\mathbf{u}^{e+/-} = \mathbf{T}^e \mathbf{N}_w^e d\mathbf{w}^e \quad \text{at } \Gamma_d^e, \quad (19)$$

where  $\mathbf{B}^e$  is the strain-nodal displacement matrix, and  $\mathbf{D}^e$  and  $\mathbf{T}^e$  are the linearised constitutive matrices for bulk and discontinuity, respectively.

Finally, Eqs. (14) and (17) to (19) are inserted into Eq. (13), leading to the following discretised set:

$$\mathbf{K}_{\hat{a}\hat{a}}^e d\mathbf{a}^e - \mathbf{K}_{aw}^e d\mathbf{w}^e = d\hat{\mathbf{f}}^e = \int_{\Omega^e \setminus \Gamma_d^e} \mathbf{N}^{eT} d\bar{\mathbf{b}}^e d\Omega^e + \int_{\Gamma_d^e} \mathbf{N}^{eT} d\bar{\mathbf{t}}^e d\Gamma^e, \quad (20)$$

$$-\mathbf{K}_{wa}^e d\mathbf{a}^e + (\mathbf{K}_{ww}^e + \mathbf{K}_d^e) d\mathbf{w}^e = d\mathbf{f}_w^e - (\mathbf{H}_{\Gamma_d^e}^e \mathbf{M}_w^{ek})^T d\hat{\mathbf{f}}^e, \quad (21)$$

where  $\mathbf{K}_{\hat{a}\hat{a}}^e = \int_{\Omega^e \setminus \Gamma_d^e} \mathbf{B}^{eT} \mathbf{D}^e \mathbf{B}^e d\Omega^e$ ,  $\mathbf{K}_{aw}^e = \int_{\Omega^e \setminus \Gamma_d^e} \mathbf{B}^{eT} \mathbf{D}^e \mathbf{B}_w^e d\Omega^e$ ,  $\mathbf{K}_{wa}^e = \mathbf{K}_{aw}^{eT}$ ,  $\mathbf{K}_{ww}^e = \int_{\Omega^e \setminus \Gamma_d^e} \mathbf{B}_w^{eT} \mathbf{D}^e \mathbf{B}_w^e d\Omega^e$ , and

$$\mathbf{B}_w^e = \mathbf{B} \mathbf{H}_{\Gamma_d^e}^e \mathbf{M}_w^{ek}.$$

It is worth pointing out that: i) when all forces are applied at the nodes, it can be shown that  $d\mathbf{f}_w^e - (\mathbf{H}_{\Gamma_d^e}^e \mathbf{M}_w^{ek})^T d\hat{\mathbf{f}}^e = \mathbf{0}$ ; and ii) only three degrees of freedom are required per element due to the rigid body movement assumption. Since the available degrees of freedom are indeed four (i.e. two nodes placed on the edges of the discontinuity) an additional constraint assures that the shear along the discontinuity remains constant. This is herein done by simply adding the following penalty matrix to  $\mathbf{K}_d^e$  (where  $w_p$  is the chosen penalty weight):

$$\mathbf{K}_p^e = \frac{w_p}{2} \begin{bmatrix} 1 + \cos(2\alpha^e) & \sin(2\alpha^e) & -1 - \cos(2\alpha^e) & -\sin(2\alpha^e) \\ \sin(2\alpha^e) & 1 - \cos(2\alpha^e) & -\sin(2\alpha^e) & -1 + \cos(2\alpha^e) \\ -1 - \cos(2\alpha^e) & -\sin(2\alpha^e) & 1 + \cos(2\alpha^e) & \sin(2\alpha^e) \\ -\sin(2\alpha^e) & -1 + \cos(2\alpha^e) & \sin(2\alpha^e) & 1 - \cos(2\alpha^e) \end{bmatrix}. \quad (22)$$

## 2.2 Transient heat transfer problem

This section describes the formulation for transient heat transfer. For this purpose, the body is now subjected to internal heat generated at a certain rate,  $\mathbf{g}$ , and to temperature,  $\bar{T}$ , and heat flux,  $\mathbf{q}_n$ ,

applied at the external boundaries  $\Gamma_T$  and  $\Gamma_q$ , respectively. With the adopted notation,  $\Gamma = \Gamma_T \cup \Gamma_q$  and  $\emptyset = \Gamma_T \cap \Gamma_q$ , while the internal discontinuity,  $\Gamma_d$ , divides the body into two subdomains,  $\Omega^+$  and  $\Omega^-$ .

The governing field equations in the strong form are:

$$\rho C_p \frac{\partial T}{\partial t} + \nabla \mathbf{q} = \mathbf{g} \quad \text{in } \Omega \setminus \Gamma_d, \quad (23)$$

$$\mathbf{q} = -k \nabla T \quad \text{in } \Omega \setminus \Gamma_d, \quad (24)$$

with corresponding boundary conditions:

$$T = \bar{T} \quad \text{at } \Gamma_t, \quad (25)$$

$$-\mathbf{q}^T \hat{\mathbf{n}} = q_n \quad \text{at } \Gamma_d, \quad (26)$$

$$0 = q_d \quad \text{at } \Gamma_d, \quad (27)$$

where  $\rho$  is the density of the material,  $C_p$  is the specific heat and  $k$  is the thermal conductivity.

The derivation of the mechanical formulation in the previous section can be easily reapplied to derive the discretised set of equations for the transient heat transfer problem, as is therefore omitted. It should be highlighted that the common framework used in the derivations assures compatibility between models.

### 3. Implementation

In the example discussed in the next section, mechanical and heat transfer problems are dealt with independently. The purpose is to gain a first insight on the performance of the embedded formulation for heat transfer analysis and to assess the feasibility of further extending it to a fully coupled thermo-mechanical model.

According to the adopted methodology, the mechanical analysis is first used to characterise the damaged state of the structure and corresponding crack pattern. In this stage, a discontinuity is assumed to always cross an entire finite element, being the additional degrees of freedom placed at the extremities (as represented by nodes 'i' and 'j' in Fig. 1b). An existing crack is propagated whenever the stress at the tip reaches the tensile strength of the material, with propagation angle orthogonal to the first principal stress.

After the mechanical analysis stage, heat transfer analysis is carried out independently for selected time steps with the underlying geometry defined in the mechanical analysis. A generic implicit solution scheme, known as Crank-Nicholson method, is used to then solve for the transient problem.

### 4. Single edge notched beam

This section uses the single edge notched beam benchmark test by Schlangen (29). The beam was  $400 \times 100 \times 100 \text{ mm}^3$  and had a notch located at the top with  $5 \times 20 \text{ mm}^2$ , as illustrated in Fig. 2a.

#### 4.1 Mechanical behaviour

The simulation of the behaviour of the single-edge notched beam until failure is herein presented and the complexity of the adopted constitutive models is kept to a minimum. The bulk is considered linear elastic with the following parameters: Young's modulus  $E = 35 \text{ GPa}$ ; Poisson ratio  $\nu = 0.15$ ; tensile strength  $f_t = 3.0 \text{ MPa}$ . The non-linear behaviour is solely due to the presence of discontinuities, which are modelled using a non-isotropic constitutive law from (30), with fracture energy  $G_F = 0.1 \text{ N/mm}$ , normal stiffness  $k_n = 10^5 \text{ N/mm}^3$  and shear stiffness  $k_s = 4 \times 10^2 \text{ N/mm}^3$ .

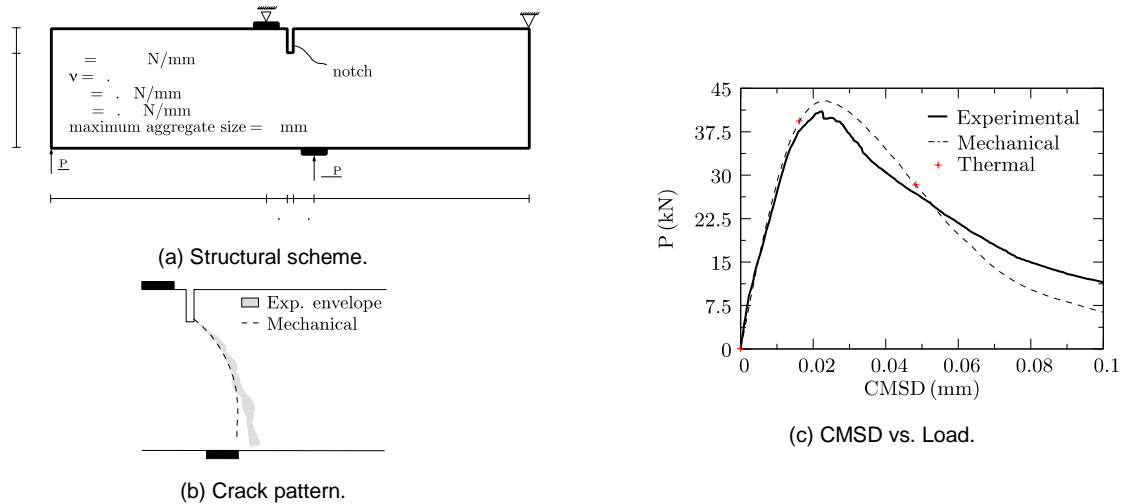

The loading procedure is controlled using the arc-length method, where the relative sliding displacement of the notch (CMSD) is monotonically increased. The discontinuity is propagated from the notch following the procedure detailed in Section 3.

The corresponding CMSD vs. load curve and crack path are shown in Figs. 2b-c, where it can be observed the good agreement between numerical and experimental results despite the simple constitutive representations specified in the modelling, highlighting that the structural response is predominantly governed by the development of the discontinuity. Near the support, the crack deflects towards the support due to the localised high gradients. These results could be further improved by adopting a more refined model.

#### 4.2 Heat transfer analysis

The proposed algorithm is now applied to simulation of transient heat transfer within the beam at different stages. A prescribed heating curve is imposed at the top left surface, as identified in Fig. 3, whereas null normal flux is specified at all remaining edges. The domain is assumed to have a constant density of  $2500 \text{ kg/m}^3$ , a conductivity of  $1.4 \text{ W/m}^\circ\text{K}$  and a specific heat of  $840 \text{ J/kg}^\circ\text{K}$ . A constant time step of  $100 \text{ s}$  is adopted for all calculations.

**Figure 2. Single edge notched beam.**

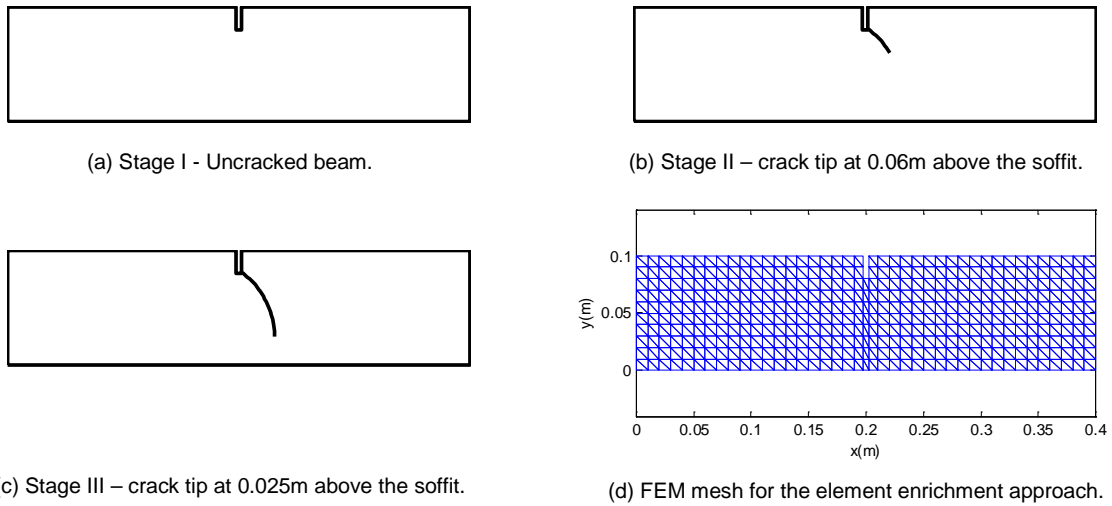

The three different stages of crack propagation previously identified on Fig. 2c, and characterised in Figs. 4a-d, are selected to illustrate the performance of the formulation and the impact of the crack length on both internal and surface temperature distributions of the beam. The same underlying FEM mesh is used throughout the analysis, being the discontinuities embedded using the technique described earlier in Section 2.

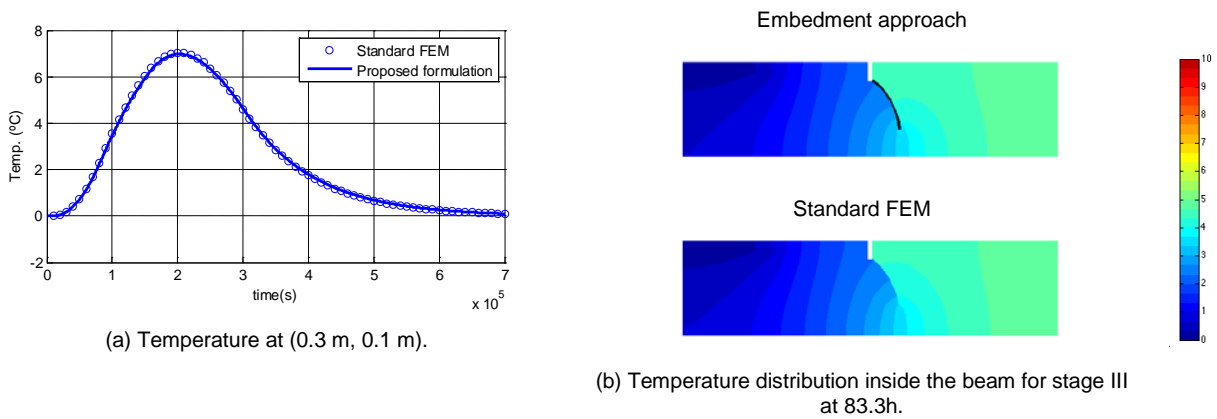

**Figure 3. Definition of the heat transfer problem.**

To first assess the accuracy of the proposed method in comparison with standard FEM, an additional FEM mesh with the crack fully discretised is considered in stage III. Fig. 5a shows the comparison between temperatures measured at a certain nodal location using both models, whereas Fig. 5b shows the internal temperature distribution at 83.3h. It is highlighted the good agreement between both approaches.

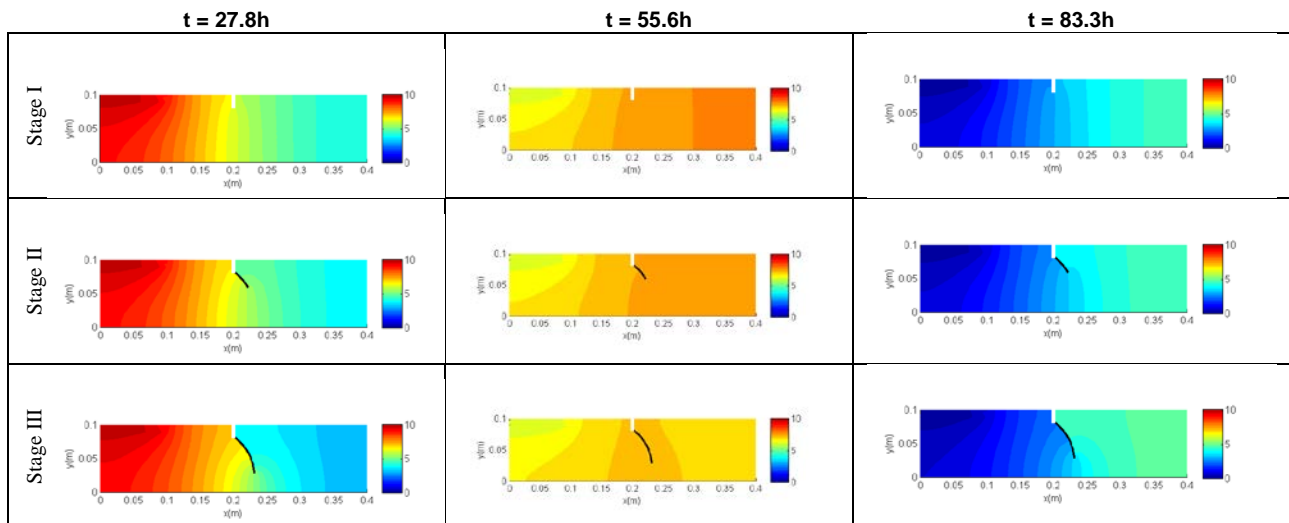

Following this preliminary validation, the internal temperature distribution is calculated for different time steps, i.e. 27.8h, 55.6h and 83.3h, and for all three stages. Fig. 6 shows the corresponding patterns.

**Figure 4. Stages of analysis.**

**Figure 5. Comparison between standard FEM and proposed embedment method.**

**Figure 6. Map of temperature distribution inside the beam for stages I, II and III.**

Fig. 6 clearly shows that the presence of the embedded discontinuity, across which there is no heat flux, modifies the temperature distribution by directing the heat flow towards the region between the soffit and the crack tip. As expected, this effect is more important as the crack extends, i.e. from Stages I to III.

Fig. 7 illustrates the variation of the peak temperature registered at the top edge of the beam. In particular, the maximum temperature decays exponentially in stage I between the heating source and the top-right corner. The notch can be identified by a sudden temperature drop which occurs at 0.2 m. As soon as the crack extends, the temperature drop becomes even higher. In fact, the presence of the crack severely restrains the heat flux along the beam. For this reason, when compared with Stage I, the maximum temperature on the top edge, between heat source and notch, tends to be higher. Opposite trend is observed moving away from the notch. In Stage III, the maximum temperature at the right side of the notch and on the top edge reaches a value which is about 70% of the prescribed maximum temperature and nearly constant throughout.

**Figure 7. Maximum temperature reached at the top edge of the beam.**

## 5. Conclusions

This paper presented a preliminary study on a new element enrichment approach for simulation of transient heat transfer problems in concrete structures. The formulation was derived in the scope of the discrete crack approach with the same variational framework for both mechanical and heat transfer analyses. According to the new formulation, the elements crossed by the discontinuity were directly enriched with the minimum kinematic degrees associated with the “rigid body” movement between the two sides of the discontinuity. This is a very effective way of embedding strong discontinuities on the displacement field, in the case of the mechanical problem, and on the temperature field, in the case of transient heat transfer problem.

In this study, both mechanical and heat transfer simulations were performed independently and their accuracy was evaluated against results obtained from known solutions. In particular, in the case of the heat transfer analysis, calculated values showed good agreement with those obtained using standard FEM, although avoiding the need for remeshing algorithms. The new embedded approach significantly decreased the number of additional degrees of freedom required in the analysis, particularly when compared to other existing nodal enrichment approaches, and adequately represented the thermal response on the entire domain of analysis. The proposed approach, in which discontinuities are described by means of embedded discontinuities, provides the basis for the development of a thermo-mechanical coupled model for the simulation of concrete structures.

# In-plane behavior of unbonded post-tensioned concrete walls

Reza Hassanli<sup>1</sup>

PhD Student, School of Natural and Built Environments, University of South Australia

**Abstract:** In this study the behavior of unbonded post-tensioned concrete walls is investigated using experimental results. The displacement ductility of unbonded post-tensioned concrete walls is studied and the general behavior of PT-CWs is examined. The accuracy of an analytical approach to predict the force-displacement response of such walls is investigated using experimental results. The analytical method considers displacement compatibility and geometric compatibility conditions. According to the results, the approach can successfully predict the lateral strength, stiffness and neutral axis depth and the general behavior of the test walls, hence, is recommended to be considered for design purposes.

**Keywords:** post-tensioned, concrete walls, ductility, force-displacement, stiffness, unbonded

## 1. Introduction

Due to rocking mechanism, the rotation of the unbonded post-tensioned walls occurs mainly at the wall footing interface. Unbonded post-tensioning induces self-centering behavior to the structural systems and accordingly helps to eliminate or reduce the residual drifts and limits the structural damages [1-9]; hence, the system maintains its integrity following a ground excitation event. Moreover, the damage zone is limited to the walls' toe and the repair cost is minimal [5-6].

The seismic behavior of unbonded post-tensioned concrete walls (PT-CW) is not yet well understood and the ductility and force displacement response of these walls are needed to be more studied.

In this study, a total of 32 unbonded post-tensioned concrete walls (PT-CW) were collected as the experimental database. All the walls were tested by Henry [1-3] and the specifications are provided in Table 1. The walls were tested under monotonic lateral displacement applied to the top of the walls.

This study use the experimental test results to:

- i) Investigate the accuracy of an analytical approach to predict the force-displacement behavior of PT-CWs.
- ii) Study the ductility of PT-CWs

## 2. Analytical model

An analytical approach is employed to predict the force displacement response of wall specimens. The approach was developed based on mechanics of rocking walls and considers displacement and geometric compatibility conditions. The accuracy of the method has been validated against experimental results of unbonded post-tensioned masonry walls (PT-MWs) [10-11]. In this section the effectiveness of the approach to predict the force-displacement response of unbonded PT-CWs based on experimental results is investigated. The steps of the approach are not presented here due to space limitations and can be found in the referenced article [12]. Eight walls (series E and F) tested by Henry [1] (Table 1) were considered for validation. These walls were selected as they were the only specimens for which reliable strain measurements were reported [1].

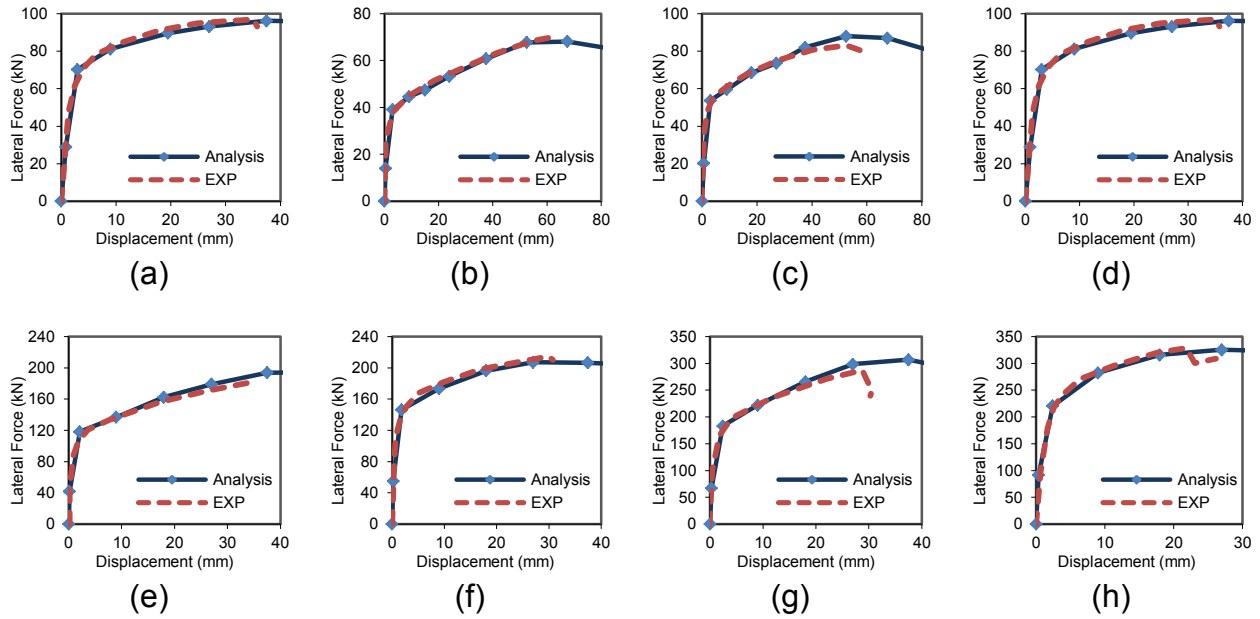

Figure 1 compares the lateral force-displacement curves determined using the analytical approach and the results obtained during the experimental work. As shown in the figures, the model can correctly predict the wall strength, initial stiffness and rotational capacity. The model can also capture the displacement recorded at the peak strength.

\* $h_e$ : wall effective height,  $b_w$ : wall thickness,  $l_w$ : wall length,  $f'_c$ : concrete compressive strength  
 $f_c$ : axial stress on the wall,  $f_{py}$ : yield stress of pre-stressing steel

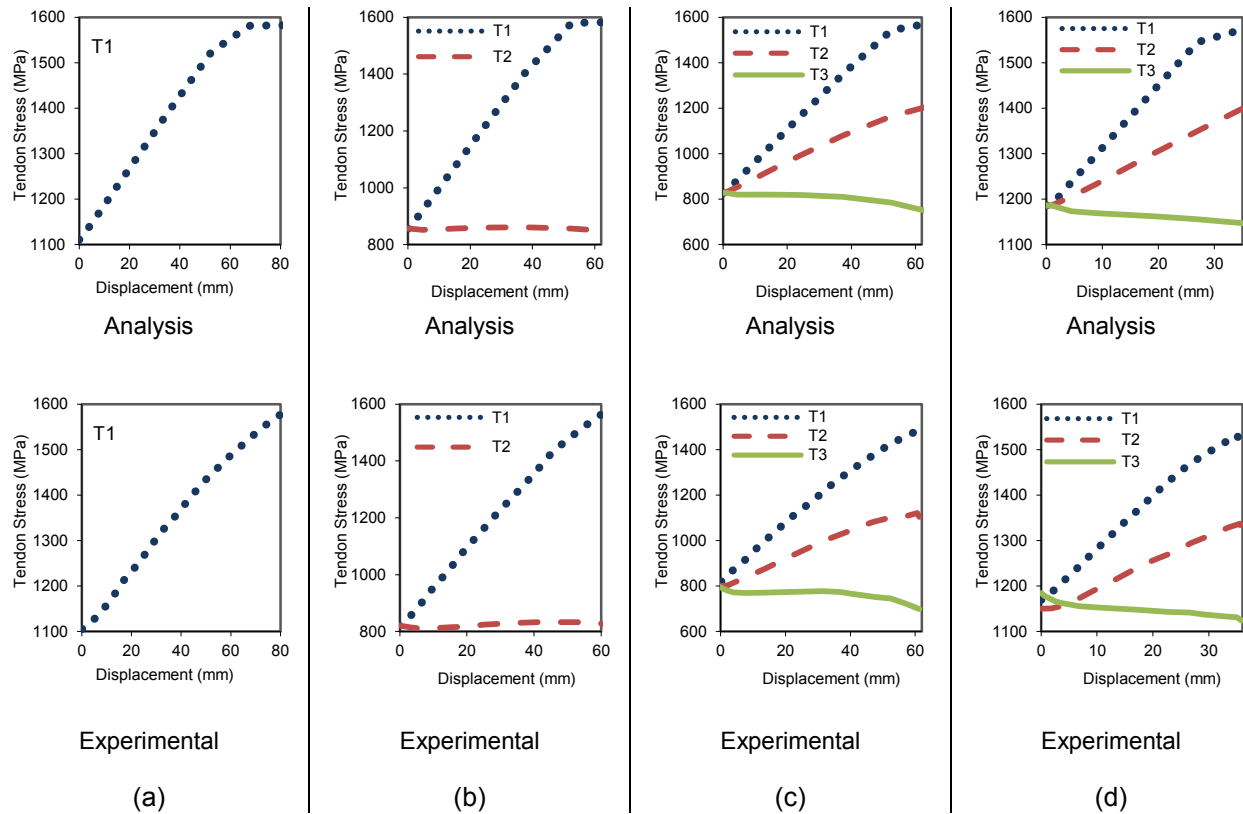

**Figure 1. Comparison of the experimental and analytical force displacement curves of walls (a)Ei, (b)Eii, (c) Eii, (d) Eiv (e) Fi, (f) Fii, (g) Fii, and (h) Fiv**

Table 2 compares the strength of the walls obtained from the experimental work,  $V_{EXP}$ , with the strength obtained from the analytical approach,  $V_{Analysis}$ . As presented in the table, the analytical approach could accurately predict the strength of the walls. According to the table, the predicted strength of the specimens using the analytical approach falls within  $\pm 6\%$  of the test results.

**Table 2. Prediction of the strength using analytical approach**

	Ei	Eii	Eiii	Eiv	Fi	Fii	Fiii	Fiv
$V_{Analysis}$	36.4	68.1	88.0	96.2	195.0	207.1	306.7	325.2
$V_{EXP}$	38.4	69.9	83.1	96.9	182.4	214.7	287.2	328.4

Figures 2 and 3 compares the force developed in the Tendons obtained from the experimental work and analytical approach for series E and F of tested walls, respectively.  $T_i$  is the force in the tendon  $i$ . As shown, the analytical approach could effectively predict the force developed in tendons in different drift ratios. According to Figure 2 and Figure 3, in general the analytical model demonstrated a reasonable correlation with the experimental results, but slightly overestimated the force in some tendons. This can be attributed to the losses occurred in the tendons during testing.

**Figure 2. Force in tendons of series E of walls (a) Ei, (b) Eii, (c) Eiii , and (d) Eiv**

Figure 4 compares the neutral axis depth obtained from analytical approach and recorded during the experimental work. In general, the analytical model provides a reasonable correlation with the experimental data. However, for small displacement, the analytical approach tends to underestimate the neutral axis depth.

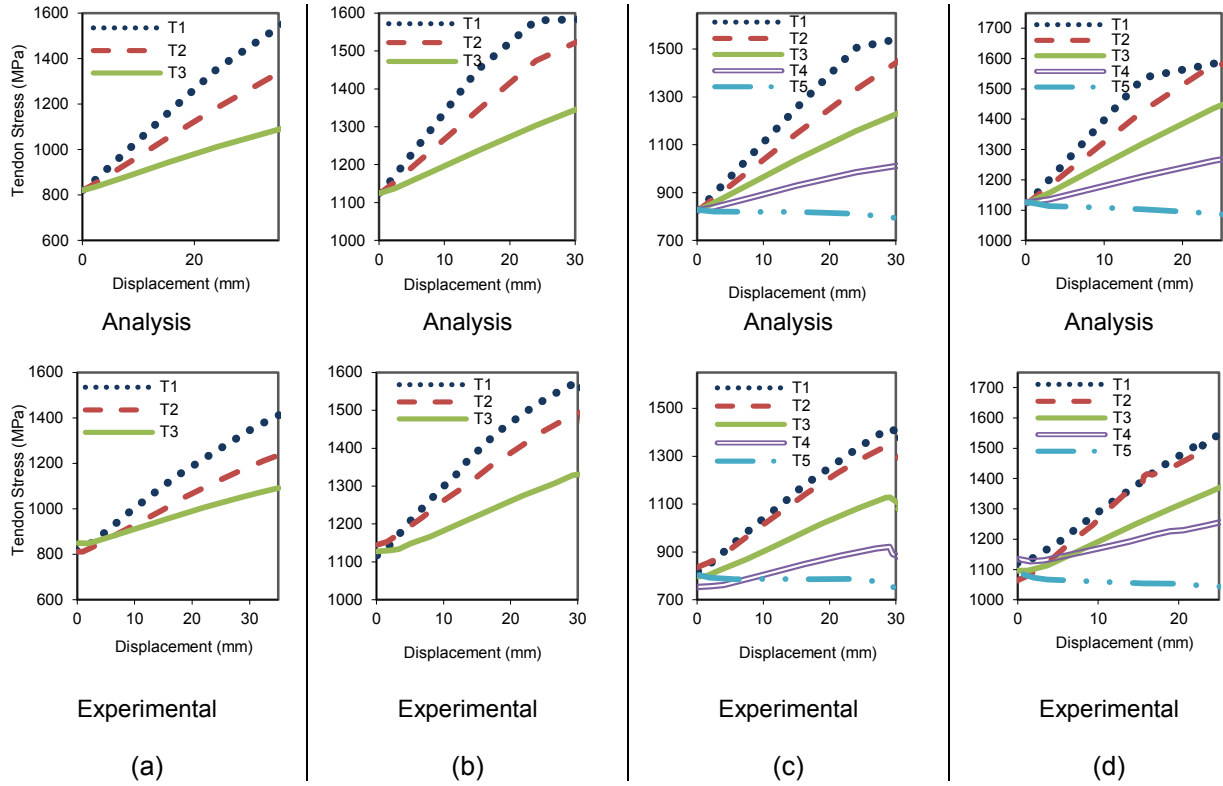

Figure 3. Force in tendons of series F of walls (a) Fi, (b) Fii, (c) Fiii, and (d) Fiv

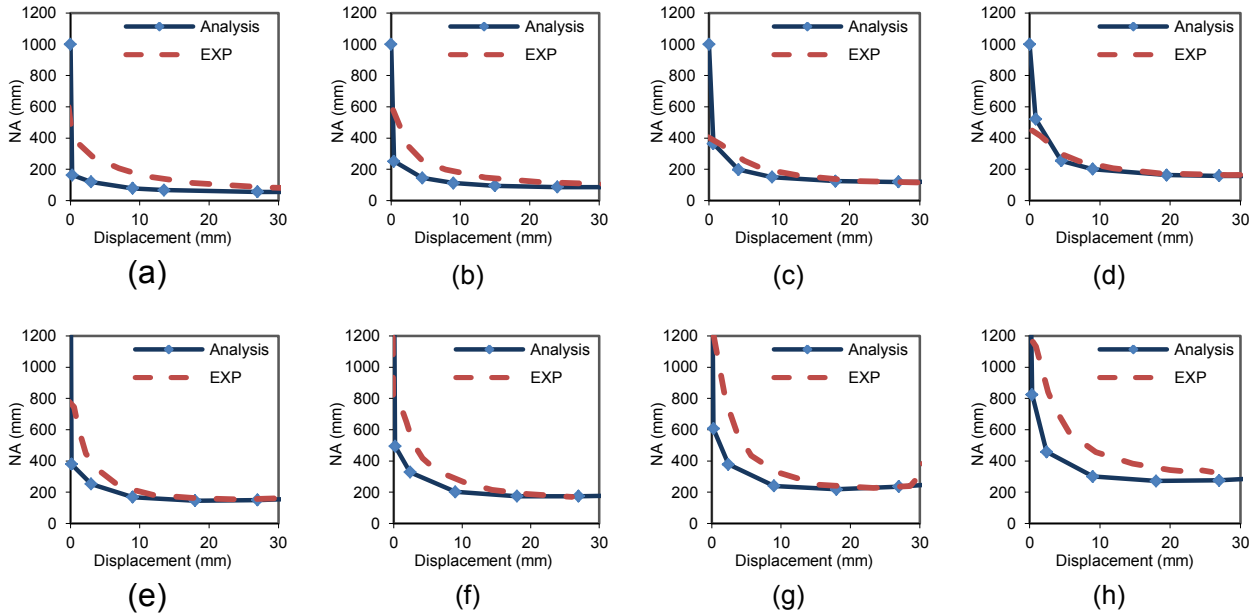

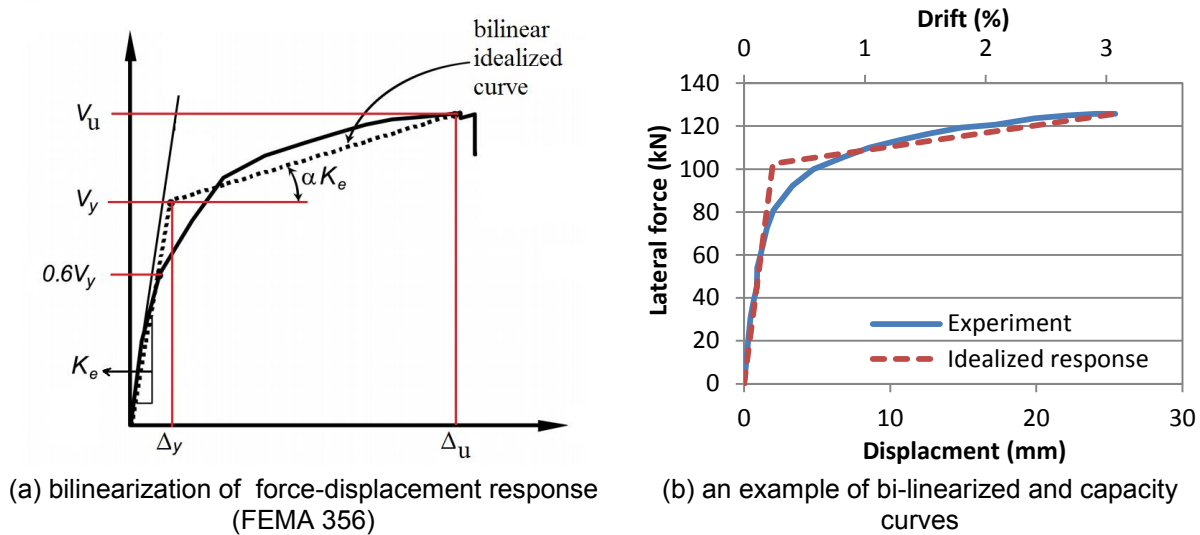

Figure 4. Neutral axis depth in, Analysis versus Experimental, of walls (a) Ei, (b) Eii, (c) Eii, (d) Eiv (e) Fi, (f) Fii, (g) Fiii, and (h) Fiv

### 3. Displacement ductility

The wall specimens presented in Table 1 are considered to investigate the seismic response of PT-CWs. Bilinear approximation of the force-displacement response is used to calculate the displacement ductility,  $\mu$ . The procedure provided by FEMA 356 [13] for force-displacement response with positive post-yield slope is used to obtain the idealized bilinear curves. As shown in Figure 5(a), the ultimate displacement,  $\Delta_u$ , is the displacement at the peak strength,  $V_u$ , and  $f_y$  and  $\Delta_y$  are the effective yield strength and yield displacement, and  $K_e$  and  $\alpha K_e$  are the effective yield and post-yield stiffness, respectively. Iterative procedure was used to determine the bilinear idealized curves. According to FEMA 356 [13], the idealized relationship can be determined by balancing the area above and under the capacity curve. The idealized and actual curve should also intersect at strength of  $0.6V_y$ . An example of bilinear approximation of the load displacement curve of the tested specimens is shown in Figure 5(b). As showed in Figure 5(b), the unbonded PT walls provide approximately a bilinear elastic response. Similar bi-linear elastic responses were also observed for the rest of the wall specimens of the database.

**Figure 5. Bi-linearization of the capacity curve**

Table 3 presents the parameters determined from bilinearization of the capacity curves of the test specimens. In this table  $\mu$  is the displacement ductility defined as  $\Delta_u/\Delta_y$ . As presented in the table, the considered walls presented a wide range of ductility, ranging between 7.1 and 74.8, with an average of 28.6.

In terms of ductility, of all parameters axial stress ratio seems to be the most critical one. Figure 6 presents the calculated ductility versus axial stress ratio,  $f_c/f'_c$ . The general trend of data in Figure 6 illustrates that ductility of unbonded PT-CWs is highly dependent on the axial stress ratio. Using regression analysis of ductility values of the wall specimens, the following expression is obtained to estimate the ductility of the unbonded PT-CWs.

$$\mu = 1.7 \frac{f'_c}{f_c} \quad (1)$$

Note that some of the specimens of wall test group A, presented in the Table 1, reported to have immature failure, hence, this group has been removed from analysis. The correlation between the data set and Equation 40 in Figure 10 indicates that in unbonded PT-CWs ductility is inversely proportional to the level of axial stress ratio.

Figure 6. Ductility versus axial stress ratio,  $f_c/f'_c$

#### 4. Conclusions

- The analytical approach employed in the paper could accurately predict the lateral force behavior of unbonded PT-CWs. The wall strength calculated using the analytical approach was within 6% of the experimental results. Moreover, the analytical approach could effectively predict the force developed in post-tensioned bars in different drift ratios. It could also predict the wall initial stiffness and rotational capacity.
- The ductility of unbonded PT-CWs are highly dependent on the level of axial stress ratio.
- An increase in the axial stress ratio results in a decrease in ductility. The following equation is proposed to evaluate the displacement ductility of an unbonded PT-CW:  $\mu = 1.7 \frac{f'_c}{f_c}$

## Abstract

The Australian Standard AS2870 Residential slabs and footings – Construction was first published in 1986 and is now in its 4<sup>th</sup> edition. The scope of this standard is generally limited to single dwelling houses or multiple townhouse developments and buildings classified as Class 1 and 10a under the BCA (3) but can be applied to commercial and industrial buildings if they are similar to houses in size, loading and superstructure flexibility. However, the unilateral application of AS2870 to large industrial buildings is problematic in terms of technical relevance and practicality given the significant differences in serviceability requirements, loadings and economics associated with larger plan area buildings as compared to housing or smaller scale Class 10a buildings.

This paper focuses on the engineering principles involved in the design of slabs and footing systems for larger commercial and industrial buildings such as situated in the highly reactive clay sites NW of Melbourne and western Sydney. Particular emphasis is placed on soil structure interaction, site characteristics, displacement sensitivity and the practicalities of footing system alternatives for large commercial and industrial buildings. Examples are presented to compare footing system solutions based on misapplication of AS2870 principles compared to systems based on fundamental geotechnical and building serviceability principles.

*Keywords:* Industrial footing systems reactive clay

## 1.0 Introduction

There is no independent Australian design guideline or standard that deals specifically with the design and construction of concrete slab and footing systems for large industrial and commercial buildings. The Australian Standard AS2870 - 2011 Residential slabs and footings (1) is often referred to in geotechnical reports and in legal expert reports as having relevance to these forms of slab and footing systems.

This paper details a number of technical issues and concepts that need to be addressed by the design and construction industry when considering the relevance of AS2870 to the design of concrete slab and footing systems for large industrial and commercial buildings and in particular those slab and footing systems constructed on reactive clay sites.

## 2.0 Practical issues – discussion

### 2.1 Serviceability

Most soils exhibit some form of reactivity (i.e. change in volume as the soil moisture changes), such as would occur throughout the year. These movements cannot be prevented but appropriate attention to design and construction details can go a long way to minimise their impact on a structure

The usual form of construction for industrial and commercial buildings differs from that for residential buildings. In the case of large industrial and commercial buildings the more common forms of construction generally involve the use of large open plan areas, highly articulated precast concrete facades, metal clad walls, glazing systems, and suspended ceiling and partition wall systems. In the case of residential buildings, the more common forms of construction still used in Australia involve the use of brick and brick veneer facades with limited articulation and plasterboard clad stud walls generally constructed with fixed plaster cornices at wall/ceiling junctions resulting in no internal wall articulation. In addition residential buildings typically have much smaller plan areas and as such

residential structures are far more visually susceptible to soil reactivity induced movements than large area industrial and commercial forms of construction.

## 2.2 Forms of construction

Large plan area industrial buildings constructed to accommodate modern warehousing and distribution materials handling requirements commonly require that floor slab construction be built to very tight levelness tolerance and high standards of finish. As such these floors are commonly constructed in relatively large areas using laser guided equipment and are generally articulated (i.e. jointed) in such a way as to minimize restraint to concrete shrinkage that might result in uncontrolled cracking. On the other hand, residential construction generally utilizes ribbed or stiffened raft slab construction to minimize slab distortion that could result in superstructure cracking. Such construction however often results in restraint to shrinkage (at the stiffening ribs) that generally results in slab cracking, albeit that such cracking is usually covered and hidden by non-brittle floor finishes.

Large industrial facilities often involve the construction of office space as part of the overall large area building footprint. Whilst these may be considered similar to a house and fall within the auspices of AS2870, these office areas may be relatively large in area and of multi-level construction resulting in higher wall or column loads in comparison to typical loadings for residential buildings. The office areas associated with industrial facilities are generally more open plan than residential buildings. The internal partitions that are provided are often of the demountable type and not fixed to the ceiling in the same manner as for residential buildings (i.e. no fixed cornices).

## 2.3 Construction methodology

The large spans of industrial and commercial buildings require the use of steel frame construction which is commonly incorporated with precast concrete and metal clad walls or glazed facades. Where site access allows, it is common practice to initially erect the steel framing, the roof cladding and then erect and fix the façade elements. This order of construction allows for the floor slab construction to be undertaken very late in the construction program and therefore in the protected environment which is required in order to achieve the higher level of finish required for warehouse floors. It does require however that footings for the columns and walls are constructed early and well in advance of floor construction whereas residential floor slabs are generally much smaller in area and constructed in the open air with the balance of the superstructure supported directly from the slab.

## 2.4 Economics and optimal performance

From an overall community point of view the cost of failures of footing systems should ideally be balanced against the costs of excessive construction and design costs (2) and as such the performance requirements and expectations should not be unrealistic. This issue is recognised in AS2870 which states at clause 1.3.1 that "*Buildings supported by footing systems designed and constructed in accordance with this Standard on a normal site that is (a) not subject to abnormal moisture conditions; and (b) maintained such that the original site classification remains valid and abnormal moisture conditions do not develop; are expected to experience usually no damage, a low incidence of damage category 1 and an occasional incidence of damage category 2*" and at clause 1.4.2 "*Foundation movement shall be assessed as the movement that has less than 5% chance of being exceeded in the life of the building, which is taken as 50 years*".

Further to the above, AS2870 Appendix B includes information on foundation performance and maintenance which expresses an expectation of some damage (cracking) occurring to residential buildings. At clause B1 AS2870 notes "*it is neither practicable nor economical to design for the extreme conditions that could occur in the foundation if a site is not properly maintained*" and "*some minor cracking and movement will occur in a significant proportion of buildings, particularly those on reactive clays*". AS2870 places a maintenance requirement on owners that involves attention to site drainage, limitations on gardens, restriction on the planting of trees and the need to repair leaking services, etc. all of which are applicable to industrial and commercial buildings.

In some regard it is not unreasonable to expect that a higher standard of maintenance on commercial and industrial properties would occur than would for a residential property. Also given the larger allotment sizes involved with industrial facilities as compared to residential subdivision should result in far less detrimental influences emanating from neighbouring properties (i.e. neighbours trees and poor neighbouring drainage control).

### 3.0 Technical issues – discussion

#### 3.1 Engineering design principles for reactive sites – residential buildings

AS2870 places emphasis on the use or modification of standard designs for residential buildings which are based on typical forms of residential construction and loading. However, the Standard also includes provisions for design by engineering principles which are primarily based around soil structure interaction through an idealized “soil mound” model. (i.e. it is assumed that more stable soil moisture conditions exist beneath the centre of the slab than at the edges). The idealized soil mound shapes in AS2870 represent the range of ground movement that could be expected over the life of the structure, on normal sites not subject to abnormal moisture conditions. In the case of central heave, the mounding is the result of an increase of soil moisture under the building cover (i.e. the slab) combined with a decrease in soil moisture around the perimeter. In the case of edge heave, the primary cause of the idealized mound shape is that the moisture increase occurs around the perimeter relative to the centre. Figures 1.1 to 1.4 below show the behaviour of covered areas in terms of moisture movements and expected ground heave for both centre heave and edge heave conditions.

CENTER HEAVE (FIGURE 1.1)

CENTER HEAVE (FIGURE 1.2)

$Y_m$  = Total differential due to combination of increase in moisture content under the slab and decrease in moisture content at edges.

Centre wetter than edge

EDGE HEAVE (FIGURE 1.3)

EDGE HEAVE (FIGURE 1.4)

Edge wetter than centre

The fundamental outcome of the soil mound model is the determination of bending moment and shear force effects on the footing system. For the central heave case the bending moments result from a “cantilevering” of the loaded edges of the building (i.e. loading primarily imposed by the external walls which also generally support roof and upper floor structure). The edge heave allows for determination of the impacts of internal loads on the slab span between edge mounds. Figures 2.1 and 2.2 show the resulting slab bending moments for the central and edge heave conditions.

CENTRE HEAVE (FIGURE 2.1)

EDGE HEAVE (FIGURE 2.2)

### 3.2 Engineering design principles for reactive sites – industrial and commercial buildings

In the case of large industrial and commercial buildings the idealized soil mound concept can still be considered applicable but needs further consideration of the structural loading, slab shrinkage and structure articulation behaviour before application.

The edge loadings imposed by large industrial building construction (i.e. heavy column loads, heavy precast concrete wall loads, multi-level perimeter column loads and the like) would, likely result in excessive bending moments on an integrated raft or grillage beam style footing system. Hence, in practical and economic terms it is essential that these heavy concentrated type loads be supported directly on separate footings utilising the bearing capacity of the underlying soils. A similar argument can be made for high internal column loads. Hence the design task is to limit the formation of the centre heave mound or edge heave as much as possible so that footing systems do not need to be fully integrated.

In order to achieve desired practical and economic outcomes for industrial and commercial building construction it has been common practice over the past 30 years to incorporate either a deep wall/ footing “cut off” construction detail or impermeable paving to the building perimeter in combination with good site preparation, drainage design and limitations on the planting of trees or large bushes near the building perimeter.

The aims behind this approach have been to limit the initial soil heave that occurs when the floor slab is placed over the soil and at the same time limit edge effects at the perimeter caused by soil drying. Good drainage design limits the potential for edge heave effects and the limitation on tree planting is a fundamental requirement to prevent the development of excessive and abnormal moisture conditions that have been found to have the potential to cause excessive movement to almost any footing system. Site preparation should target obtaining as uniform as possible moisture regime over the area as close as possible to the expected long term conditions. When placing fill, care must be taken to ensure that the moisture content of the placed material is within the specified range and that there has not been excessive compaction of the materials (over compaction can be as detrimental to long term performance as would under compaction). In highly reactive ground this does require closer control of the operations than would a less reactive site.

Figures 3.1 to 3.4 show the behaviour of covered areas in circumstances where lateral moisture cut-off is provided by way of deep footing/wall construction or the adoption of perimeter paving external to the building perimeter.

## **4.0 Performance experience**

The performance experience with industrial footing and slab systems is difficult to quantify for a number of reasons not the least being the likely variability in performance expectations of industrial and commercial property owners or their tenants and a propensity for most legal disputes involving alleged footing system failures in the commercial arena to settle out of court and remain confidential. Accordingly, performance experience does have to rely largely on Engineering Practitioner experience.

While recent developments indicate that the commercial/industrial community performance expectations may be changing and may be becoming unrealistic, it is, however, the authors' collective experience that reported failures of footing systems for industrial and commercial buildings have been relatively minor over at least the past 30 years and that when taking into account the age of the overall industrial and commercial building stock in at least Melbourne and Sydney, the failure rate of slab and footing systems for industrial and commercial buildings is very low. The experience of the relatively recent severe drought conditions in Melbourne from around 1995 through to late 2009, which should have resulted in severe deep seated climate effects on building footing systems has not presented as being a particular cause of failures or damage during this period.

Similarly, the construction of industrial and commercial buildings during the extreme dry periods up until late 2009 should theoretically have resulted in at least transient edge wetting effects; however, to the authors' knowledge such incidences have not been widely reported.

In the case of buildings designed and constructed in the past 30 years and for which the authors have had experience or direct involvement, the total number would be many hundreds of which reported problems associated with the slab and footing systems would be less than 2% and actual failures requiring substantial structural rectification works minimal. It has also been the authors' collective experience that the reported failures of older style industrial building footing systems (i.e. brick wall, strip footing, bluestone footings etc) and more recent forms of concrete construction have been found to be primarily associated with the presence or development of abnormal moisture conditions caused by the planting and growth of trees too close to the footing systems or the general failure to maintain the drainage and plumbing systems in and around these buildings. The authors have also observed numerous failures of AS2870 compliant residential footing and slab systems where abnormal moisture conditions have been the primary cause of failure despite the inherent strength and stiffness built into these integrated forms of footing systems. In other words Practitioner observations are that it is the development of abnormal moisture conditions during the life of a building that are the major concern when it comes to footing and slab system performance irrespective of the structure and footing type.

## **5.0 Misapplication of AS2870 design principles to industrial and commercial buildings**

### **5.1 Soil classification issues**

A common observation in geotechnical reports carried out for industrial and commercial buildings is the reference to the Soil Classification based around AS2870. While most reports will qualify such classification as being a guide only, some designers in the industry tend to equate this classification to the general requirements and limitations of AS2870. These requirements and limitations include the exclusion of non-integrated footing and slab systems such as strip footing and infill slab construction on sites with classifications other than Class A and S.

Other observations are that designers feel compelled to adopt stiffened "infill" slabs (i.e. raft slabs built within a strip footing arrangement) in order to simply comply with particular AS2870 standard slab designs for site classifications other than Class A and S.

### **5.2 Soil Compaction Issues**

The large allotment sizes associated with industrial and commercial buildings often result in significant cut/fill requirements for developments and the resulting depth of fill means that these sites would technically be classified as "P" sites under AS2870 for which a common reaction is to resort to piles or piers despite the fact that the standard for earthworks on large industrial sites is expected to be at a higher level of supervision and testing in terms of moisture conditioning and compaction.

AS2870 places a limit of 400mm on controlled fill in the case of non – sand material before 'requiring an initial classification of 'P'. Because of the allotment sizes associated with commercial and industrial

sites the cut/fill depths will often exceed 400mm by a considerable margin. In such circumstances it has been the authors' experience that non – integrated footing systems and non-piled systems have performed satisfactorily on controlled fill depths greater than 400mm that have been compacted in accordance with Australian Standard "AS 3798 – 2007 Guidelines on earthworks for commercial and residential developments" to at least 98% standard compaction and within an appropriate range of moisture content.

### **5.3 Design by engineering principles to AS2870**

The rules for "design by engineering principles" as included in AS2870 require that the footing system be designed for the effects of the idealized mound model, which in the case of houses implies using two acceptable methods of analysis (i.e. Walsh or Mitchell) and an integrated footing system.

In the case of residential buildings the typical perimeter loading implied in the AS2870 standard designs is in the order of 25kN/m as an edge wall load which is equivalent to around 100kN concentrated load at the end of a cantilevering rib or grillage beam. The Standard does allow for loading from two level construction including suspended concrete floor slabs, however the latter is limited to Class A and S (i.e. non-reactive) sites.

For the case of two - level office buildings with suspended concrete slabs the concentrated load from roof and suspended floor construction on a perimeter column is likely to be in the order of 350kN – 400kN subject to the form of construction. Depending on the type of building façade the total concentrated load effect from floor loading and edge loading could be in the order of 450kN to 550kN excluding the self-weight of the footing system and the ground level superimposed loads. Accordingly, the proportioning in size and reinforcement of structural members for a fully integrated system designed for an idealized mound model will be influenced by the significant increase in load although the effects of this increase in load will impact on soil-structure interaction and in particular the calculation for the value of "Ym" and the edge distance "e". Essentially the idealized mound models used in AS2870 cannot be readily or reliably applied to commercial and industrial loading.

### **6.0 Cost implications**

The cost implications of adopting fully integrated footing and slab systems on large industrial and commercial buildings on all reactive clay sites would be significant in terms of increased design and construction costs resulting from the need for one off analysis of relevant soil-structure interaction effects and the likely increase in concrete and reinforcement requirements. While it is likely that the values for "Ym" and "e" will be reduced by the effects of the heavier loads the resulting design bending moments and shear forces for the centre mound condition are likely to be significantly increased in comparison to residential construction.

### **7.0 Non – integrated footing and slab systems**

The Commentary to AS2870 – 2011 states at clause C4.1, "*the design methods in Section 4 may be useful for strip footings although, more often, past satisfactory experience is appropriate*". As noted previously it has been the authors' 30 years+ experience that non-integrated footing and slab systems have been successfully adopted on industrial and commercial buildings in the reactive clay areas of Melbourne and Sydney for many years. The authors' also recognise their experience with the performance of older building stock which includes the common use of non – integrated footing and slab solutions.

#### **7.1 Design principles adopted**

It is the authors' experience that the primary design requirement with any footing and slab system is the avoidance of abnormal moisture conditions that may develop over the life of the building. In most cases abnormal conditions develop due to poor maintenance or non-adherence to design requirements and limitations, particularly related to the planting of trees too close to the footing system. It has been the authors' experience that these abnormal moisture conditions are equally problematic for both fully integrated and non – integrated slab and footing systems.

For the case of non – integrated systems the other key measures have been found to include:

- Good site preparation including moisture conditioning of the subgrade in order to limit initial heave effects caused by moisture increases resulting from the effect of the building cover.

- Provision of a deep perimeter moisture cut-off in the form of edge beams or wall and deep strip footings in order to minimise the drying effect of moisture migration from under the slab or the effects of moisture increase from external landscape areas to under the perimeter of the slab.
- Adequate external drainage away from the perimeter of the building so as to avoid the ponding of moisture and subsequent moisture migration under the perimeter of the slab.
- Adequate sealing of service trench penetrations under the slab at the point where they pass beneath the building edge. This includes the sloping of trenches away from the building perimeter and clay plugging at the point of penetration under the footing system.
- Adequate sealing of perimeter walls to the top of footings, particularly for precast concrete wall panels
- Avoiding the use of irrigation systems close to building edges.
- Provision of perimeter impervious pavement wherever possible.

By adopting and maintaining the above design features the development of the theoretical centre heave mound can be limited to that which occurs due to the effect of the building cover. The building cover cuts off evaporation and alters the moisture condition of the subgrade under the slab and depending on initial moisture content can result in very early heave of the slab. It is the combination of this initial heave and any subsequent edge drying that may occur due to poor detailing and maintenance that results in the formation of the full differential edge-centre movement.

## **7.2 Design circumstances and detail**

### **Warehouse Buildings**

For the case of large warehouse areas the adoption of integrated footing solutions is not practical or viable for many reasons including:

- Floor flatness and levelness requiring the use of laser guided screeds which need a relatively flat sub – base and which could not effectively operate over the top of slab rib trench excavations.
- The need to erect the superstructure prior to the construction of the floor slabs in order to avoid heavy construction traffic on the floor slabs and to provide protection from the elements during the construction of the floor slabs.
- The increasing adoption of steel fibre reinforced concrete floor slabs that require complete isolation from the structure and the sub-base in order to avoid major cracking due to shrinkage restraint conditions.
- High storage rack loads around the perimeter of buildings that would have a major impact on structural thickness requirements if the floor was to be designed as an integrated raft slab subject to edge drying effects.

For the above reasons warehouse floors are designed and constructed as relatively thin slabs of uniform thickness and generally fully isolated from the main building structure and placed on slip membranes in order to minimize shrinkage restraint conditions. The perimeter of the building is generally protected from edge drying effects by either impervious external pavements and surface drainage systems or the use of relatively deep cut off walls at the outside edge of the slab. In addition, these forms of floor construction are often articulated by control joints to minimize shrinkage restraint cracking.

Figures 4.1 and 4.2 shows the expected behaviour of a very large covered area such as a warehouse and which includes deep cut off footings, isolated pad footings and perimeter paving. These types of buildings are often large clear span structures involving relatively large external column loads and precast concrete wall loads and concrete floors that require articulation in the form of construction joints and shrinkage crack control joints. External drainage is usually provided by purpose designed and constructed in ground pipe systems and extensive use of impermeable pavement.

CENTER HEAVE (FIGURE 4.1)

CENTER HEAVE (FIGURE 4.2)

x.Ym = occurs over a large distance

Reports on slab edge failures in warehouse construction has been minimal in the authors' experience other than in extreme circumstances involving the growth of trees close to the building perimeter. Experience has shown that slab edges do tend to drop relative to the centre of the slab. Whilst it is usually difficult to determine if this is due to continuing centre heave or edge settlement, the degree of differential movement has generally been found to be minimal with no reports of slab failure caused by rack post loading of unsupported slab edges.

## Office Buildings

For the case of office buildings that are connected to or built into warehouse buildings, the slab and footing system requirements are often considered by engineers to be more stringent than for the warehouse part of the building. While there may be an argument that floor movement sensitivity in office areas is more problematic than warehouse areas, this is not necessarily the case depending on the use of the warehouse as there are some warehouse levelness limitations that can be more stringent than the general requirements of AS2870 for concrete floors. However, the issue with office areas appears to be seen as more problematic due to the presence of internal partitions, glazing and brittle finishes such as wall and floor tiling. In response, the engineering solution is often to incorporate a raft slab to the office areas even in circumstances involving multi-level construction where heavy column loads or wall loads are supported on independent pad and strip footings. Such solutions are thought likely to be in response to unwarranted pressure to be seen as responding to AS2870 solutions despite the fundamentals not supporting this approach. An isolated raft slab built within the confines of a multi – level structure serves no real purpose in the context of controlling the effects of soil movement.

As noted previously, the more flexible nature of construction detail in office buildings as compared to residential construction allows for more structural movement to occur without necessarily resulting in completely unacceptable incidences of damage or damage that cannot easily be repaired similar to Category 1 and 2 damage in residential buildings. The practical and economic solutions lay in the detail and in the adoption of more sophisticated and supervised earthworks and moisture migration protection/prevention measures that can be built into the office structures. Such measures may include the provision of a capping layer placed as early as possible over the slab area to induce as much initial site heave as possible in combination with a deep perimeter moisture cut off wall/footing arrangement that minimises subsequent edge drying effects and thus formation of the full extent of the idealized mound. Perimeter planting needs to be avoided in order to eliminate the risk of extreme abnormal moisture conditions and other solutions found for landscape and beautification treatment. If necessary such features can be placed within areas constrained by deep root barriers. In cases where internal partitions are built using plasterboard fixed to metal studs (as distinct from modular

demountable partitions) more attention needs to be paid to articulation of the walls and wall junctions, if only to reduce the need for minor maintenance and repair from time to time.

The authors' experience with regard to reports on office floor movement and damage have on occasion indicated likely incidences of initial heave caused by the building cover effect or in some cases lateral migration of moisture, however, the majority of cases have involved either the development of abnormal moisture conditions or defective construction detail, (for example the lack of recognition of potential movement when installing partitions and suspended ceilings can result in floor movements lifting partitions and hence ceiling panels, which while in themselves of no real consequence, appear unacceptable to an end user).

## **8.0 Conclusions**

On the basis of Practitioner experience over a period of 30 years, including a period of very severe and prolonged drought conditions from 1995 through to late 2009, it is the authors' view that current design methods incorporating the use of non – integrated slab and footing systems for industrial and commercial buildings on reactive clay sites have provided an economical and serviceable solution to the commercial and industrial user community. Where problems have been observed they have generally been associated with the development of abnormal moisture conditions caused by poor maintenance practices, non-conforming construction detail or the planting of trees too close to the footing system.

The approach taken by AS2870 to slab and footing design and construction is essentially based around single dwelling houses, town houses or similar structure with the intention of providing standard solutions wherever possible to take into account the inherent limitations in residential construction practices, particularly earthworks and to reduce overall costs to the general community whilst accepting that structures built in accordance with the code can never be considered damage free.

On the other hand large industrial and commercial building structures generally involve more sophisticated design input, construction techniques and supervision which allow the engineering designer more scope in achieving particular performance requirements.

The design and construction of non-integrated slab and footing systems which include pad, strip or pile footings are adequately covered by relevant Australian Standards such as AS3600 (4). It is just the application of such slab and footing systems on reactive clay sites that appears to invoke the use of AS2870 whereas in fact the application of logical engineering principles can be applied to these structures without the addition of unreasonable cost impost.

**Abstract:** Creep of cracked polymer fiber reinforced concrete is complex and not well understood. Fiber reinforced concrete creep can be attributed to fiber creep as well as interfacial fiber-matrix creep. The present work discusses the long-term behaviour of individual fibers and short-term bond strength between fiber and matrix. Polypropylene fibers, used as structural reinforcement, are being tested. A novel measuring method was adopted to measure the creep elongation of the fibers. Laser displacement sensors continuously measure the elongation of the fiber at a rate of 1 Hz. Different initial fiber lengths and sustained load levels are considered. The results show that at moderate load levels, the creep strain at failure can be an order of magnitude greater than the instantaneous strain. Additionally, experimental results of pull-out tests of the same fiber are reported. The results suggest that the age of the matrix is not influential in the pull-out behaviour. On the other hand, the matrix composition and imbedded length of the fiber have an important influence on the maximum pull-out force. The fiber embossment can increase post-peak performance. For the reported fiber, a continuous stress buildup and debonding mechanism is proposed to describe post-peak behaviour.

## 1. Introduction

Fiber reinforced concrete (FRC) is a composite material in which fibers are added to the fresh concrete mix [1, 2]. These fibers can improve the properties of the concrete in the fresh or hardened state. In structural applications, fibers can partially or totally replace the traditional reinforcement. For these purposes, the fibers provide an enhanced post-cracking tensile strength in the hardened state by bridging crack faces [3]. Commercially available fibers can be made from a number of different materials: steel, glass, synthetic and natural being the most common types [4]. Steel fibers are widely used in structural applications [5-8]. However, steel fiber reinforced concrete (SFRC) may not be suitable for all applications, and synthetic fiber reinforced concrete (SyFRC) [7] and glass FRC (GFRC) [9] have been successfully used as well.

Considerable research effort has been devoted in the last decades to study the properties of the fresh and hardened state of FRC [10-13]. It has been shown that the inclusion of fibers decreases plastic shrinkage cracking [14] and flowability [15] in the fresh state. In the hardened state, fibers provide a post-cracking strength as is shown in references [16-18]. However, only very limited research has been done on the long-term structural properties of FRC [19-21]. Time dependent effects may significantly alter the behaviour of structural elements, both in the serviceability limit state (SLS) and in the ultimate limit state (ULS). In the former, creep may cause unwanted and unacceptable deflections of FRC beams [22, 23], whilst in the latter, the residual load-bearing capacity of elements may be significantly lower than the design value based on the short-term strength assessment. Therefore, time-dependent effects should be taken into account during the design of FRC elements. The recently published Model Code 2010 [24] acknowledges this fact but does not provide design rules. It is clear that further research on the long-term structural properties of FRC is required.

One of these time-dependent phenomena is creep. Creep of FRC elements is different from creep of traditionally reinforced elements as the creep deformations of FRC are generally concentrated in the tensile zones. After matrix cracking, fibers allow forces to be transmitted across cracks. A crack can widen due to two main mechanisms: pull-out creep and fiber creep. Pull-out creep is the mechanism in which the fiber gradually slides out of the concrete matrix [25-27]. Fiber creep, on the other hand, is the time-dependent elongation of a stressed fiber itself. This fiber creep deformation is mainly a problem for synthetic and natural fibers [28, 29], but steel and glass fibers can exhibit creep behaviour at high temperatures as well.

In this paper, the first results of an multi-scale experimental program are presented. Firstly, results from creep tests on a polypropylene (PP) macrofiber are shown. A macrofiber is defined in EN14889-2 [30] as a polymer fiber of which the (equivalent) diameter  $d > 0.3$  mm. Secondly, pull-out tests of the same fiber from different matrices are reported as well.

## 2. Experimental setup

### 2.1 Fiber creep setup

A straight polypropylene fiber used for structural concrete reinforcement is tested. The fiber has an equivalent diameter of 0.95 mm, making it a class II fiber, according to EN14889-2 [30]. Two different initial lengths  $l_0$  are considered: 500 mm, and 200 mm. At its ends, the fiber is firmly held in place by a clamping system, which uses a combination of gluing and bolting to prevent fiber end slippage. An exploded view of the clamping system is shown in Figure 1. The fiber is pretreated with a chemical primer to increase the surface energy, which is quite low for polyolefins such as PP. This increase in surface energy allows the fiber to bond with a rapidly-drying cyanoacrylate adhesive. The fiber is glued to a roughened L-shaped aluminum plate over a length of 80 mm. The L-shaped plate has a thickness and width of 2 mm and 40 mm, respectively. As soon as the fiber is securely glued between the plates, 6 M6 bolts and nuts are fastened. The clamping action of the bolts actively holds the two plates together, and in combination with the rapidly drying adhesive prevents fiber slippage.

Figure 1: Exploded view of the clamping system

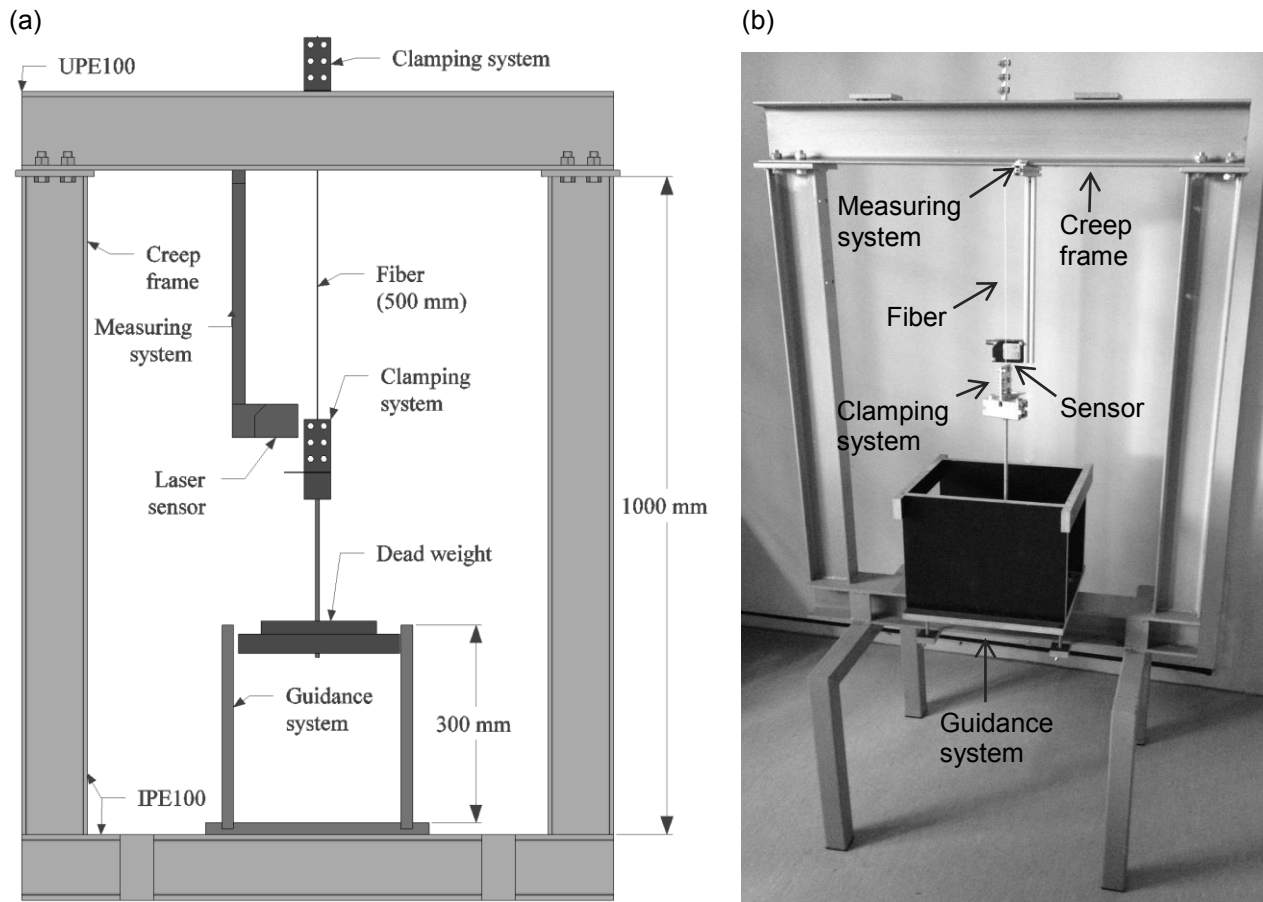

The creep specimen is placed in a creep frame in a climate controlled chamber at 20 °C and 60 % relative humidity. This frame is a steel structure consisting of 3 parts: a supporting frame, a measuring system, and a guidance system. An overview of the creep frame, and its 3 parts is shown in Figure 2 (a). A photo of the actual creep is shown in Figure 2 (b). There are 8 frames in total. It has been a deliberate choice to test only one specimen per frame. Failure of one of the specimens might induce unacceptable vibrations in the other samples if each frame supported more than one specimen.

The supporting frame serves as the main supporting structure for both the specimen and the guidance and measuring systems. The fiber with its two clamping systems attached is placed into the frame.

The measuring system is able to measure the fiber elongation. For this experiment, a contactless system was chosen. Optical laser sensors are fixed to a set of small (20 mm x 20 mm) aluminum profiles that allow the sensor to be moved in all directions. Measurements are taken at a rate of 1 Hz. The sensor has a maximum range of 250 mm and an accuracy of  $\pm 0.1$  mm. The maximum range corresponds to a maximum measurable strain of 50 % and 125 % for an initial length  $l_0$  of 500 mm and 200 mm, respectively.

In the reported setup, iron plates are used as dead weight to apply the tensile load to the specimens. Preliminary tests have shown the specimen may rotate at the application of the load. This may cause

problems for the optical measurement system. Therefore, all rotations of the specimens around its axis should be avoided and a guidance system is installed around the iron plates. The guidance system is made out of concrete plywood plates screwed together. The friction between the plywood plates of the guidance system and the iron plates is thought to be negligible during the creep test. This system simultaneously serves as an impact absorber at fiber failure.

**Figure 2: (a) Simplified creep frame with different components. The three parts of the creep frame are shown. Not shown is the supporting base (b) Picture of the actual creep frame**

In total, 16 creep specimens have been tested. The characteristics of the specimens are shown in Table 1. In this table, the load ratio is defined as the ratio between the applied load and the average fiber strength. The applied load is the sum of the weight of the clamping system and the dead weight, i.e. iron plates. The strength of the fiber is determined in a uniaxial tensile test on 6 test specimens which yielded an average value of 274 N and a standard deviation of 7 N.

**Table 1: Fiber Creep Specimens**

Category	Initial length	Dead weight / Load ratio	Number of specimens
1	500 mm	15 kg / 53 %	6
2	500 mm	12 kg / 43 %	2
3	500 mm	10 kg / 36 %	2
4	200 mm	15 kg / 53 %	6

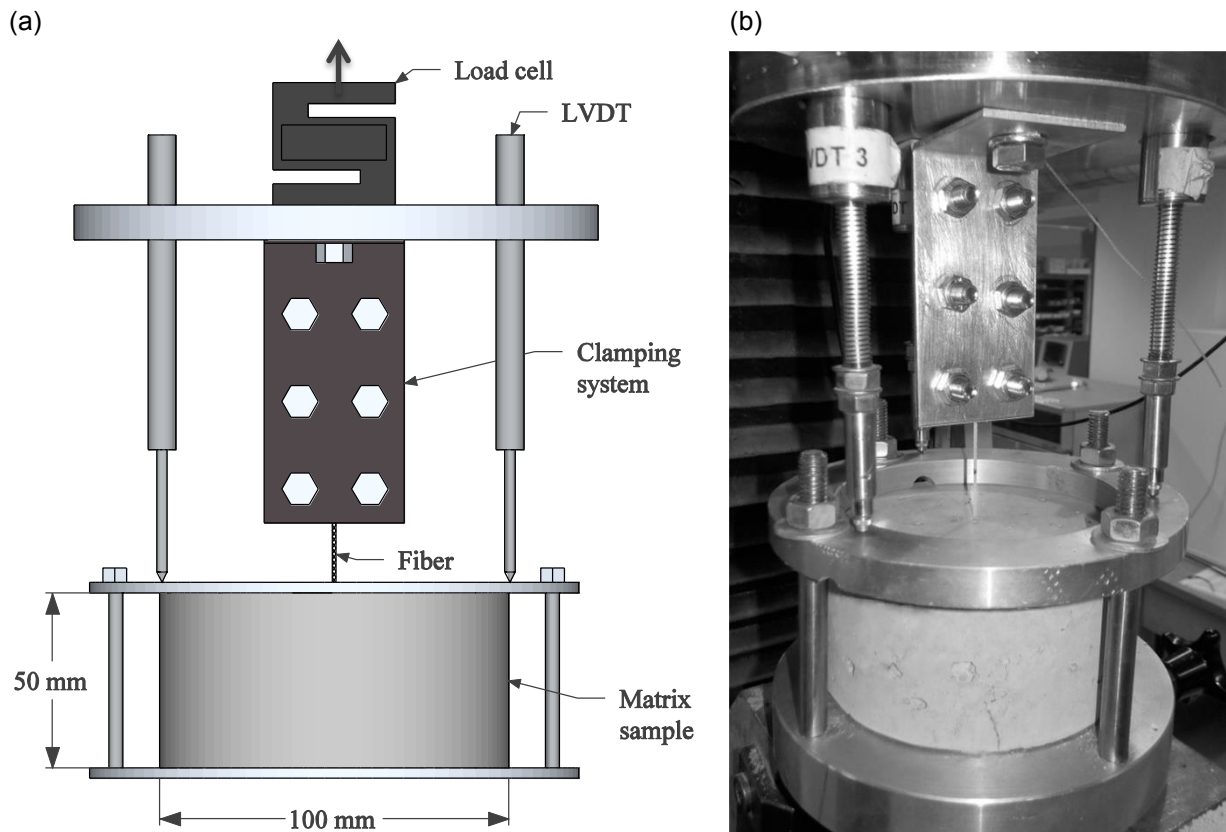

## 2.2 Pull-out setup

The same macro-synthetic fiber is subjected to pull-out tests as well. Three different matrices are considered: (1) a concrete matrix, (2) a mortar matrix obtained by omitting the coarse aggregates in the concrete matrix (3) a mortar matrix obtained by substituting the coarse aggregates of the concrete matrix with fine aggregates, i.e. sand. Table 2 summarizes the three matrices and presents the composition.

**Table 2: Matrix Composition**

	Concrete matrix	Mortar matrix 1	Mortar Matrix 2
CEM I 42.5R HES [kg/m <sup>3</sup> ]	350	350	350
Water [kg/m <sup>3</sup> ]	175	175	175
Sand 0-4 [kg/m <sup>3</sup> ]	835	1934	835
Gravel 4-14 [kg/m <sup>3</sup> ]	1099	0	0
Superplasticizer [kg/m <sup>3</sup> ]	1	1	1

The tests are performed on a universal test machine in a displacement controlled regime. The displacement rate is chosen to a relatively high value of 10 mm/min in order to minimize the effect of creep on the measured deformation. The initial length between the clamping system's end and the matrix sample is 20 mm. The displacement of the crosshead is accurately measured by 3 LVDTs placed around the fiber. The LVDTs can measure deformations up to 30 mm with an accuracy of  $\pm 0.01$  mm. The forces imposed on the system during the test are recorded by an external load cell with a capacity of 900 N. This load cell has a declared accuracy of  $\pm 0.05$  %. The load cell, LVDTs and matrix sample are held in place by steel profiles. In Figure 3, (a) a simplified drawing and (b) photo of the pull-out setup is shown.

**Figure 3: (a) Simplified pull-out setup (b) Picture of the actual pull-out sample**

In total, 18 specimens have been tested. The different specimens are reported in Table 3. During casting, the mold is filled in three layers, with manual compaction after every layer. The initial imbedded length of the fiber during casting is 30 mm in all cases. However, the first tests on the concrete matrix have shown that partial pull-out can occur during demolding. This problem has since been addressed and for the last concrete samples and for mortar samples, the actual imbedded length prior to testing is equal to the initial embedded length during casting. All samples are demolded 1 day prior to testing.

**Table 3: Pull-out Specimens**

Matrix	Age at testing [days]	Number of specimens [-]	Imbedded length [mm]
Concrete	11	3	30, 29, 24
Concrete	27	3	28, 28, 22
Mortar 1	7	3	All 30
Mortar 2	9	6	All 30

### 3. Results

#### 3.1 Fiber creep results

Table 4 presents the failure mode for the completed tests. Of the 16 specimens, 11 failed due to creep failure and 5 tests were aborted because the creep elongation had become or would become greater than 250 mm, the maximum range of the sensor. The experimental results are shown in Table 5. In this table,  $t_{failure}$  denotes the average time to failure in seconds. The average total strain at failure is denoted as  $\epsilon_{failure}$  in %. The results from the completed creep tests are shown in Figure 4 (a) and (b) on a linear and logarithmic time scale, respectively.

**Table 4: Failure Mode of the Completed Experiments**

Category	Number of specimens [-]	Failure mode (number of specimens)
1	6	Creep failure (5), Aborted: sensor out of range (1)
2	2	Aborted: sensor out of range (2)
3	2	Aborted: sensor out of range (2)
4	6	Creep failure (6)

**Table 5: Experimental Results**

Category	$t_{failure}$ [s] (#, s)	$\epsilon_{failure}$ [%] (#, s)
1	$2.00 \times 10^5$ (5, $25 \times 10^3$ )	35.8 (5, 1.8)
2†	$> 3.24 \times 10^6$ (2, N/A)	$> 50$ (2, N/A)
3†	$> 4.38 \times 10^6$ (2, N/A)	$> 33.7$ (2, 0.8)
4	$1.86 \times 10^5$ (6, $31 \times 10^3$ )	40.1 (6, 3.0)

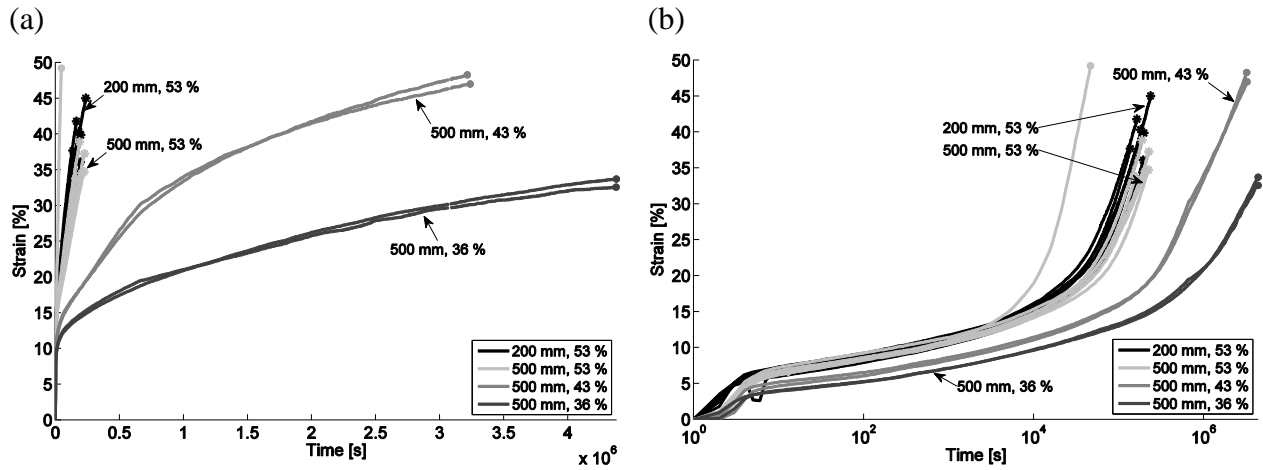

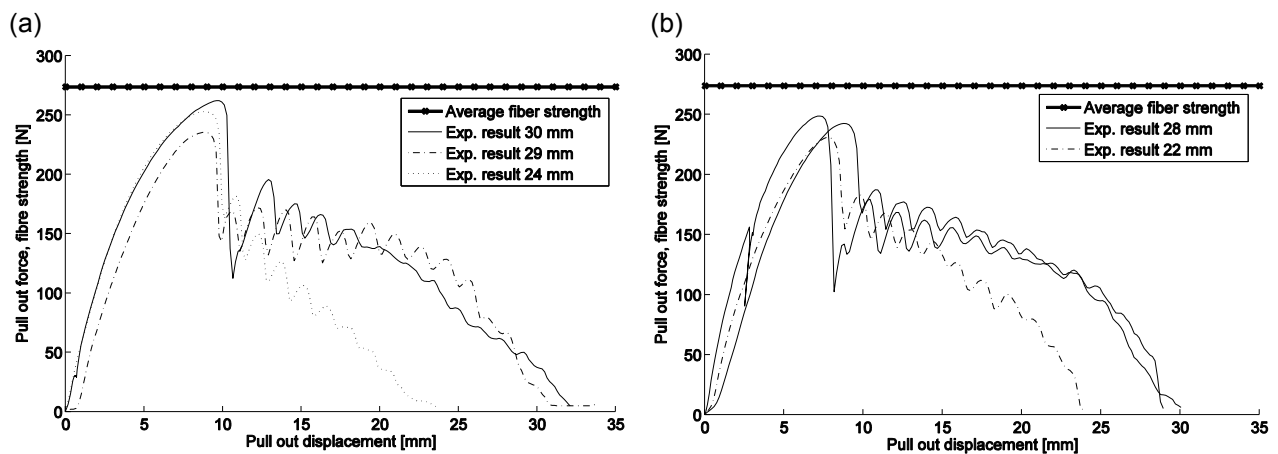

Figure 4: Total strain at (a) linear time and (b) logarithmic time. ○ denotes aborted tests, sensor out of range, × denotes fibre breakage due to creep failure.

### 3.2 Pull-out results

Table 6 presents the average maximum pull-out force  $F_{max}$ , as well as the standard deviation  $s$ , measured during testing. The number of specimens is shown as well. The pull-out results are presented in Figure 5 for all experiments. Shown as well is the average fiber strength in Newton. The fiber is pulled out from the matrix in all cases.

Table 6: Experimental Results of the Pull-out Specimens

Matrix	Age at testing [days]	$F_{max}$ [N]	$s$ [N]	Number of specimens [-]
Concrete	11	250	11	3
Concrete	27	240	7	3
Mortar 1	7	68	35	3
Mortar 2	9	217	27	6

## 4. Discussion

### 4.1 Fiber creep

From Figure 4, it can be observed that the total deformation greatly exceeds the instantaneous deformation. Let the creep coefficient  $\varphi(t)$  be defined as in Eq. (1)

$$\varphi(t) = \frac{\varepsilon_{creep}(t)}{\varepsilon_{inst}} \quad (1)$$

Where  $\varepsilon_{creep}(t)$  is the creep deformation at failure as a function of time, and  $\varepsilon_{inst}$  the instantaneous elastic deformation. Furthermore, let Eq. (2) and Eq. (3) hold

$$\varepsilon_{total}(t) = \varepsilon_{inst} + \varepsilon_{creep}(t) \quad (2)$$

$$\varepsilon_{inst} = \varepsilon_{total}(0) \quad (3)$$

Where  $\varepsilon_{total}(t)$  is the total strain that is measured experimentally. Using the results from Table 5, values for the creep coefficient  $\varphi(t)$  at  $t = t_{failure}$  are summarized in Table 7.

Table 7: Creep Coefficient Values of Completed Tests

Category	$\varepsilon_{inst}$ [%]	$\varepsilon_{creep}(t_{failure})$ [%]	$\varphi(t_{failure})$
1	5.0	30.8	6.2
2	3.8	> 46	> 12
3	3.0	> 30	> 10
4	5.0	35.1	7.0

It is very clear that for this type of fibers the creep strains can become many times greater than the instantaneous elastic strains. For samples loaded at 53 % of the ultimate load, the creep coefficient varies between 6 and 7. Furthermore, the creep coefficient increases as the load ratio decreases, exceeding 12 for samples loaded at 43 % of their ultimate load. Since these tests were aborted, the final creep coefficient is likely even greater.

### 4.2 Pull-out results

From Figure 5, it is clear that the pull-out behaviour from a concrete matrix is rather similar for 11 and 27 days. This has been confirmed in the literature as well [31]. The matrix composition, however, greatly

affects the pull-out behaviour. When replacing the coarse aggregates in a concrete matrix with sand, as has been done in mortar 1, the mix becomes very dry. This leads to a profound decrease of the maximum measured force  $F_{max}$ . On the other hand, a mortar with only a small amount of aggregates with respect to cement paste, such as mortar 2, can achieve almost the same maximum force  $F_{max}$  as a concrete matrix.

The maximum force measured during pull-out is related to the imbedded length of the fiber and to the interfacial bond strength between the fiber and the matrix. However, longer embedment lengths do not necessarily lead to higher maximum forces as can be seen in Figure 5 (a) and (b). This suggests that interfacial bond strength is not the only factor in play. Further research is needed to confirm this observation.

Shortly after  $F_{max}$  is achieved, a sudden drop in the load-displacement curve is observed. Experimentally, this drop corresponds to a snapping sound in the specimen, suggesting a sudden debonding of the fiber. After this maximum load, a recurring pattern of stress buildup and debonding is observed, giving rise to an oscillating curve. This process is repeated until the bonded length becomes too small to allow stress buildup in the matrix and the fiber is simply pulled out from the matrix. This can be observed for all matrices and at all ages. The surface embossment of the fiber can be the determining factor in this process.

## 5. Conclusions

The first results of an multi-scale experimental program are presented. Firstly, an experimental setup is shown used to determine the creep behaviour of a polypropylene fiber for structural concrete reinforcement. Three different load levels are considered: 53 %, 43 % and 36 % of the ultimate strength of the fiber, as determined in a uniaxial tension test. Two different initial fiber lengths are considered as well, 200 mm and 500 mm. The results show that the creep deformation can greatly exceed the instantaneous deformation, with creep coefficient values greater than 6 for all reported test results. Secondly, an experimental setup to determine the pull-out behaviour of the same fiber is presented. The results show that the age of testing does not greatly influences fiber performance. On the other hand, the matrix composition and imbedded length have a profound effect on the maximum pull-out load. The fiber embossment can increase post-peak performance of the fiber. For the reported fiber, a continuous stress buildup and debonding mechanism is proposed to explain post-peak behaviour.

# Using FRP as Reinforcement in Precast Concrete Panels for Soil-Concrete Bridges

Sameh Salib

Adjunct Professor, Civil Engineering Department, Ryerson University, Toronto, Canada

**Abstract:** Concrete is one of the most common construction materials world-wide. However, the corrosion of steel, conventionally used as concrete reinforcement, raises major durability and safety concerns for all types of concrete structures. This presents major risk for bridges as they are directly exposed to weather conditions, and further to the attack of de-icing salts in continents like North America and Europe. Therefore, soil plays a key role in improving the durability of buried concrete structures such as soil-concrete bridges. Besides, these bridges integrate the soil within their structural system which significantly reduces both the cost and time of construction. Yet, the need for steel reinforcement poses a challenging problem to durability. Recently, Fibre-Reinforced Polymers (FRP) are considered viable solution to such problems due to their non-corrosive nature. Herein, an innovative approach of using prefabricated/curved FRP deck units as formwork and reinforcement of precast concrete panels is proposed to form the structure of these bridges. A soil-structure interaction Finite Element Modelling (FEM) has been developed to conduct a parametric study that addresses the bridge structural capacity. This approach promises to introduce superior durability and, moreover, marks a substantial step towards a global sustainability of structures; above and below ground.

**Keywords:** FRP, precast concrete, reinforcement, buried structures, soil-structure interaction.

## 1. Introduction

Concrete is considered one of the first man-made materials to be used for massive construction projects. The utilization of concrete compressive strength in structural elements, subject mainly to compressive forces such as arches, ignited the idea of a three dimensional version of arches in the form of domes. Successfully, the Roman engineers were the first to introduce such approach in a colossal scale as in the 43 m diameter dome of the Pantheon about two millennia ago (1,2). Later, especially during the last few decades, concrete has been used to form structural elements subject to various straining actions like flexure, shear and torsion where significant tensile stresses are induced. Therefore, steel, with its significant tensile strength, is commonly used to reinforce concrete elements in order to provide the required tensile resistance. However, steel corrosion poses a significant threat to both durability and structural safety. Structural steel-reinforced concrete elements exposed to direct weather conditions like bridge decks and girders are severely damaged due to steel corrosion. Despite the billions of dollars spent every year world-wide over inspection, maintenance and repair of reinforced concrete bridges, several catastrophic failures are reported annually due to corrosion-related issues (3,4).

For special types of bridges, e.g. soil-steel and soil-concrete bridges, additional protection against weather conditions is achieved through their top soil cover. Therefore, these bridges are also classified as buried structures. Earlier, Abdel-Sayed and Salib (5) studied the behaviour and strength of soil-steel bridges with relatively long spans (up to 22m) and the recommendations of the study for an optimum depth of soil cover were considered through the Canadian Highway Bridge Design Code 'CHBDC' (6). Yet, steel corrosion still raises durability concerns of such buried structures especially under the attack of severe environmental conditions and de-icing salts in North America and Europe. During the last decade, FRP have been successfully introduced as a non-corrosive reinforcement alternative for bridge decks and girders in various forms such as bars and panels. Further, recently in USA, curved FRP tubes have been used as arch girders for soil-concrete bridges in few pilot bridges where the tubes were filled with concrete on-site and received a cast-in-place concrete layer over FRP corrugated sheets (7,8).

Herein, an innovative approach is proposed to utilize prefabricated/curved FRP deck units, fully or partially filled with concrete, as precast reinforced concrete panels to form the structure of soil-concrete bridges. This approach is encouraged by the recent achievements in producing FRP units with complex three dimensional geometry and curvatures; not only for aero-space industry and transportation vehicles but also for structural engineering applications (9). A FEM has been developed to present the soil-structure interaction of the investigated bridges. Through the developed FEM, a parametric study has been conducted to address the influence of bridge span, depth of soil cover and percentage of panel voids filled

with concrete on the bridge behaviour and strength. The conducted study provides an overall assessment of the performance of such bridges as well as guidelines for their optimum design.

It is believed the presented approach enables high quality control over of the produced structure, significant savings in both schedule and budget of construction and superior durability throughout the service life of the bridge. Moreover, this approach can be a major step towards achieving a substantial sustainability of transportation structures.

## 2. Material Properties

The material properties and cross section dimensions of the investigated Glass FRP (GFRP) deck have been proposed based on various GFRP decks available in the market, fabrication methods and related standards (10). The cross section of the deck is shown in Fig. 1. Also, the material properties of the deck, concrete and soil are listed in the Tables 1, 2 and 3 respectively.

**Fig. 1. GFRP deck cross section dimensions.**

**Table 1. The material properties of GFRP deck.**

Specific Weight (kN/m <sup>3</sup> )	Tensile Modulus of Elasticity (MPa)	Tensile Strength (MPa)	Compressive Strength (MPa)	Transverse Shear Strength (MPa)
18	32000	450	200	180

**Table 2. The material properties of concrete.**

Specific Weight (kN/m <sup>3</sup> )	Compressive Strength (MPa)	Modulus of Elasticity (MPa)
23.5	25	23000

**Table 3. The material properties of soil.**

Soil type	Specific Weight (kN/m <sup>3</sup> )	Angle of Internal Friction, $\phi$ (°)	Cohesion, C (kN/m <sup>2</sup> )
Native Soil	22	40	45
Compacted Granular Backfill	21	35	0

### 3. Live Load

The live load applied in the present study complies with that defined by the CHBDC (6) for the CL-625-ON standard truck as shown in Fig. 2.

Fig. 2. The CHBDC standard truck 'CL-625-ON' (6).

### 4. Finite Element Analysis (FEA)

#### 4.1 Modelling

A non-linear 2D-FEM has been developed to investigate the subject soil-structure system as shown in Fig. 3. Plate elements and beam elements have been used to model the soil and the concrete-GFRP panels (buried structure) respectively. The structure has a half circle profile with a radius equals the span ( $S$ )/2.

#### 4.2 Investigated Parameters

Four different spans ( $S$ ) have been investigated; 10m, 15m, 20m and 25m. Also, different soil cover ( $h$ ) to span ( $S$ ) ratios are studied; 0.10, 0.15, 0.20, 0.25. These values of  $S$  and  $h/S$  are believed to cover the practical range of span and soil cover of such structures (5). Further, the influence of having half of the GFRP deck voids filled with concrete versus fully filled deck has been evaluated. This influence has been considered to reflect the interaction between the structure self-weight, stiffness and strength.

Fig. 3. Finite Element Model (FEM) geometry and materials

### 4.3 Assumptions

The analysis has been performed under the following assumptions:

- The model represents a typical 0.30m width of an infinite bridge width;
- The non-linearity of the soil behaviour is considered through the Drucker-Prager material modelling;
- There is full bond between concrete and GFRP deck;
- The FEM nodes along the model vertical sides are restrained in the horizontal direction while the nodes at the bottom edge are restrained in both horizontal and vertical directions;
- The live load is applied along the model top edge;
- The model represents a 0.30m width of a standard truck lane (i.e. carries 1/10 of the truck loads);
- The transverse distribution of the truck axle loads in the soil is considered with dispersion lines of slope equals 1 (horizontal) to 2 (vertical). Overlapped distributed loads at the level of the structure due to multiple adjacent lanes are considered as well; and
- The load and material strength factors are according to the CHBDC (6).

Also, the investigated soil-structure system is assumed to reach failure if one (or more; almost simultaneously) of the following conditions is satisfied:

- Shear (and/or tensile) failure of soil;
- Tensile failure of GFRP deck;
- Compressive failure of GFRP deck;
- Transverse shear failure of GFRP deck;
- Compressive failure of concrete; and
- Transverse shear failure of concrete.

## 5. Results and Discussion

The stresses induced in the soil-structure system due to the applied loads are obtained by the FEM. Fig. 4 shows an example of the obtained shear stresses in the soil under the own weight of the soil-structure system for a structure having a span ( $S$ ) of 25.0m and soil cover ( $h$ ) of 6.25m, i.e.  $h/S$  ratio of 0.25. For each component of the subject structural system (i.e. soil and concrete-GFRP panels) at each failure condition, the ratio between the factored strength of the component and the corresponding factored stress obtained due to the application of the entire dead and live loads has been calculated. The minimum value of these ratios obtained for each investigated bridge configuration is considered the Factor of Safety (F.S.).

Fig. 4. Contours of maximum shear stress obtained by FEM under self-weight of soil and structure ( $S=25\text{m}$  and  $h=6.25\text{m}$ ).

Tables 4 and 5 list the configuration of each investigated bridge and the obtained failure conditions corresponding to full and half deck voids filled with concrete respectively. Also, the results are illustrated in Figs. 5 and 6.

**Table. 4. Analysis results-full deck voids filled with concrete.**

S (m)	h/S	h (m)	F.S.	Mode(s) of Failure	Location

25	0.25	6.25	0.63 < 1.0	Concrete/FRP; Compression & Soil; Shear-Tension	At Foundations

It can be seen that filling the entire deck voids with concrete has, in general, a positive impact on improving the overall strength (i.e. higher values of F.S.) and eliminating the compressive failure of the concrete-GFRP panels. On the other hand, increasing the soil cover (h) to span (S) ratio results in soil and/or structure failure for relatively large spans. This observation can be interpreted as the associated significant increase of soil weight carried by the soil-structure system utilizes most of the system capacity with little or no reserve left to accommodate the applied live load. Similar behaviour was reported by Abdel-Sayed and Salib (5) and Abdel-Sayed et al. (11) for soil-steel bridges.

From the construction cost perspective, a value of F.S. just above 1.0 can be looked at as an indication to the optimum usage of material that achieves a safe design. In this case, for relatively large spans (20m to 25m), h/S ratio of 0.15 along with a GFRP deck fully filled with concrete achieves an optimum design with an F.S. value around 1.2 (Fig. 5). Further, the same h/S ratio (i.e. 0.15) provides an optimum design for relatively short spans (10m to 15m) with a value of F.S. equals approximately 1.5 when the GFRP deck is half filled with concrete (Fig. 6).

Fig. 6. Factor of safety-half panel voids filled with concrete.

## 6. Proposed Future Research

Few research programs have been dedicated to address the buckling of GFRP structural sections (12,13). Based on the available data, it is believed that the investigated concrete-GFRP panels should not experience global or local buckling prior to the considered modes of failure. However, it is recommended that future studies investigate this aspect in more details for verification purposes. Also, the influence of major structural behaviour and buckling parameters of the GFRP deck such as the modulus of elasticity, the depth and the thicknesses of both webs and flanges can be studied for further design refinement and cost optimization.

## 7. Conclusions

The paper presented an innovative approach to utilize prefabricated GFRP curved deck units, fully or partially filled with concrete, as precast reinforced concrete panels to form the structure of soil-concrete bridges. Based on the investigated configurations and the corresponding results of the conducted analysis, the following conclusions can be obtained:

- Filling the GFRP deck with concrete has significant improvement of the overall structure strength and eliminates the compressive failure of the concrete-GFRP panels;
- Increasing the top soil cover to span ratio does not necessarily increase the capacity of the soil-structure system. Further, ratios larger than 0.15 can cause soil and/or structure failure especially for relatively large spans;
- An optimum design can be achieved with top soil cover to span ratio around 0.15 along with panels fully filled with concrete for relatively large spans and partially filled panels for shorter ones;
- The presented approach enables high quality control over of the produced structure, significant savings in both schedule and budget of construction and superior durability through the service life of the bridge. Moreover, it is believed that this approach can be a major step towards achieving a substantial sustainability of such type of transportation structures; and
- Future research, especially in the area of GFRP deck buckling, can lead to further verification and optimization of the presented design.

**Abstract:** To increase the strength of concrete members, numerous research studies on flexure and shear have been reported using carbon fibre-reinforced polymer (CFRP) with the near-surface mounted (NSM) strengthening technology, as it is considered a promising technology. However, to date research on torsional strengthening has been provided only for the externally-bonded reinforcement technique (EBR) and no studies have been conducted on NSM strengthening technology. In this paper, reinforced concrete (RC) beams with CFRP are considered and ATENA software is used to build a 3-D model of the beams and to analyse the beam structure. Finite element and experimental results of the control beam and beams strengthened for torsion with CFRP sheets using the EBR technique are compared. Further computer analysis of beams strengthened with CFRP laminate using the NSM strengthening technology is achieved by considering many parameters. The type of the adhesive, the method of strengthening, and the spacing between the grooves were examined. The performances of the beams and the ultimate strengths of the control and beams strengthened using the EBR technique were predicted with high accuracy by the models employed. According to the results for the beams strengthened using the NSM technique, the overall torsional behaviour of the beams with CFRP was improved by different percentages and the beams became stronger.

**Keywords:** Torsion, FRP laminate, strengthening, NSM, concrete beam, ATENA 3-D

## 1. INTRODUCTION

Reinforcement concrete members may be presented with torsion in combination with bending and/or shear. Strengthening for torsion with carbon fibre reinforced polymer (CFRP) composite material has become an important matter and could be essential for members subjected to a torsional force (1). For torsional strengthening along with shear strengthening of concrete beams, CFRP materials can be applied by the following two major techniques: externally-bonded FRP sheets and strips applied to the external faces of the elements, and near-surface mounted (NSM) (2). Many configurations have been used to evaluate the contributions of external transverse FRP reinforcements applied to beams with rectangular cross-sections, such as full wrapping and U-jacketing (3). Hii and Al-Mahaidi (4) carried out an experimental study to examine the torsional behaviour of three solid reinforced concrete (RC) beams with vertical strips of FRP using the externally-bonded reinforcement (EBR) technique. The beams were 2700 mm long and 140 × 260 mm in cross-section. The results of this study showed that the use of EBR CFRP is applicable for the torsional strengthening of RC beams and it can increase the strength by a good percentage, depending on the spacing between the strips. Disregarding the increase in strength and ductility, the use of the U-jacket FRP strengthening technique is quite practical for most existing beams (Salom et al.(5)). Ameli et al. (6) tested four rectangular cross-section beams strengthened with U-jackets along the entire beam and U-jacket strips. The results were compared with full wrapping along the entire beam and strips. They found that the ultimate torque of the beams with the U-jacket strengthening technique can be increased by an acceptable percentage. However, the ultimate strengths for the full-wrap technique, were much higher than for the U-jacket technique. Early de-bonding has become a major issue in the EBR CFRP strengthening technique. To reduce this problem, the near-surface mounted (NSM) technique (Nanni et al. (7) provides greater resistance to de-bonding, and it has the ability to reduce the possibility of harm resulting from mechanical damage, fire, and vandalism. Many studies using epoxy adhesive as a bonding material have indicated that the NSM technique is feasible and beam strength capacity can be increased significantly compared with EBR application (Barros and Dias (8)). Because of the problems of epoxy with elevated temperature, cement-based adhesive has been used as an alternative bond material to epoxy. The first use of cement-based adhesive with the NSM technique was reported by Al-Abdwais and Al-Mahaidi (9).

The use of carbon fibre-reinforced polymer (CFRP) laminates with the NSM technique is one of the methods suggested for the strengthening and rehabilitation of concrete members. Both types of bonding agent, epoxy and cementitious adhesive, can be used to improve the torsional behaviour of RC members. In this paper, the experimental result of Hii and Al-Mahaidi (4) are compared with the FE analysis results using ATENA 3-D software in order to simulate and gain further understanding of the beams' behaviour and to validate the numerical modelling. Additional numerical analysis for beams strengthened with CFRP laminate using the NSM strengthening technology is reported for both epoxy and cement-based adhesive.

## 2. EXPERIMENTAL WORK

Three RC beams with 140 × 260 mm cross-section and a middle test zone of 1200 mm were constructed and tested by Hii and Al-Mahaidi (4). The concrete compressive strength of the concrete on the testing day was 51.3 MPa. The cover of the concrete was 20mm all round. All three beams were identical in the layout of the internal steel reinforcement. 12 mm diameter bars were used for the longitudinal steel, and two were at the top, while the bottom steel included three 12mm diameter bars. The diameter of all stirrups was 6 mm. The spacing between the stirrups in the test zone was 120 mm, while to avoid unwanted failure outside the test zone, the spacing was decreased to 60mm. The steel reinforcement properties are presented in Table 1. The beams were designed according to Australian code AS3600-2001 (10), and were intended to be deficient in torsion under new loading requirements. The first beam, C1, was the control beam, where no strengthening technique was applied. The second and the third beams were strengthened with CFRP sheet strips using the EBR strengthening technique. CFRP single layer hoop strips 50 mm wide were used to increase the torsional capacity for the second beam (F1) and the third beam (F2). The spacing between the strips was 130 mm centres, which is 0.5 of the full depth of beam (D) for the second beam. However, it was 195mm (0.75D) for the third beam. The beam dimensions, the steel reinforcement details, and the strengthening schemes are illustrated in Figure 1.

**Figure 1. (a) Side view of half of the beam, (b) beam cross-section, (c) strengthening for beam F1, (d) strengthening for beam F2.**

**Table 1. Steel properties**

Property	Area (mm <sup>2</sup> )	E (MPa)	Yield strength (MPa)	Ultimate strength (MPa)
Longitudinal Ø12	113.1	216000	600	733
Vertical Ø6	28.3	222000	450	515

The CFRP sheet and the resin were supplied by Master Builder's Technologies (MBT 2002), and the MBrace Application Guidelines (MBT 2003) were followed to apply it. The beams were tested using a special test rig and the results as shown in Figure 2.

### 3. FINITE ELEMENT ANALYSIS

In order to shed further light on the torsional behaviour of RC beams strengthened with EBR FRP, examine the modelling reliability, and provide a parametric study, non-linear finite element (FE) analysis was carried out using the ATENA 3-D software (Cervenka and Cervenka (11)). The data from parametric analysis can be used to identify future experimental work and provide advance understanding of the theories. The formulas recommended by CEB-FIP Model Code 90 have been adopted in this software to define the structural material and geometry. Figure 3 presents the complete uniaxial stress-strain results for concrete and mortar and the numbers 1-4 in this diagram are used in the results analysis for denoting the cases of damage. Figure 4 shows exponential crack opening law, whereas the area under the curve is a shear retention factor. To constitute the structural geometry for the beams using ATENA 3-D, basic steps taken during pre-processing should include: material properties, geometrical model, supports and actions, finite element mesh, and solution procedure.

3-D Nonlinear Cementitious is a fracture plastic model in ATENA 3-D used for brittle materials such as concrete and mortar. The 3-D elastic isotropic model is a suitable choice to model the test steel arm and the steel plates around the beams at each end to avoid any unrealistic stress concentration at the loading and support regions (Cervenka (12)). Reinforcement material can be used to define both steel and FRP material properties and the stress-strain laws for the steel and FRP are presented in Figure 5. 3-D interface material was used to define the contacts between the adhesive (mortar or epoxy) and the concrete. Three-dimensional solid regions called macro-elements with a higher order sophisticated 20-node brick element can be used in ATENA 3-D to model the geometry of the specimens. This element shows better numerical stability and convergence rates at higher load levels. Concrete and mortar and the steel arm and plates were modelled using this 20 node iso-parametric solid brick element with 120 degrees of freedom. The reinforcement pars elements were used in ATENA 3-D to model both the horizontal and vertical steel reinforcements.

Figure 3. Uniaxial stress-strain for concrete and mortar (Cervenka et al. (13)).

Figure 4, exponential crack opening law and shear retention factor (Cervenka et al. (13)).

**Figure 5. Stress-strain law for: (a) steel reinforcement bars, (b) the CFRP laminate.**

Brick elements were created for the beam and an adequate mesh size was selected to make the analysis satisfactory. The Newton-Raphson method provided in ATENA 3-D was applied as the non-linear finite element solution method using displacement control to predict the numerical behaviour. The designated displacement per load step size was defined as 0.001m, which is equal to angle 0.11°. Displacement, residual and energy errors were found by assigning convergence criteria, and they were 0.01 for displacement error, 0.01 for residual error, and 0.0001 for energy error. A good compromise between the time and the accuracy was achieved by using these values. The load was applied on the end of the beam and the boundary conditions were used to simulate the experimental test.

The numerical model in Figure 6 (a) was adopted for control beam C1. Non-linear FE analysis was carried out using the ATENA 3-D computer program, as presented in Figure 6 (b). The results of the numerical analysis were compared with the experimental results. Figure 7 shows the torque-rotation curves for control beam C1. From the experimental and FE results, it is clear that the stiffness and ultimate failure load are captured with reasonable accuracy with excellent approximation to the experimental ultimate strength. The overall ultimate load was 1.1% lower than the experimental value. The failure mode and the crack pattern matched the experimental results. A good correlation between the experimental and numerical results is also achieved. Therefore, this model was used for the base in the F1 and F2 models.

**Figure 6. FE model of control beam , (a) microelements and the reinforcement bar model, (b) failure model.**

**Figure 7. Torque vs. rotation curves for beam C1 (numerical and experimental analysis).**

### 3.1 EBR MODELLING

Numerical models have been presented in this paper to compare the overall torsional performance in order to check the validity of the FRP modelling, the beams strengthened with the EBR FRP strips (beam F1 and F2) were numerically modelled and analysed prior to undertaking the parametric studies. The base model for beam C1 was strengthened with FRP strips with 135mm spacing for F1 and 195 mm for F2, as shown in Figure 8.

Figure 8. FE model for beams F1 and F2.

The FRP-epoxy layer was modelled using 3-D brick elements with 2 mm thickness around the beam cross-section. The 3-D linear elastic isotropic material was assigned to this layer using epoxy properties, and the FRP was defined as embedded FRP using the smeared reinforcement method. The FE predictions for torque-rotation responses for beams F1 and F2 are presented in Figure 9 and 10 respectively and compared with the experimental responses. These figures show that good correlations were accomplished with FE predictions. The predicted ultimate loads were higher than the experimental values by 6.6% for beam F1 and 1.5% for beam F2. Spiralled large cracks formed near the FRP strip before the failure of the beams, which provides a good correspondence to the experimental failure mode and crack patterns.

### 3.2 NSM MODELLING

To the authors' knowledge, to date no theoretical or experimental studies have been carried out using the NSM technique to strengthen beams against torsion. The NSM technique can be used to strengthen beams against torsion by making grooves around the concrete cross-section in the concrete cover, and installing CFRP strips into the grooves using a bonding material.

From the previous numerical analysis, the validity of the FE models has been confirmed. In the following section, the same FE modelling steps are used to model the beams strengthened using the NSM technique, and the results of the parametric study are reported. The data from parametric analysis can be used to identify future experimental work by predicting the performance of the beams. It can also provide further understanding of torsional theories and provide data to develop theoretical models and design guidelines. Several parameters from many options of groove spacing and FRP configurations have been

selected and the results are presented and discussed. Both epoxy resin and cement-based adhesives were used as the bonding agent in this parametric study.

### 3.2.1 EPOXY

A new geometry was modelled for the beam by adding grooves around the beam cross-section with the same material properties and boundary conditions as the beam, as illustrated in Figure 11. The groove dimensions were 5 mm wide and 18 mm deep in the concrete cover (ACI 440.2R-2008(14)). It was known from the previous results that using the smeared model with FRP provides good results when the adhesive is epoxy. Therefore, 3-D brick elements filled the grooves as an epoxy adhesive material and the FRP was assigned as embedded FRP using the smeared reinforcement method. ATENA Interface elements were used to define the contact surface between the epoxy and the concrete.

**Figure 11. FE model for the beams strengthened using the NSM technique and epoxy adhesive.**

Many parameters were considered in this part of the study. First, it was assumed that the CFRP laminate strips were used and no connection between the laminate strips at the beam corners was achieved. The same FRP percentage as that in beam F1 was calculated and used with 195 mm spacing between the strips in the first FE model. The accomplished ultimate load was 6.5 % less than the value of the EBR model with a similar behaviour; a loss in the pre-cracking and cracking stiffness of the beam was also observed, where making the grooves around the beam may have been the reason. As it was not possible to apply the same FRP percentage in the groove and also to increase the FRP confinement efficiency, second and third beams were analysed with 97.5 mm strip spacing. To provide the same total FRP percentage per meter length, half FRP percentage was applied in each groove. The ultimate load in this case was almost similar to the EBR model value with more ductility. To provide the double FRP percentage per metre length, full FRP percentage was applied in each groove. The ultimate load in this case was 8.5% more than the EBR model value and a more ductile behaviour was revealed. The results of the three cases and the comparison with the EBR model result are presented in Figure 12.

For the EBR technique, it has been reported that complete wrapping around the cross-section is important to increase the torsional capacity of the beam (Ghobarah et al. (3); Mohammadzadeh et al. (15)). Two further FE analysis approaches were conducted to exhibit the difference in the results between the continuous FRP and non-continuous FRP at the beam corners. In the first analysis, small FRP sheet patches (50 × 50mm) were applied at each corner of the beam to increase the connection between the two embedded laminates in the adjacent beam faces, as shown in Figure 13. The second FE analysis was achieved by replacing the non-continuous laminate by equivalent continuous FRP rope. However, a bigger groove size needs to be used for the FRP rope in practice. The results for the two FE analysis cases compared with the previous FE case (non-continuous FRP) are presented in Figure 14. The comparison shows that small improvements in the ultimate loads of about 6.1 and 3.6 percentages were accomplished for the first and the second FE cases respectively.

Many existing beams in practice do not allow complete strengthening around the beams. To simulate this case, another FE model was implemented and analysed with U-jacketed NSM FRP laminate (three faces). The grooves were made on the bottom and both vertical sides of the beam cross-section. The comparison with the result of full groove wrapping is demonstrated in Figure 15. Although the ultimate load dropped by 3.11%, it was 20.6% more than the ultimate load of the control beam model.

### 3.2.2 CEMENT-BASED ADHISIVE

Because of the problems of epoxy with elevated temperature and the hazardous toxic fumes, the use of cement-based adhesive as an alternative bond material has become important in some cases.

Figure 12. Torque vs. rotation curves for beam F1 (NSM and EBR models comparison).

Figure 13. FE model for the NSM strengthened beam with FRP sheet patch.

The FRP modelling in the previous section using the smeared model provides a good correlation with the experimental work when the adhesive is epoxy, as there is no bond slip failure observed with the NSM strengthening technique (Dias and Barros (16)). However, a clear bond slip failure mode has been observed in experimental work using cement-based adhesive as the bonding agent (Al Bayati and Al-Mahaidi (17)). In order to model the cementitious mortar, the bond slip model for the CFRP laminate with modified cement-based adhesive proposed by Al Bayati and Al-Mahaidi (17) was adopted in this modelling. The CFRP laminate was modelled as discrete bars near the concrete surface with the area coinciding with the total CFRP cross-section (Pryl and Cervenka (18)), and the bond slip model was applied to these bars. Figure 16 shows the FE model for the beam strengthened using NSM and cement-based adhesive.

Figure 14. Torque vs. rotation curves for beam F1 (NSM continuous and non-continuous comparison).

Figure 15. Torque vs. rotation curves for beam F1 (NSM full groove wrapping and U-jacket).

Figure 16. FE model for beams strengthened using NSM technique and cement-based adhesive.

Many parameters were taken in consideration in this stage of the study. First, the same CFRP percentage used in EBR technique was used with mortar. The full percentage of CFRP was applied in the grooves of 195mm and 97.5 mm spacing. For the grooves of 97.5 mm spacing, double percentage per meter length was provided. Also, half FRP percentage in each groove (full percentage per meter length) was applied in the grooves with 97.5 mm spacing. The FE results of the three cases were drawn and contrasted with FE analysis of the control beam C1, and the results are displayed in Figure 17. As the figure shows, increases of 11.9% and 5.6% were obtained using full FRP percentages at 195 mm and 97.5 mm spacing respectively. However, only 1.6 % was obtained using the half FRP percentage in each groove at 97.5 mm spacing with an increase in the ductility of the beam. The mortar experienced less adhesive strength than epoxy, and increasing the groove numbers per meter length may reduce the whole stiffness of the beam, leading to reduced beam strength.

In order to investigate the effect of increasing the connection at the beam corners, a new FE analysis was accomplished for the beam strengthened using the NSM technique, cement mortar, and small FRP sheet patches (50x50 mm) applied at the each corner of the beam. These patches were intended to increase the connection between the laminate around the beam cross-section, but this does not simulate the real case of applying continuous FRP around the beam cross-section. The results were evaluated and compared with those for the control beam and non-continuous laminate strengthened beam, as shown in Figure 18. The figure shows improvement of about 15% for the strengthened beam and by 28.7% for the control beam.

In order to simulate the practical case, U-jacketed NSM CFRP laminate (three faces) was applied on a new beam FE model. The results for the comparison with the result of full groove wrapping appear in Figure 19. The comparison shows a slight difference between the two cases (three and four face strengthening), which may indicate the type of beam failure. It is assumed that the four-face strengthened beam failed before the top laminate involved in the strengthening, which again indicates the less adhesive property of the mortar.

## 6. Conclusions

Numerical models have been presented in this paper to compare the overall torsional performance with the experimental results of RC beams strengthened with EBR CFRP sheet, and to predict the torsional behaviour of RC beams strengthened with NSM CFRP laminate using the ATENA 3-D computer program. According to the numerical results presented in this study, the main conclusions are as follows:

- 3-D finite element models are capable of simulating the performance of beams strengthened for resistance to torsion. The model results were successfully compared with the experimental data and provided good predictions for all tested beams.
- The influence of several parameters was predicted, the results were evaluated for both types of adhesives, and the following conclusions are indicated:-
  - It appears that using the same FRP percentage with less spacing between the grooves was effective for epoxy, and provides more improvement in the ductility and torsional strength, as more confinement is supplied to the beam. However, this is not the case if the bonding agent is not sufficiently strong.
  - The need to increase the connections at the beam corners between the two embedded laminates into adjacent faces was not effective enough with epoxy as the highly confined adhesive already provided, but it was more effective with the mortar. In practice, using FRP rope with mortar may be more efficient. However it may require different groove size. Further investigation is needed in this area.
  - Three-sided strengthening with NSM CFRP shows a significant reduction in the ultimate strength with epoxy.
- Further investigation is needed for developing and determining the mortar characteristics to increase the CRRP contribution in strengthening. It is recommended that future experimental torsion tests of beams strengthened using the NSM technique should consider the current results in choosing the CFRP configurations.

**Abstract:** FRP reinforcement has emerged as an attractive alternate of steel reinforcement due to its higher ultimate tensile strength and weight ratio, and corrosion resistant properties. This study presents the behaviour of Concrete Filled Fibre Reinforced Polymer Tubes (CFFT) with and without longitudinal FRP reinforcing bars under flexural loading. Four circular normal strength CFFT (two carbon FRP tubes and two glass FRP tubes) specimens and a steel reinforced concrete specimen (Reference) of 204 mm and 200 mm diameters respectively were cast and tested. One of the CFFT of each type of CFRP and GFRP CFFT was unreinforced while the other was reinforced. The reinforced CFRP and GFRP CFFT were reinforced with longitudinal 6Ø15 CFRP reinforcing bars and 6Ø15.875 GFRP reinforcing bars, respectively. All the CFFT were tested under increasing flexural load until the fibres at the bottom of the CFFT were ruptured. Significant increases in the ultimate flexural load and ultimate midspan deflections were observed for reinforced CFFT than unreinforced CFFT. GFRP and CFRP reinforced CFFT demonstrated identical flexural behaviour while GFRP CFFT attained even higher ultimate flexural load than the Reference specimen, although both CFFT have similar ultimate midspan deflections.

**Keywords:** FRP Tube, FRP Reinforcement, CFFT

## 1. Introduction

Fibre Reinforced Polymers (FRP) has emerged as one of the most suited alternate option for steel reinforcement in Reinforced Concrete (RC) columns and beams. FRP reinforcement offers a number of advantages such as higher ultimate tensile strength, reduced corrosion and lower self-weight than steel reinforcement [1]. Pantelides et al. [2] concluded that larger proportion of the corrosion in steel RC specimens take place in steel helix. In the last two decades, to reduce the corrosion phenomenon in steel RC specimen, a new technique of Concrete Filled Fibre Reinforced Polymer Tube (CFFT) has been the focus of the research studies as an alternate of steel reinforcement particularly for steel helix. Ozbakkaloglu [3], Vincent and Ozbakkaloglu [4], Mirmiran et al. [5], Hong and Kim [6], Lillistone and Jolly [7], Mohamed and Masmoudi [8] investigated the effect of different geometrical aspects of FRP tubes such as tube thickness, orientation of fibres, height to diameter ratio and tube manufacturing method, unconfined concrete strength, bond between concrete and tube, and internal reinforcement ratio on the load and ductility capacity of CFFT. Nanni and Norris [9], Mirmiran et al. [10], Fam and Rizkalla [11] and Fam and Rizkalla [12] were amongst the early researchers who investigated the combined axial and flexural behaviour of CFFT. These studies showed that CFFT had significantly higher flexural strength and ductility capacity than steel (longitudinal bars and helix) reinforced specimens. Davol et al. [13] presented analytical models to characterise the flexural behaviour of circular CFFT and validated the models using a large scale 7.92 m long CFFT under flexural loading (four point loading).

Recently, FRP longitudinal reinforcing bars have also attracted significant research attention. Cole and Fam [14] investigated the flexural behaviour of longitudinal steel and FRP bars reinforced glass FRP (GFRP) CFFT. The study concluded that flexural strength and ductility attained in case of longitudinal steel bars reinforced CFFT were significantly greater than FRP reinforced CFFT; however, GFRP tubes exhibited a superior flexural behaviour than helical steel reinforcement as GFRP tubes confined the larger concrete area. Fam and Rizkalla [12] studied the flexural behaviour of circular concrete filled GFRP tubes, hollow GFRP tubes and steel tubes. They showed that the flexural behaviour of CFFT was dependent on modulus of elasticity of tube and diameter to thickness ratio of tube. Mohamed and Masmoudi [15] investigated the flexural behaviour of CFFT reinforced with longitudinal FRP and steel reinforcing bars. The study showed that confinement provided by FRP tube to the concrete core significantly increased both the flexural strength and ductility capacity. The study further showed that

CFFT exhibited smaller deflections, and higher strength and stiffness than commonly used steel reinforced beam specimens.

This experimental study investigates the flexural behaviour of unreinforced CFFT and longitudinal FRP bar reinforced CFFT under flexural loading (four point loading). In this study, the flexural behaviour of tested CFFT and steel RC (Reference) specimen is also compared.

## 2. Experimental Program

The experimental program reported in this study comprised four circular CFFT and a steel RC (Reference) specimen. The main objective of this study is to assess the behaviour of circular unreinforced and reinforced CFFT under four point loading. A comparison of flexural behaviour of circular unreinforced and longitudinal FRP bars reinforced CFFT, and the Reference specimen in terms of flexural load and midspan deflection has also been investigated. The key parameters studied in this experimental program were GFRP tubes, CFRP tubes, and GFRP and CFRP reinforcing bars. All the tests were conducted at the High Bay Laboratories of the School of Civil, Mining and Environmental Engineering, University of Wollongong, Australia.

### 2.1. CFFT Specimens and materials

Table 1 provides details of manufacturer provided values of modulus of elasticity ( $E$ ), ultimate tensile strength ( $f_{tu}$ ) and ultimate tensile strain ( $\epsilon_{tu}$ ) of fibres and FRP composites used in this experimental study. Moreover, steel reinforcing bars used in this experimental study has modulus of elasticity of 200 GPa and yield strength of 500 MPa.

**Table 1. FRP Tube and longitudinal FRP bars properties as reported by the manufacturer [16]**

Material	Modulus of Elasticity of fibres ( $E$ ), GPa	Ultimate tensile strength of fibres ( $f_{tu}$ ), MPa	Ultimate tensile strain of fibres ( $\epsilon_{tu}$ ), %	Modulus of Elasticity of FRP ( $E$ ), GPa	Ultimate tensile strength of FRP ( $f_{tu}$ ), MPa	Ultimate tensile strain of FRP ( $\epsilon_{tu}$ ), %
CFRP Tube	230	5080	2.2	146.1	3222.6	2.2
GFRP Tube	80	2000	2.5	49.3	1224.0	2.5
CFRP Bar	140	3100	2.2	78.4	1732.0	2.2
GFRP Bar	-	-	-	62.6	1184.0	1.9

Table 2 provides details of the type of FRP tubes, internal diameter, length and thickness of FRP tubes, types of longitudinal reinforcement, and number and diameter of longitudinal reinforcing bars. All the specimens tested in this study were designed to have a length to diameter ratio (H/D) of four. The internal diameter opted for CFFT and the Reference specimen was 204 mm and 200 mm, respectively.

**Table 2. Details of the specimens reported in this study**

Specimen Designation	Internal Diameter (D), mm	Length (L), mm	Type of FRP Tube	Nominal FRP Tube Thickness, (t) mm	Type of Longitudinal Reinforcement	Longitudinal Reinforcement
CT	204.07	812	CFRP	0.50	-	-
GT	204.00	812	GFRP	1.50	-	-
CT-CR	204.00	812	CFRP	0.50	CFRP	6Ø15
GT-GR	203.88	812	GFRP	1.50	GFRP	6Ø15.875
Reference	200	800	-	-	Steel	4N12

### 2.2. Specimen Designation

The CFFT specimens reported here were designated according to the type of FRP tube and type of longitudinal FRP reinforcing bars used in reinforced CFFT. In this experimental program the influence of two types of FRP tubes i.e., CFRP tube (CT) and GFRP tube (GT), and two types of longitudinal FRP reinforcing bars i.e., CFRP reinforcing bars (CR) and GFRP reinforcing bars (GR) have been investigated. For example a Specimen CT represents a concrete specimen confined with carbon tube with no longitudinal FRP reinforcement and tested under flexural loading. The control specimen was labelled as the Reference specimen i.e., a concrete specimen confined with helical steel reinforcement with longitudinal steel reinforcing bars and tested under flexural loading.

### **2.3. Fibre Reinforced Polymer (FRP) Tubes**

In this experimental program, CFRP tubes and GFRP tubes were used. CFRP tubes comprised 63% of carbon fibres and 37% of resin by volume, whereas GFRP tubes comprised 60% of glass fibres and 40% of resin by volume [16]. Both CFRP and GFRP tubes were designed to have an inner most layer of fibres oriented along the hoop direction (90° to the longitudinal direction) followed by skew layer of fibres (60° to the longitudinal direction). This stacking sequence of 90° and 60° was repeated until the required thickness of FRP tubes was achieved [16].

### **2.4. Fibre Reinforced Polymer (FRP) Reinforcement**

In this experimental program, two types of FRP reinforcing bars i.e., CFRP reinforcing bars and GFRP reinforcing bars were used. Both CFRP and GFRP reinforcing bars comprised 55-60% of fibres and 40-45% of resin by volume [16]. In both types of bars all of the fibres were oriented along the longitudinal direction.

### **2.5. Unconfined Concrete Strength**

A ready mix concrete was obtained from a local company in Wollongong. The target 28<sup>th</sup> day unconfined concrete strength of 32 MPa with maximum aggregate size of 10 mm and slump of 120 mm was requested. The unconfined concrete strength attained after 28 days was 37 MPa.

## **3. Test Methodology and Instrumentation**

All specimens were tested in flexure in the Denison 5000 kN Universal Testing Machine (UTM). The testing arrangement with CFFT loaded in flexure in the UTM is shown in Figure 1. All the specimens were initially loaded to 100 kN under a load control rate of 50 kN/minute and then they were unloaded to 20 kN. This was done so that specimen could align within the loading plates of the UTM and minor eccentricities due to unparallelled plate surfaces could be adjusted. After the initial loading and unloading, the specimens were loaded at a displacement control rate of 0.3-0.5 mm/minute until failure.

**Figure 1. Flexural testing arrangement used in this study**

The flexural testing arrangement consists of two platen rigs i.e. bottom platen rig and top platen rig having clear spans of 705 mm and 235 mm, respectively. The bottom platen rig was placed on bottom loading platen of the UTM. The specimen was placed on the two supports of bottom platen rig with equal portion (53.5 mm) of the specimen hanging from the supports. The specimen length between the supports of the bottom platen rig was equally divided into three segments of 235 mm length each. The top platen rig was then placed on the specimen centred over the middle segment. The top loading platen of the machine was lowered until it touched the top platen rig. The specimen was loaded in the UTM until the final failure due to rupture of the bottom FRP tube fibres was reached. The desired mode of failure under flexural testing (bending) was the rupture of the bottom fibres within the middle segment of the CFFT.

All specimens were instrumented with two Linear Variable Displacement Transducers (LVDT) fixed along the diagonal corners of the loading plates of the UTM, and laser triangulation fixed in the mid on the tension side of the specimen to measure midspan deflection. The UTM also recorded the midspan deflection along with the flexural load taken up by the specimens.

**4. Experimental Results and Discussions**

This section deals with the failure modes observed in circular CFFT and the Reference specimen, and the flexural load-midspan deflection behaviour of reinforced and unreinforced CFFT. It also investigates the influence of FRP tube and FRP reinforcement on the flexural load and midspan deflection. The ultimate flexural load and ultimate midspan deflection for all the specimens are presented in Table-3.

**Table 3. Summary of experimental results**

Specimen Designation	Ultimate Flexural Load (kN)	Ultimate Midspan Deflection (mm)
CT	93.2	26.61
GT	115.6	27.26
CT-CR	223.5	44.96
GT-GR	448.4	43.13
Reference	346.9	33.16

**4.1. Observed Failure Modes**

The observed failure mode in all of the CFFT was due to the rupture of the bottom fibres within the middle segment of the specimen as shown in Figure 2a and 2b. The failure in CFFT was initiated with snapping sound of the bottom fibres tearing apart followed by the tearing of the fibres along the hoop direction. Afterwards, crushing of concrete occurred and eventually fibres at the top compressive side were torn apart.

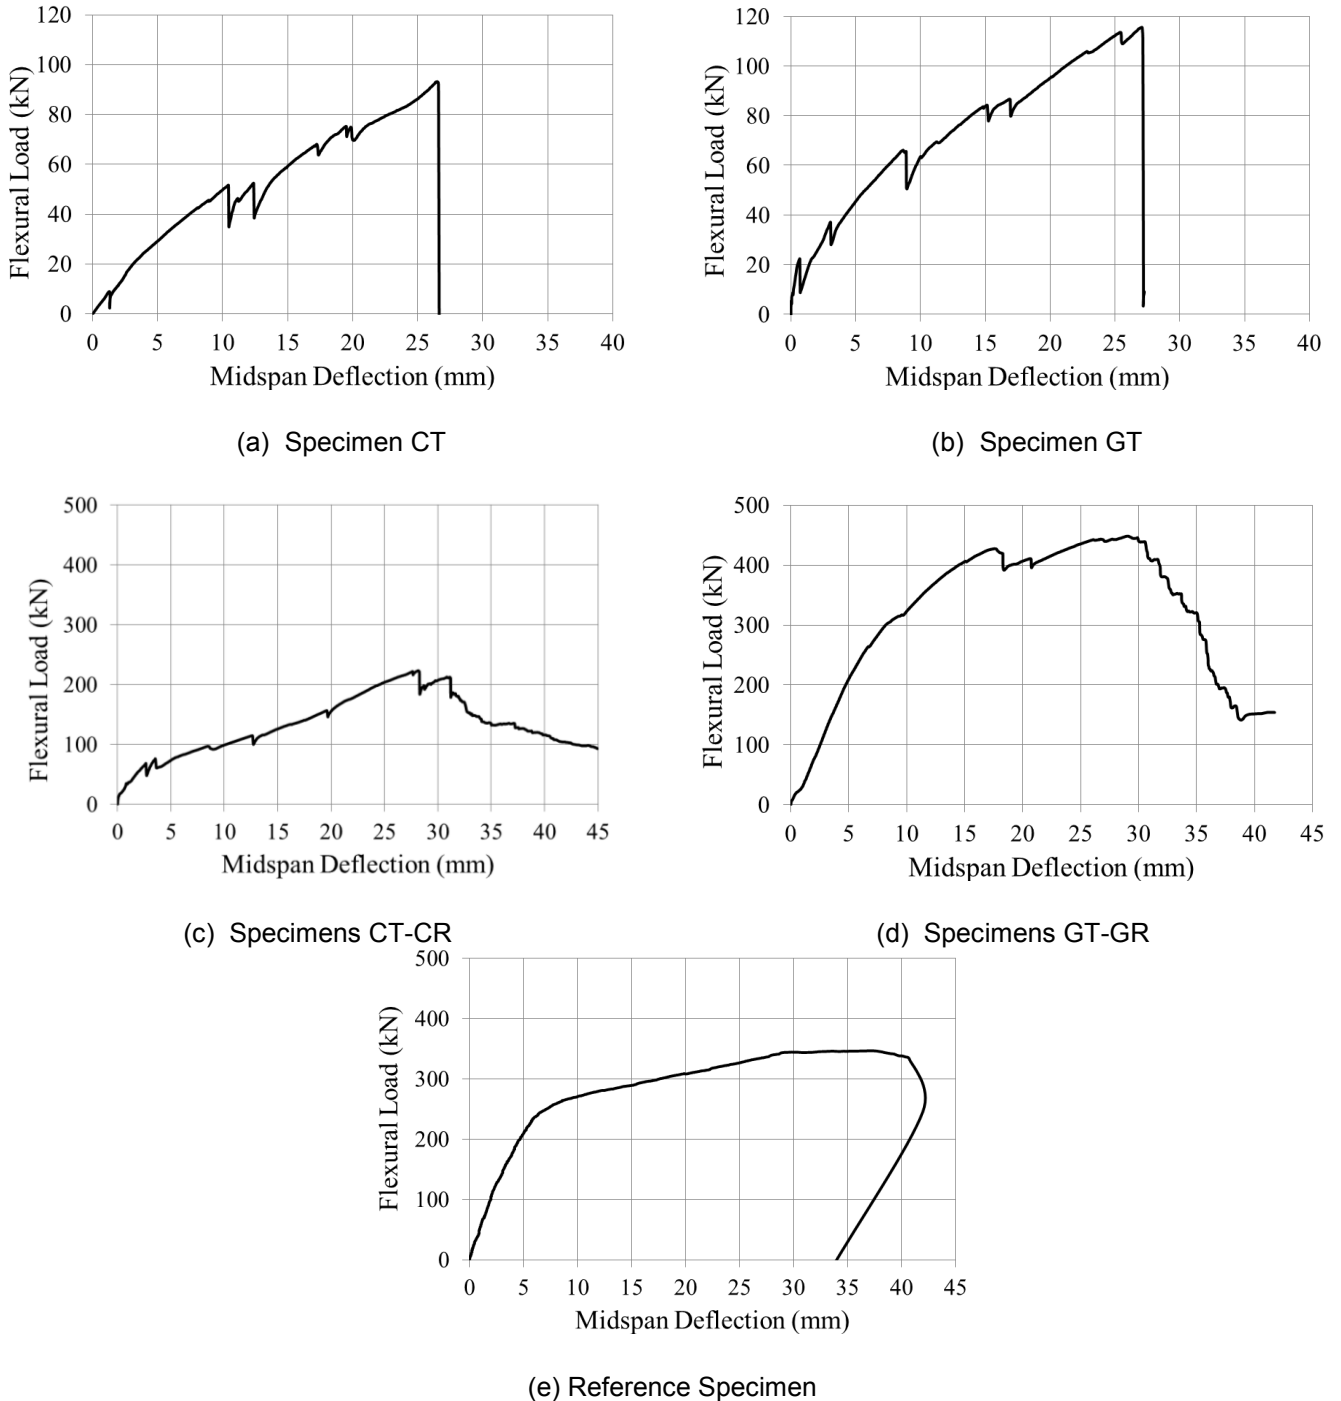

**Figure 2. Observed failure modes of the tested specimens**

The observed failure mode in case of the FRP bars reinforced CFFT was slightly different from that in the unreinforced CFFT. In FRP reinforced CFFT, FRP bars slipped with increasing flexural load as

shown in Figure 2c and 2d. The slippage observed in CFRP bar reinforced CFFT (CT-CR) was significantly more than that observed in GFRP bar reinforced CFFT (GT-GR). This was due to the fact that CFRP bars were smooth whereas GFRP bars were sand coated. Sand coating significantly increased the friction between the bars and the concrete and hence reduced the slippage of the bars and also increased the flexural strength of the CFFT.

#### 4.2. Flexural Load-midspan Deflection behaviour

Figure 3 shows the flexural load versus midspan deflection for all the specimens. It was observed that for CFFT, the flexural load-midspan deflection curve was not as smooth as of the Reference specimen.

**Figure 3. Flexural load versus midspan deflection behaviour of the tested specimens**

This difference was because in circular CFFT an increasing flexural load resulted in tearing apart of the inner layers of fibres which resulted in a sudden fall of load. However, the outer layers of fibres were still intact and resulted in again rise in load. It was noted that unreinforced CFFT failed in a highly brittle manner (Figure 3a and 3b) illustrating a sudden drop in the flexural load carrying capacity.

However, FRP bar reinforced CFFT (Figure 3c and 3d) experienced a reasonable ductile failure condition exhibiting a gradual decrease in flexural load similar to the Reference specimen (Figure 3e).

#### 4.3. Flexural load-midspan deflection behaviour of unreinforced CFFT

Flexural load-midspan deflection behaviour of unreinforced CFFT (Figure 3a and 3b) was characterised by a mild rising curve followed by a vertical falling curve. The rising curve has several drops in load which indicated rupture of inner fibres with increasing applied flexural load. However, the curve continued to rise until the inner and outer fibres were significantly ruptured and was followed by a vertical falling curve indicating a sudden release of applied load. The final failure mode was the rupture of the fibres initiated on the bottom tension side and completed with the rupture of the top compression fibres. Both unreinforced carbon and glass tubes (CT and GT) have exhibited an identical behaviour. However, Specimen GT has manifested higher flexural load and midspan deflection than Specimen CT.

#### 4.4. Flexural load-midspan deflection behaviour of reinforced CFFT

Flexural load-midspan deflection behaviour of FRP reinforced CFFT (Figure 3c and 3d) was characterised by a mild rising curve followed by a mild falling curve. Similar to unreinforced CFFT, mild rising curve in case of reinforced CFFT (CT-CR and GT-GR) also have several drops in load with an increasing applied load. However, drops in load were significantly smaller than those observed in unreinforced CFFT indicating the effectiveness of FRP reinforcement. Moreover, the mild rising curve continued to rise with longitudinal FRP reinforcing bars bending, and inner and outer layers of fibres rupturing with increasingly loud snapping sounds. After reaching the peak load, the load carried by the reinforced CFFT continued to decrease mildly with bending of FRP bars, and rupturing of inner and outer layers of fibres with increasingly louder snapping sounds. The test was stopped when the applied load stopped decreasing. During testing of FRP bar reinforced CFFT, a stage was noted when the flexural load almost stopped decreasing with increasing midspan deflection. Moreover, Specimen GT-GR has exhibited significantly higher flexural load than Specimen CT-CR, but identical midspan deflections in both types of tubes were observed.

#### 4.5. Comparison of flexural load-midspan deflection behaviour of CFFT and Reference specimens

Flexural load-midspan deflection behaviour of both unreinforced (CT and GT) and FRP longitudinal bars reinforced (CT-CR and GT-GR) CFFT, and a steel RC (Reference) specimen is presented in Figure 4. Unreinforced CFFT have exhibited about 4.5 and 2 times lower flexural load and midspan deflections, respectively, than the Reference specimen. However, reinforced CFFT have depicted a significant improved flexural behaviour than unreinforced CFFT. Specimen GT-GR has exhibited higher flexural load and midspan deflection than the Reference specimen, whereas, Specimen CT-CR has exhibited lower flexural load but higher midspan deflection than the Reference specimen. Lower flexural load capacity of Specimen CT-CR than the Reference specimen was attributed to the slippage of CFRP bars.

Figure 4. Comparison of flexural load-midspan deflection behaviour of the tested specimens

#### 4.6. Influence of Fibre Reinforced Polymer (FRP) Tubes

In this study two unreinforced CFFT specimens (CT and GT) were cast and tested to study the influence of FRP tubes on flexural load-midspan deflection. The experimental results presented in

Figure 3(a) and 3(b) showed that Specimens CT and GT have almost identical ultimate midspan deflections. However, Specimen GT has exhibited almost 24% higher flexural load capacity than Specimen CT.

#### **4.7. Influence of Fibre Reinforced Polymer (FRP) Reinforcement**

In this study two FRP reinforced CFFT (CT-CR and GT-GR) were cast and tested to study the influence of FRP reinforcement on flexural load-midspan deflection. The experimental results presented in Figure 3(c) and 3(d) showed that Specimen CT-CR exhibited slightly higher midspan deflection than Specimen GT-GR. The flexural load carrying capacity of Specimen GT-GR was almost 50% greater than that of Specimen CT-CR. The lower flexural load carrying capacity observed in Specimen CT-CR was due to the fact that CFRP reinforcing bars used in this experimental study were smooth bars without sand coating. This resulted in reduced friction between the CFRP reinforcing bars and concrete and consequently, CFRP reinforcing bars slipped towards the middle portion of the specimen.

### **5. Conclusions**

In this experimental study, four circular CFFT (two CFRP CFFTs and two GFRP CFFTs) were tested under flexural loading (four point loading). Two circular CFFT (one CFRP CFFT and one GFRP CFFT) were unreinforced and the other two CFFT (one CFRP CFFT and one GFRP CFFT) were reinforced with longitudinal FRP reinforcement. The experimental results of CFFT were compared to the steel RC specimen (Reference). The main outcomes of this study are as follows:

The observed failure mode in all CFFT was initiated by the rupture of the FRP tube fibres on the tension side followed by the crushing of concrete, and finally rupture of the fibres on the compression side. Longitudinal FRP bars reinforced CFFT failed in more progressive manner with significantly larger midspan deflections than unreinforced CFFT.

GFRP unreinforced CFFT exhibits moderately higher flexural load than unreinforced CFRP CFFT. However, GFRP longitudinal bar reinforced GFRP CFFT exhibited significantly higher flexural load carrying capacity than CFRP longitudinal bars reinforced CFRP CFFT. Moreover, midspan deflections in both types of CFFT were identical.

**Abstract:** Conventional steel reinforced concrete is one of the most commonly used building materials, yet it has shortcomings in terms of weight, thick concrete covers, and durability namely corrosion of the reinforcement. Textile Reinforced Concrete (TRC), a combination of fine-grained concrete and non-corrosive fibre grids, has emerged as a promising alternative; corrosion is no longer an issue and much thinner and light-weight elements can be designed. Although TRC has been expansively researched, unknowns pertaining to the long-term durability arise when attempting to implement such innovative building materials. The aim of this article is to study the effect of accelerated aging on the tensile strength of various textile fibre grids according to ISO 10406-1 [1]. Carbon, basalt and alkali-resistant (AR) glass fibre grids were immersed into high alkali environment and elevated temperature for 30 days. Direct tensile tests were conducted before and after aging to observe the degree of stiffness and tensile strength loss. After aging, the carbon fibre grids were marked by an increase in both tensile strength and stiffness, while AR-glass and basalt were degraded to the extent that tensile tests could not be conducted. Specimens were therefore exposed to alternative conditions to identify the governing degradation factor.

**Keywords:** durability, aging, fibres, experimental tests, alternative reinforcement

## 1. Introduction

Textile reinforced concrete (TRC) is a combination of fine-grained concrete and non-corrosive fibre grids. Furthermore, it can be characterized as a three-phase material consisting of a cementitious matrix, fibre/yarn structure as well as a fibre/matrix interface. The individual fibres incorporated in the yarns which form the textile fibre grid are most often coated by a sizing material serving as a surface protection and improvement of bond between the fibres. This applied sizing could greatly influence the degradation process and long-term performance of the composite [2, 3]. During the service life, TRC could face harsh boundary conditions such as the highly alkaline environment of the concrete pore solution, varying temperature and humidity loads, carbonation as well as sustained and cyclic loading and fatigue which could all have an effect on its long-term mechanical behaviour and durability. Consequently, the critical zones of degradation are most likely the fibre sizing/coatings and the fibre/matrix interface.

Durability performance is most accurately measured in real-time [4]; however, as time is usually a constraint, accelerated aging tests or experimentally calibrated numerical models [5] have been used to predict the long-term performance of textile reinforcement or fibres in concrete. A common method to accelerate the ageing of the fibres, consists of immersing them, in the form of fibre-reinforced polymer (FRP) rods or textile reinforcement, in a simulated or actual concrete pore solution (i.e. alkaline environment) while simultaneously being exposed to high temperature [6].

In this study, accelerated tests paired with direct tensile tests were performed according to ISO 10406-1 [1] on fibre-reinforced polymer (FRP) bars and grids. Carbon, basalt and AR-glass fibre grids were immersed in a high alkali environment (pH=14) with elevated temperature (60 °C) for 30 days. It was of key interest to forecast the so-called long-term mechanical behaviour and material degradation of various commercially available textile reinforcement products for potential use in new façade solutions within the project H-HOUSE funded by the European Commission.

## 2. Experimental program

### 2.1 Materials

The durability related to the alkali-resistance of three commercially available textile fibre grids of carbon, basalt and alkali-resistant glass (AR-glass), listed in Table 1, were investigated in this study. TRC building applications have primarily focused on the use of AR-glass and carbon fibre materials, but natural and polymer fibres have also been researched for this application [4]. For the most part, the use and durability of AR-glass has been deeply investigated for use in TRC as it has been both cost effective and readily available [7]. Basalt fibres are mineral fibres extracted from volcanic rock and are often compared to glass fibres, such as E-glass and AR-glass, due to existing similarities in their chemical composition [2, 8].

**Table 1. Overview of tested textile fibre grids.**

Material	Sizing/coating	Grid spacing 0°/90° (mm)	Weight (g/m <sup>2</sup> )
Carbon	Styrene-butadiene resin (SBR), 15%	17/18	250
Basalt	Undisclosed resin, 17%	10/10	165
AR-glass	Styrene-butadiene resin (SBR), 20 %	7/8	210

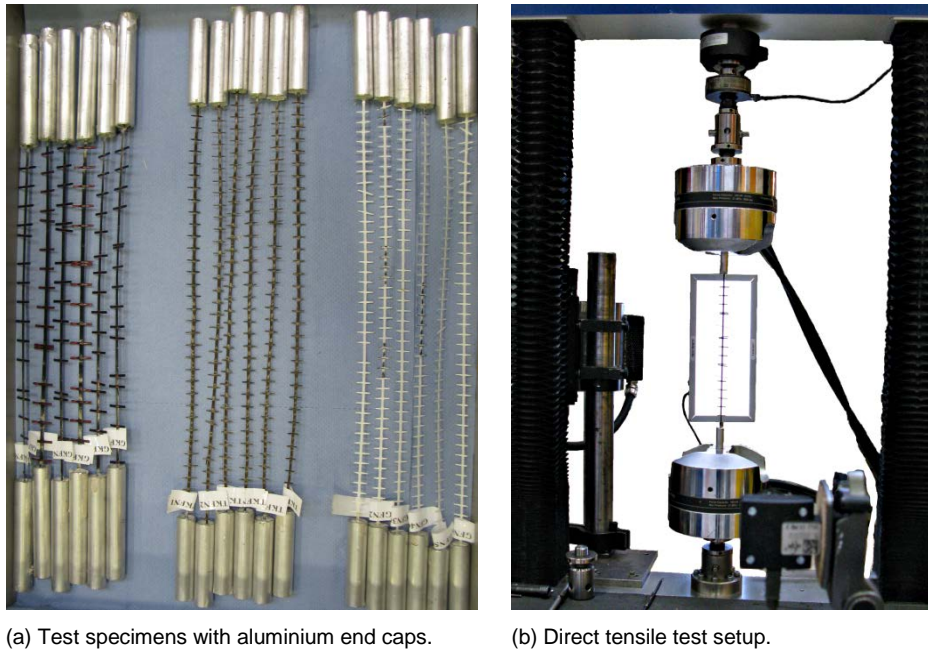

### 2.2 Direct tensile tests

Direct tensile tests were conducted on both reference samples and aged samples, denoted as pre-immersion (Case 1) and post-immersion (Cases 2 or 3), respectively. A total of five tests were conducted for each alternative before and after immersion. The tests were carried out using a universal testing machine (Sintech 20D) illustrated in Figure 1b and the force was recorded by a load cell with an accuracy of 1%. The deformation was measured by a Messphysik Videoextensometer ME46 with backlight technique in the background and digital camera in the foreground. A great advantage of using a video extensometer is that it is possible to measure the deformation up to failure of the specimen, i.e. the ultimate strain can be determined directly. A mechanical extensometer most often has to be removed before failure to avoid risk of damage, thereby causing the ultimate strain to be extrapolated by the assumption of linear elasticity.

The fibre reinforcement grid was cut into so-called individual yarns with a remaining 2 mm projection of the cross-points (crossbars) as well as a minimum of three cross-points along the length. An aluminium tube with epoxy resin as infill was found to be the most suitable solution for the end anchorage of the linear samples (Figure 1a). The main purpose of the end anchorage is to transmit only tensile force along the longitudinal axis of the sample. The tubes had a varying length of 75-100 mm, outer diameter of 15 mm and inner diameter of 12 mm. The inside of the tubes were roughened and cleaned with acetone to achieve superior bonding with epoxy.

The main outputs of the direct tensile tests were the tensile capacity, tensile rigidity and ultimate strain of the different alternatives. The tensile rigidity was calculated from the load-strain relation as the secant modulus between the load level at 20% and 50% of the ultimate tensile capacity. In addition, the tensile capacity retention rate was computed to measure the relative mechanical degradation of the post-immersed versus the pre-immersed specimens.

**Figure 1. Direct tensile testing.**

### 2.3 Accelerated testing

The accelerated tests involved the immersion of linear pieces of fibre reinforcement grid in an alkaline solution ( $\text{pH} > 13$ ) while being exposed to a temperature of  $60 \pm 3 \text{ }^\circ\text{C}$  for 30 days. The alkaline solution prepared according to ISO 10406-1 [1] consisted of 8.0 g of NaOH and 22.4 g of KOH in 1 l of deionized water. The pH of this solution was measured to be  $\text{pH}=14$ . The linear test pieces were bundled and sealed by epoxy resin end caps to prevent infiltration of the solution. These bundles were immersed in the alkaline solution in plastic cylindrical containers (see Figure 2) which were sealed and placed in a climate chamber. Once removed from the alkaline solution, the test specimens were rinsed in dionized water and visually examined prior to commencing with the aforementioned end anchorage preparation necessary for the direct tensile testing.

**Figure 2. Accelerated aging test setup.**

When tensile tests could not be conducted due to the extent of sample degradation based on the standard boundary conditions, which particularly applied to basalt and AR-glass, additional tensile tests related to alternative boundary conditions were executed. In the standard accelerated test (Case 2), the specimens face two upper bound variables simultaneously in terms of temperature (60 °C) and alkalinity (pH=14), which, in turn, makes it problematic to identify the actual cause of material degradation. Accordingly, in this study, test samples were also aged for 30 days at 60 °C and pH=7, denoted as Case 3.

### 3. Results and Discussion

#### 3.1 Visual observations

The external appearance of the fibre grid specimens was examined pre- and post-immersion, for comparison of colour, surface condition and change in shape. Photos depicting the visual macroscopic changes are shown in Figure 3.

**Figure 3. Visual observations pre- and post-immersion.**

For carbon fibre grids, no significant visible change of colour or surface texture were observed after 30 days of immersion in pH=7 and pH=14 at 60 °C (Cases 2 and 3). The basalt samples aged according to the standard conditions (Case 2) were marked by colour change and what appears to be the lifting of the coating to the surface. These samples lost a great deal of stiffness to the point that they broke prior to removal from the solution. For those exposed to Case 3, the observed degradation was similar to the Case 2 samples, yet these could be further tested in tension. The AR-glass specimens exposed to Cases 2 and 3 lost the majority of cross-threads which revealed an uncoated and transparent surface in these locations. These samples also lost a significant amount of physical stiffness and could be easily broken by hand at the cross-points.

#### 3.2 Experimental results

A compilation of the mean tensile test results along with the associated standard deviations are reported in Table 2. It can be seen that both basalt and AR-glass samples aged according to the standard conditions (Case 2) were unable to undergo direct tensile testing due to the resulting extent of sample degradation. When exposed to alternative boundary conditions of 60 °C and pH=7 for 30 days (Case 3), however, basalt and AR-glass fibre grid samples could undergo direct tensile tests.

**Table 2. Mean tensile test results.**

Case	Reinforcement	Mean properties (st. dev.)			
		Tensile capacity (kN)	Ultimate strain (%)	Tensile rigidity (kN)	Tensile capacity retention rate (%)
(1) Reference	Carbon	1.88 (0.23)	0.87 (0.06)	221.38 (5.05)	-
	Basalt	0.62 (0.03)	2.85 (0.08)	23.73 (0.49)	-
	AR-glass	0.41 (0.02)	1.91 (0.10)	22.49 (0.49)	-
(2) 60 °C, pH 14, 30 d	Carbon	2.36 (0.03)	1.01 (0.03)	235.68 (18.60)	125 (2)
	Basalt	Not measurable			
	AR-glass	Not measurable			
(3) 60 °C, pH 7, 30 d	Carbon	2.14 (0.21)	0.91 (0.14)	234.33 (6.75)	114 (11)
	Basalt	0.39 (0.01)	1.70 (0.10)	23.13 (0.66)	62 (2)
	AR-glass	0.15 (0.03)	0.73 (0.10)	20.54 (2.62)	35 (7)

The tensile test results for the pre-immersed (Case 1) samples are compared to the post-immersed samples (Cases 2 and 3) in terms of applied load versus strain in Figure 4. The carbon fibre specimens appear to have increasing tensile capacity (14-25%) and rigidity (6%) after immersion which is thought to be due to a stiffening effect of the applied coating. In addition, the basalt and AR-glass samples were observed to have a significant degradation even after aging according to Case 3. The tensile capacity and rigidity of basalt were reduced by 38% and 3%, while those corresponding to the AR-glass decreased by 65% and 9%, respectively. It can be drawn from this outcome that AR-glass appears to have a greater sensitivity to the temperature effect. Furthermore, for all tested specimens, there was no significant difference in failure mode noted before and after immersion and failure primarily occurred at the cross-points.

**Figure 4. Applied load versus strain curves for all specimens.**

#### 4. Conclusions

The tensile capacity and alkali resistance of selected textile fibre grids were investigated using ISO 10406-1 [1]. According to the results, it can be concluded that the tested carbon fibre grid has a superior alkali and temperature resistance in comparison to the other alternatives. It was not possible to quantify the material degradation for basalt and AR-glass according to the standard boundary conditions. A downside of this method is that it simply describes the relative difference in durability between different samples, but does not predict the actual durability of the material neither does it specify requirements to be met.

It is believed that further parametric studies, in terms of varying boundary conditions, are needed to gain a deeper understanding of the degradation processes. Statistical analyses of these presented results could

also help highlight the significance of the observed trends. Moreover, the time-dependent degradation of fibre cross-sections could be additionally investigated using an electron-microscope to observe the effectiveness of sizings/coatings.

**Abstract:** Plastic macro fibres, inclusive of virgin and recycled plastic fibres, are becoming more popular in the construction of concrete footpaths, precast panels and shotcrete mine tunnels. In particular, the use of recycled plastic fibres has become increasingly attractive due to their low cost and sustainability. However, due to their production and service history, the recycled plastic fibres normally have lower mechanical properties than the virgin plastic fibres. Therefore, the feasibility of using recycled plastic fibres in concrete may be in doubt. This research assessed reinforcing effects of the recycled Polypropylene (PP) fibre and compared it with those of the virgin PP fibre. Crack mouth opening displacement (CMOD) and round determinate panel test (RDPT) were carried out to assess the post-cracking behaviours of the recycled PP fibre reinforced concrete. The results showed that the recycled PP fibre produced by the same process as the virgin PP fibre obtained lower tensile strength but higher Young's modulus than the virgin PP fibre. Although the recycled PP fibre had lower tensile strength, in the CMOD and RDPT the recycled PP fibre showed comparable reinforcement to the virgin PP fibre owing to its higher Young's modulus.

**Keywords:** Recycled PP fibre, fibre reinforced concrete, mechanical properties, CMOD, RDPT.

## 1. Introduction

Steel fibre and steel mesh have been widely and successfully used to reinforce concrete or shotcrete for industrial pavements (1, 2), non-structural precast elements (pipes, culverts and other small components) (3), and tunnels and underground structures (4, 5). However, the production of steel fibre and mesh is costly and leads to large amounts of carbon emission. For instance, around 180 kg carbon dioxide equivalents are emitted for the production of steel fibre and mesh, which are normally used to reinforce 1 m<sup>3</sup> concrete structures (6, 7). Therefore, more and more macro synthetic fibers, such as polypropylene (PP) (8, 9), high-density polyethylene (HDPE) (10) and polyethylene terephthalate (PET) fibres (11, 12), are used to replace steel fibre and steel mesh to improve post-crack behaviour, and to control dry and plastic shrinkages in concrete (13). These synthetic fibres can be eight to ten times cheaper than steel fibres and steel mesh, and emit significantly less carbon dioxide equivalents (around 16 kg for reinforcing 1 m<sup>3</sup> concrete structures) (14, 15).

These synthetic fibres are predominantly made of virgin plastics and have a tensile strength of 300-600 MPa and a Young's modulus of 4-10 GPa, depending on the materials and manufacturing techniques (16, 17). In recent years, recycled synthetic fibres have attracted great interest around the world. For example, Fraternali et al. (18) showed that the recycled PET fibre produced by extrusion, spinning and stretching could achieve 550 MPa of tensile strength and 27% of ultimate strain. Ochi et al (12) used analogous processing method to make the recycled PET fibre's tensile strength greater than 450 MPa. They also demonstrated that good workability could be achieved with up to 3% recycled fibres added to concrete mix. Another preparation method is to melt waste PET bottles first, and then press and roll them into a roll-type sheet (0.2-0.5 mm in thick), before slitting the sheets into thin strands. In this way the fibres could achieve 420 MPa of tensile strength and 10 GPa of Young's modulus (19, 20). Moreover, de Oliveira and Castro-Gomes (21) and Foti (11) produced lamellar fibres and 'O'-shaped fibres by simply cutting waste PET bottles, but the fibres have lower mechanical properties, in the order of 150 MPa in tensile strength and 3 GPa in Young's modulus.

Most of the past researches have focused on the use of recycled PET fibres in concrete; however, literature on recycled PP fibre is very limited. With this in view, this research focuses on application of recycled PP fibres to improve post-cracking behaviour of concrete. In this study, recycled PP fibres were produced by extruding, spinning and stretching recycled PP granules, which are made of industrial PP wastes (scrap off-cuts and off-specification items in the manufacturing industry that are not used by consumers). It is well known that fibre reinforcement is an effective means of enhancing the fracture

characteristics of concrete, where the fibres can effectively control the opening and slippage of concrete cracks (22). In this research, post-crack behaviour of the recycled PP fibre reinforced concrete was quantified through the crack mouth opening displacement (CMOD) test and round determinate panel test (RDPT).

In order to clarify the relationship between flexural load and post-cracking behaviour, which more accurately reflects how the fibres control cracks, crack-tip opening displacement (CTOD) and CMOD are normally measured in the flexural beam tests (18). According to ASTM E1290 (23), the CTOD is the displacement of the crack surfaces normal to the original (unloaded) crack plane at the tip of the fatigue precrack. However, due to inherent difficulties in the direct determination of CTOD, the CMOD test is considered a more appropriate test to assess post crack performance of the fibre reinforced concrete (24). The CMOD test just needs a displacement transducer mounted along the longitudinal axis at the mid-width of the test specimen, in accordance with the BS EN 14651:2005+A1:2007 (25). The test can clearly display the ability of fibres to redistribute stresses and bridge the cracks formed.

Panel tests are generally considered to better represent the relative behaviour of different fibre reinforced concrete in tunnel linings. The panel-based performance assessment is desirable because panels fail through a combination of stress actions that reflect the behaviour of an in-situ lining more closely than other mechanical tests (1). The round determinate panel test, based on ASTM C1550 (26), involves bi-axial bending in response to a central point load, and shows a mode of failure related to the in-situ behaviour of structures such as concrete slabs-on-grade and sprayed tunnel lining construction (27). This test has a significantly lower variation in post-crack performance than concrete beams, and hence energy absorption in the round determinate panel is considered the most reliable test method of post-crack performance assessment (28).

Recycled PP fibres used in this research were produced by using recycled PP granules. Its production processes and conditions are similar to those of commercial virgin PP fibre. The recycled PP fibre was also produced with the same size and indentation as the virgin PP fibre. Mechanical properties including tensile strength and Young's Modulus were tested for both virgin and recycled PP fibres. The performance of virgin and recycled PP fibre in reinforcing concrete was also tested through series of compressive strength, flexural strength with CMOD, and the round determinate panel tests to study the viability of using recycled PP fibre in concrete.

## 2. Material properties

### 2.1 PP fibres

The production processes of both recycled and virgin PP fibres were similar. The PP granules were extruded at 210-250 °C, and then spun and stretched at 140-170°C, before being stabilised at 110-130 °C. Smooth fibres with diameter of 0.8-0.9 mm were then produced. Further, indenting roller dies with line indents were used to mark indents on the smooth fibres to increase fiber-concrete adhesion. After indentation, the fibres were wound, polywrapped and finally cut into a length of 47 mm (Figure 1).

Figure 1. Virgin (a) and recycled (b) PP fibres

Tests for tensile strength and Young's modulus were performed on the virgin and recycled PP fibres according to ASTM D3822-07 (D3822, 2007). The tensile test instrument used for the tests was United STM 'Smart' Test System (STM-50KN) from United Calibration Corporation and was equipped with a 2 kN load cell and data acquisition software. Distance between the clamps was adjusted to obtain a gauge length of 25.4 mm, and extension speed was set as 60% of the gauge length/min (15.24 mm/min). 30 specimens were tested for each sample. Testing temperature was  $20 \pm 2$  °C.

Figure 2 shows stress-strain curve for recycled and virgin PP fibres. Table 1 presents average tensile strength, Young's modulus and elongation at break of these two PP fibres and their standard deviation. The virgin PP fibre showed higher tensile strength (359.2 MPa) and elongation at break (15 %), but lower Young's modulus (only 2801 MPa). The recycled PP fibre produced by the same processing method obtained much lower tensile strength (284.7 MPa), but much higher Young's modulus (5549 MPa) than those of virgin PP fibre.

**Figure 2. Typical stress-strain curves of PP fibres**

**Table 1. Mechanical properties of PP fibres**

PP fibres	Tensile strength (MPa)		Young's modulus (MPa)		Elongation at break (%)	
	Average	Standard deviation	Average	Standard deviation	Average	Standard deviation
Virgin PP Fibre	359.2	30.6	2801	564	15	2.8
Recycled PP Fibre	284.7	21.0	5549	1661	6	2.2

## 2.2 Concrete mix design

Based on industry practise, a 40 MPa standard concrete mix design for footpaths was used in this study. The concrete was delivered from the batch plant (Holcim Australia Pty. Ltd.) in a standard concrete truck without plastic fibres. The average slump of concrete was 125 mm. PP fibres were then added at a rate of 0.45% in volume ( $4 \text{ kg/m}^3$ ) and mixed using a concrete drum mixer. Good dispersion of fibres could be achieved using this method as fibres were sprinkled in to avoid fibre balling. After casting, based on AS 1012.8.1:2014 (29), all the concrete cylinders, beams and round panels were allowed to stand for 24 h in laboratory before demoulding. The demoulded specimens were cured in water at  $23 \pm 2$  °C for 28 days.

## 3. Experimental work

### **3.1 Compressive strength of concrete**

Compressive strength tests were performed on the PP fibre reinforced concrete specimens according to AS 1012.9:2014 (30). Fiber concrete cylinders of 100 mm diameter by 200 mm length were tested at an age of 28 days. The test involved axial loading of a cylindrical specimen until failure in the universal testing machine (UTM) with a maximum load capacity of 2000 kN. The results for each specimen type were based on an average value of four replicate specimens.

### **3.2 Residual flexural tensile strength with CMOD**

Post-cracking behaviour of the PP fibre reinforced concrete beams were studied using a residual flexural tensile strength test with crack mouth opening displacement (CMOD), according to BS EN 14651-2005+A1-2007 (25). All the beams had a size of 150 mm x 150 mm x 600 mm and a notch of 2 mm x 25 mm at mid-span. The notched beams were loaded using three-point loading with the distance between the supports at 500 mm, using a 500 kN hydraulic testing machine. The CMOD was measured using two clip gauges installed at the centre of the notch and averaged CMOD values were adopted. The clip gauges attached to knife edges glued to the bottom of the beam were connected to a data acquisition system Linear Variable Displacement Transformer (LVDT). The testing machine employed operated under displacement control with a constant rate of displacement (CMOD or deflection), and had sufficient stiffness to avoid unstable unloading phenomena in the softening branch of the load-CMOD curve. During the tests, the rate of increase of the CMOD was controlled at 0.05 mm/min. All the tests were carried out at K&H Geotechnical Services Pty Ltd in Australia. Three trials were performed for each test and one trial for the control.

### **3.3 Round determinate panel tests**

The round determinate panel specimens were tested in flexure according to ASTM C1550-12 (26). The diameter of the round panel was 800 mm and the thickness was 75 mm. A central point load was imposed on the round panel, which was supported on three symmetrically arranged hinged supports located on a 750 mm in diameter. The three pivoted supports ensured that load distribution was always determinate in the round panel specimens. A hydraulic universal testing machine with a capacity of 250 kN was used in this test. As specified in the standard, displacement was applied at a rate of 4.0 mm/min up to a central displacement of 45.0 mm. The deflection was recorded by a displacement transducer placed under the centre of the specimen. Three trials were performed for each test at K&H Geotechnical Services Pty Ltd in Australia.

## **4. Results and discussion**

### **4.1 Compressive strength**

Figure 3 shows compressive strength of the PP fibre reinforced concrete cylinders. As can be seen, the addition of fibres does not have significant effects on the compressive strength. Due to the relatively low fraction ( $4 \text{ kg/m}^3$ ) of fibres in the concrete matrix, the compressive strength mainly depends on the concrete mix design (8). Only at large fibre dosages (i.e.,  $13$  to  $18 \text{ kg/m}^3$ ) can improper distribution of fibres, causing balling and air voids, affect the compressive strength of concrete (12). This result correlates with the findings of many scientists (12, 31-33), who reported no notable change to compressive strength with the addition of PP fibres. Moreover, Figure 3 shows that all the recycled fibres had comparable compressive strength compared to virgin fibre. It should also be noted that, during the compression tests, the plain concrete failed suddenly with large single cracks at the peak load, while the PP fibre reinforced concrete cylinders failed with many minor cracks on the surface. The samples with fibres showed a more ductile mode of failure and a post failure structural performance.

Figure 3. Compressive strength of the recycled and virgin PP fibre reinforced concrete cylinders

#### 4.2 Residual flexural tensile strength with CMOD

Figure 4 plots opening load-CMOD curves of PP fibre reinforced concrete beams. With increase of the CMOD, the flexural opening loads of both the recycled and virgin PP fibre reinforced concrete beams reached the highest points (around 20 kN) at the limit of proportionality (LOP), and then there was a significant drop in terms of the CMOD ranging from 0.05 mm to 0.46 mm. The flexural opening loads then increased with the increase of CMOD from 0.5 mm to 2 mm, and further kept flat within the range of 1 to 5 kN. As can be seen, the recycled PP fibre showed comparable post-crack control with the virgin PP fibre. Although the recycled PP fibre has lower tensile strength than the virgin PP fibre, its higher Young's modulus contributes to the reinforcement, thus showing the similar post-crack behaviour. However, for the control specimens, after the LOP, the opening load dramatically decreased to 0 kN. This indicated that both recycled and virgin PP fibre reinforced concrete beams showed outstanding post-cracking behaviour.

Figure 4. Load-CMOD curves of PP fibre reinforced concrete beams

### 4.3 Flexural strength and toughness of round determinate panels

Round determinate panel test (RDPT) is an essential tool for assessment of post-crack performance in fibre reinforced shotcrete within the underground construction and mining industries (27). The specimens can show a very low within-batch coefficient of variation in performance than any other test method for fibre reinforced concrete, mainly because of the large crack length experienced during testing (28). Figure 5 shows the comparison of the load capacity and the energy absorption of the RDPT on the recycled and virgin PP fibre reinforced concrete specimens. Table 2 shows the comparison of RDPT results in terms of the deflection of 5, 10, 20, 30 and 40 mm. The recycled PP fibre reinforced 40 MPa concrete round panels showed slightly lower load capacity and energy absorption than the virgin PP fibre reinforced panels, proving the feasibility of the recycled PP fibre in concrete.

Figure 5. Energy absorption and load curves of round determinate panel tests

Table 2. Energy absorption and load of round determinate panel tests

	Deflection		At peak load	5 mm	10 mm	20 mm	30 mm	40 mm
	Specimens							
Energy absorption (Joules)	Virgin PP Fibre			44	74	126	166	198
	Recycled PP Fibre			42	69	108	133	149
Load (kN)	Virgin PP Fibre		32.4	6.3	6.2	4.7	3.8	2.7
	Recycled PP Fibre		31.2	5.4	5.2	3.2	2.1	1.5

## 5. Conclusion

The use of recycled plastic fibres has become increasingly attractive due to their low cost, lesser environmental impact, and sustainability. However, due to their production and service history, the recycled plastic fibres normally have lower mechanical properties than the virgin plastic fibres. Therefore, the feasibility of using recycled plastic fibres in concrete may be in doubt. This research assessed reinforcing effects of the recycled PP fibres and compared them with those of the virgin PP fibre. The recycled PP fibre produced by the same process with the virgin PP fibre obtained lower tensile strength but higher Young's modulus than the virgin PP fibre. The addition of recycled PP fibres did not have significant effects on the compressive strength, but offered the samples a more ductile mode of failure and a post failure structural performance. Although the recycled PP fibre has lower tensile strength, in the CMOD test the recycled PP fibre showed comparable reinforcement with the virgin PP fibre due to its

higher Young's modulus. In the RPDT the recycled PP fibre reinforced concrete panels showed slightly lower load capacity and energy absorption than the virgin PP fibre reinforced panels, proving the viability of the recycled PP fibre in concrete.

<sup>4</sup>Director of Marketing, Lafarge North America, Calgary, Canada

**Abstract:** A novel spandrel cladding panel design using thin section Ultra High Performance Fibre Reinforced Concrete (UHPFRC) with Glass Fibre Reinforced Polymer (GFRP) reinforcing is load tested and compared to analytical calculations and the results of a linear-elastic finite element model constructed in S-FRAME Analysis for a new construction building in Victoria, Canada. Load testing was conducted on five test spandrel cladding panels due to the limited practical and theoretical information available regarding the behaviour of the panel materials and to approximations in the analytical and finite element calculations, including disregarding the contribution of the architectural surface texture. The deflection of the test panels under serviceability wind pressure load testing agreed well with the analytical values and the finite element model, in most cases deflecting less than the design limit. The comparison with the failure load in the finite element model is limited due the linear-elastic analysis. Failure strength of the panels reached as much as four times that predicted using design guidelines mainly because of UHPC's ductility and ability to carry load after cracking.

**Keywords:** spandrel cladding panel, Glass Fibre Reinforced Polymer, Ultra High Performance Concrete.

## 1. Introduction

A curtain wall system is a means of cladding a building with the benefit of the cladding support being predominantly separate from the primary structure of the building. This allows the primary construction to proceed independently of the cladding, easing construction scheduling. The curtain wall system typically supports its own self-weight plus any horizontal loads applied to the façade such as wind loading and the induced seismic loading from the motion of the primary structure during a seismic event. The system consists of mullions spanning vertically between floors, which may be divided by horizontal transoms if required. These mullions provide support for the infill panels, which can consist of stone veneer, metal sheets, glazing, or louvers, among others.

Curtain walls have been in use for nearly 100 years, but their use increased significantly in the 1930s with advances in the use of sheet metal, in the 1950s with the advent of float glass, and again in the 1970s with the use of aluminum mullions [1,2]. The mullions provide a continuous support along the edges for positive (into the building) wind pressure, while negative (suction) pressure is resisted by bolts through the mullions. Relevant to this research, the curtain wall system provides a backing frame to which the spandrel panels are attached.

The purpose of the study was to confirm the use of Ultra High Performance Fibre Reinforced Concrete (UHPFRC) as an alternative to stone or concrete to design and build spandrel panels for use in the curtain wall system of a mid-rise seven storey building located in Victoria, British Columbia, Canada.

Through collaboration with the designer, owner, and engineers, it was determined that an UHPFRC material, would be the ideal material for use as the spandrel panels in the cladding system. The primary factors dictating the use of UHPFRC was the potential for thin sections. The ability to achieve thin sections is important to reduce the seismic loading on the structure, since Victoria, British Columbia is a high seismicity zone. It is possible to achieve these sections due to the high tensile and compressive strengths and high stiffness of the UHPFRC material. This allowed some UHPFRC cladding panel sections to be as thin as 17 mm. A typical stone system can vary from 9.5 mm to 50 mm in thickness and the stone panel is limited to maximum panel dimensions of 300 mm to 400 mm [3], whereas the UHPFRC panels used in this project are 1300 mm in height and vary from 750 mm up to 2150 mm in length. Regular precast concrete cladding can be of similar overall dimensions; however they are typically 100 mm thick or greater. These dimensions are possible for the UHPFRC due to its high strength, in this case 100 MPa in compression and 4 MPa in tension [4]. The use of organic fibre reinforcing in the UHPFRC was preferred over steel fibres to reduce the potential for rust stains appearing on the surface of the cladding panels.

Initial design was done by analytical calculations and finite element modeling [5]. Due to the uncertainty of the performance of the UHPFRC in shear for the thin members, the lack of proven design codes or standards for UHPFRC and because there was limited data on the effects of size on tensile and flexural behaviour, full-scale prototypes testing of the selected design was performed for both static loading and fatigue loading to ensure satisfactory performance of the panels throughout the design life. Similarly, there is limited understanding on behaviour of Glass Fibre Reinforced Polymer (GFRP) reinforcing bars in thin sections. To validate the real-world feasibility of the cladding panels the full-scale testing was compared to analytical design calculations and an elastic finite element analysis of the panels in order to determine the acceptability for their use on the building.

## **2. Structural Validation of the UHPFRC Panels**

### **2.1 Materials**

#### **2.1.1 UHPFRC**

The UHPFRC mix used in these panels and its material properties were provided by the Lafarge Precast Group. A special mix of the UHPFRC utilizing a white aggregate was required in order to suite the architect and owner's design for a light coloured cladding panel. Relevant material properties provided by the concrete supplier for the purpose of design are compressive and tensile strength of 100MPa and 4 MPa, respectively, elastic modulus of 30GPa and fibre length 12mm [4].

#### **2.1.2 GFRP**

Glass Fibre Reinforced Polymer (GFRP) reinforcing bars were used in each of the ribs of the panels to provide greater ductility in the panels beyond the tension failure of the UHPFRC. The GFRP reinforcing bars are important to the strength and ductility of the panels beyond the cracking of the concrete in tension as demonstrated in the analytical calculations, and as such allow a greater utilization of the compression capacity of the UHPFRC. The GFRP is composed of glass fibres and vinyl ester resin, with a textured coating to enhance the bond with the concrete. This material performs in a pure linear-elastic manner to failure. According to the manufacturer, the relevant properties of the GFRP rods used are: nominal diameter of 6.35mm, cross-sectional area of 31.7mm<sup>2</sup>, tensile modulus of elasticity 46.1GPa, nominal ultimate tensile strength 874 MPa, guaranteed design tensile strength 784 MPa, ultimate tensile strain 1.9%, Poisson's ratio 0.25 [5].

## **2.2 Panels Geometry, Design and Test Matrix**

The scope of the testing included one full-scale short panel (1300 mm in height by 1287 mm in length) for static load testing, two full-scale long panels (1300 mm in height by 1757 mm in length) for static load testing, and an additional two full-scale short panels for fatigue load testing. All panels had thickenings around the perimeter of the panel as required to properly seal the joints between panels. In addition, the long panels had a thickening in the centre of the panel to assist with load carrying capabilities. All of the prototype panels were subjected to uniform pressures. The design of the panels (strength and deflections calculations) was achieved through analytical calculations [6]. The construction details and analysis of the short panel static load testing were previously discussed [6, 7], however, Figure 1 shows the construction details for the long cladding panels. Only the static testing results of one of the long panels, Long Panel #1, will be discussed in this paper while Long Panel #2 and the fatigue tests results can be found in [6].

## **2.3 Static Load Testing of Long Panel #1**

Curtain wall panels were subjected to transient wind loading resulting in both positive and negative pressures. The intent of the static load testing is to determine the panel's ability to withstand the design loads established through the National Building Code of Canada [8], and checked against the British Columbia Building Code [9]. Given the textured ribbed surface of the panels, there is the potential for increased localized wind pressures due to vortices forming adjacent to the panels. This effect could not be adequately determined without wind tunnel testing, however, because of the scale of the ribs compared to the size of the panels (5 mm ribs compared to a minimum of 750 mm smallest panel dimension) it was

assumed to average to a neutral pressure. The resulting net unfactored positive and negative wind pressure loads, including internal pressure effects and the effects at the corner or end zone of the building were 1.54 kPa and 1.91 kPa, respectively. The loading imparts both bending stresses and shear stresses on the panels as the forces are transferred back to the supporting curtain wall framing. Various load cycles were implemented on the panel. The selected load cycles are intended to simulate positive and negative pressure on the panel at Serviceability Limit States (SLS) and Ultimate Limit States (ULS) load levels, sustained loading (for 24 hours), and ultimately taking the panels through to failure. The testing included deformation and strain measurements of the panels at various points both on the top and bottom surfaces of the panels and strain measurement on the embedded GFRP reinforcing bars.

Figure 1. Construction details of prototype long cladding panel #1 (Lafarge Precast).

## 2.4 Finite Element Analysis of Long Panel #1

After the design of the spandrel panels through analytical calculations was complete [6], a finite element analysis (FEA) of the panels was undertaken in order to determine if any unanticipated effects occurred within the panels and to compare FEA deflections to those achieved through analytical calculations. Based on the results of the analytical calculations, it was assumed that the spandrel cladding panels would be in an uncracked state for SLS loading levels and as such the GFRP reinforcing bars would have little effect on the performance of the panel. Thus, for simplicity of modelling, the GFRP bars were not modelled and a purely linear-elastic analysis was used. This eliminates the ability of the model to calculate the anticipated failure load for the panels, and reduces the accuracy of the model beyond the cracking load. This was considered to be acceptable since the goal of the FEA was to verify the distribution of stresses and to show there are no unusual stress patterns. The structural analysis program S-FRAME was chosen to conduct the FEA of these panels. This software was chosen for the ability to quickly and accurately create models for design iterations during the initial design process. Details on the element types, material properties, model geometry, boundary conditions, mesh sensitivity analysis to provide the optimal mix of computation efficiency and result accuracy for the long panels can be found in [6].

The labels used throughout the analysis for each of the elements of the panel are shown in Figure 2. The long span edge member is the top, bottom, and middle thickened portion for the long spandrel panels, with dimensions of width of 200 mm, thickness of 34 mm, and span length of 1637.3 mm. The narrow edge member is the thickened portion on the left and right sides of the spandrel panel with dimensions of 110 mm wide and 30 mm thick with a 500 mm span for the long panel. The infill sections are 17 mm thick for the long spandrel panel, and are calculated for a per-metre width of panel for the purpose of comparison. For all of the members, any contribution from the interface of the infill panel with the thickened members to create a 'T' or 'L' section was ignored since loading is possible in both positive and negative directions, and these portions would be of little benefit during negative bending.

Figure 2. Labels used to identify long panel members.

#### 2.4.1 Results of Finite Element Analysis

Only select results are presented here, predominantly from the negative load case, as this is the case that applies the greatest pressure to the panels. Given the linear-elastic nature of the analysis performed, unfactored results are presented, since determining the response at the serviceability and ultimate limit states is simply a matter of proportion.

The stresses due to the self-weight of the panel in the upright position is shown in Figure 3. From this analysis, it is shown that the self-weight in this axis is a minor contribution to the total stress. Thus, the stresses from the self-weight are minimal in comparison to the stresses in the panel due to bending (0.041 MPa compared to 6.48 MPa expected from bending, or approximately 0.6% of the maximum stress) and can presumably be ignored during further analysis. The expected deflection of the panel under unfactored negative pressure is shown in Figure 4. Scaling this to the serviceability load level (multiplying the FEA results by the 0.75 SLS factor [8]), the expected deflection becomes 3.02 mm, and likewise for positive pressure, the expected serviceability deflection is 2.43 mm. For the purpose of comparison to the analytical calculations Figure 5 displays the moments in the long members of the panel for comparison to the analytical calculations. Finally, the maximum unfactored tension principal stresses for positive and negative pressure are shown in Figure 6 in order to determine if any portions of the panel are demonstrating unexpected behavior. A summary of the maximum and minimum stresses experienced in the long panel is given in Table 1.

Figure 3. Stresses in the panel due to self-weight.

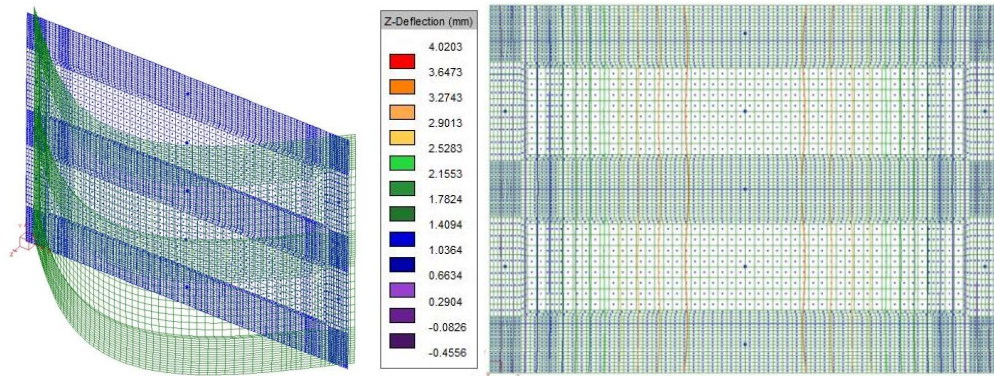

Figure 4. Undeformed and deformed geometry (left) and predicted lateral deflections (right) due to negative pressure.

Figure 5. Moments in the long members for negative pressure.

Figure 6. Maximum principal stress (tension).

**Table 1. Unfactored top and bottom stresses in long panel elements**

	<b>Positive Pressure (1.54 kPa)</b>		<b>Negative Pressure (1.91 kPa)</b>	
	Top Stress (MPa)	Bottom Stress (MPa)	Top Stress (MPa)	Bottom Stress (MPa)
Long	-4.582	6.227	5.683	-7.724
Middle	-4.461	6.450	5.533	-8.000
Infill y	-4.551	1.291	5.644	-1.601

The finite element model for the long panel shows that applying the ULS factor of 1.4 [8] to the above values, it is apparent that the stresses in many of the members of the panel exceed the cracking limit (4 MPa in tension) of the UHPFRC material. Thus, at this point it is expected that the loading has exceeded the linear-elastic nature of the finite element model and the exclusion of the GFRP reinforcing bars in the model becomes significant. In order to suitably verify the performance of the panels, it was deemed necessary to perform load testing on the panels.

## **2.5 Static Test Set-Up of Long Panel #1**

The full-scale static testing was performed with the panels in a horizontal position. Ideally, the panels would have been tested in a vertical position to include the in-plane self-weight effects in the test; however difficulties in accurately applying the required pressure made this impractical. As a result of using a horizontal test setup, the applied pressures were adjusted to account for the loading by the self-weight of the panel applied in this condition. It is important to note, however, that the deflection and strain measurements were zeroed with the panels supporting their self-weight, introducing a measurement offset bias in the testing.

The test frame was designed to replicate the supports that would be present in the real world condition, reproducing the mullions to act as primary supports. The positive and negative pressures were applied in independent tests in order to facilitate the testing setup. In order to ensure the pressure was uniformly applied to the panel, an inflatable mattress was placed between the load piston and the panel to distribute the loading. This also allowed the load to continue to be distributed as a uniform pressure even with the substantial deformations that were observed in the later stages of the testing. An example of this setup is shown in Figure 7. Once the capability of the air mattress to uniformly transfer load to the panels was exceeded in the loading to failure, the mattress was replaced with point loads at the quarter points of the panel to induce stresses similar to uniform pressure.

The load was applied in the downward direction for both tests; however the orientation of the panel was adjusted in order to test the appropriate pressure direction. For the positive load test, the panel was tested with the ribs directed upwards (external face upwards), whereas for the negative pressure case the panel was flipped, with the ribs directed downward (external face downwards).

**Figure 7. Use of an air mattress to provide uniform pressure**

### **2.5.1 Test No. 1 – Positive Pressure Supports**

Test No. 1 applied positive pressure to the panels with the panels supported on ball bearings at each of the cast-in anchors. In this configuration, the panel was oriented with the textured surface (outside face) of the panel facing upwards. A schematic of the test setup is shown in Figure 8. The use of ball bearings at the support ensured that a true pin connected was provided. A close up of the supports provided is shown in Figure 8.

**Figure 8. Schematic of Test No. 1 test setup and positive pressure support condition**

### 2.5.2 Test No. 2 and Test No.3 – Negative Pressure Supports

Test No. 2 and Test No. 3 applied negative pressure to the panels with the panels supported from rods threaded into each of the cast-in anchors and suspended from the test frame. For this test, the panel was reversed, with the textured ribs oriented downwards, as shown in the schematic test setup in Figure 9. Suspending the panels was selected as the support method in order to prevent any membrane forces from developing within the panel. This support is shown Figure 9.

**Figure 9. Schematic of Test No. 2 and No.3 test setup and negative pressure support condition**

### 2.5.3 Instrumentations

The cladding panels were instrumented with strain gauges both on the exterior surfaces of the panels and on the GFRP reinforcing bars cast within. The strain gauges were placed to allow the determination of the cracking load and – once converted to stress – for the purpose of comparison to the analytical calculations and the finite element model. Additional instrumentation installed included Linear Displacement Sensors (LDS) and Laser Position Sensors (LPS) used to measure the displacement of the panels under load.

### 2.5.4 Applied Loading

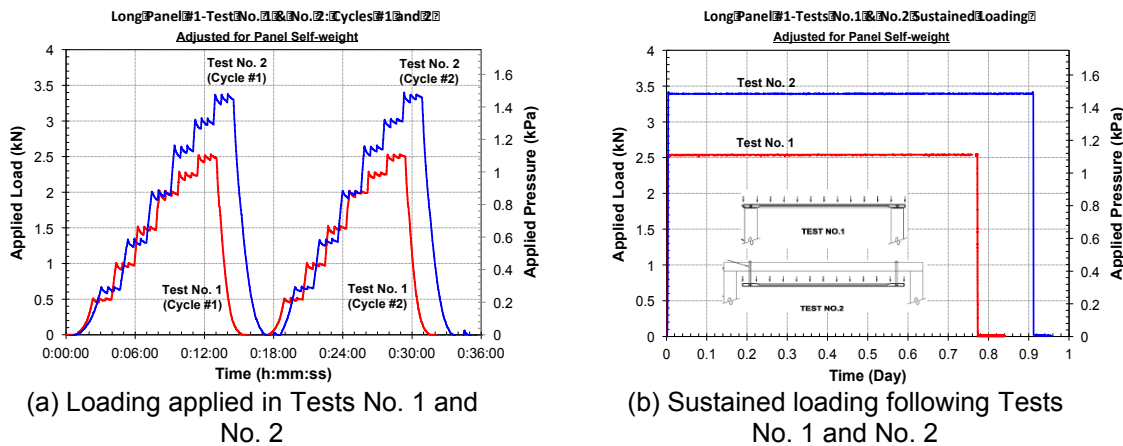

Loading of the panels in Test No. 1 and No. 2 was applied in steps and in cycles to simulate the variability of wind loading as shown in Table 2 for Test No. 1 (positive pressure) and for Test No. 2 (negative pressure). This pattern of loading is shown in Figure 10(a), with the 'Applied Load' as measured from the load cell in the testing apparatus, converted to the 'Applied Pressure' based on the area of the panel being tested. Since the panels were tested in the horizontal position, the self-weight of the panels was removed from applied loading (applied in the downward direction) in order to more accurately simulate the desired pressure. Note that in each load step the load is reinstated to the intended loading every 30 seconds to account for any load losses incurred in the system, either through dynamic effects or losses from the air mattress.

Following each of Test No. 1 and Test No. 2, a sustained load was applied to the panels for a period of 18 or 24 hours (depending on test facility availability). The intent of the sustained loading was to establish whether the panels displayed any time-dependent effects. These loading cases are shown in Figure 10(b), again as measured from the load cell during testing. The cause of the variability in applied loading in Test No. 1 is uncertain. Finally, after the previous testing was complete, the panel was loaded through to failure in Test No. 3.

**Table 2. Applied loading to long panel #1**

Load Step	% of non-Factored Load	Test No. 1		Test No. 2		Remarks
		Positive Pressure (kPa)	Positive Load (kN)	Negative Pressure (kPa)	Positive Load (kN)	
Cycle 1						
0	0	0	0	0	0	0
1	20	0.222	0.557	0.296	0.726	3 x 30 seconds
2	40	0.443	1.062	0.592	1.402	3 x 30 seconds
3	60	0.665	1.569	0.887	2.076	3 x 30 seconds
4	80	0.886	2.074	1.182	2.750	3 x 30 seconds
5	90	0.997	2.328	1.330	3.088	3 x 30 seconds
6	100	1.108	2.581	1.478	3.426	3 x 30 seconds
Cycle 2 – repeat loadings from Cycle 1						
7	100	1.108	2.581	1.478	3.426	Sustained 24 hrs

**Figure 10. Loading applied to long panel #1**

## 2.6 Static Test Results of Long Panel #1

The central deflection under Test No. 1 and Test No. 2, as shown in Figure 11 indicates that an amount of initial permanent deformation is observed in the panel prior to cycle 2. It is possible that this initial deformation is a result of 'setting-in' of the test apparatus, since in both tests, the second cycle of testing resulted in the panel rebounding to nearly the initial deformation. However, it is more likely that this permanent deformation is a characteristic of the panel, since under the sustained loading condition performed after Test No. 1 and No. 2, Figure 12(a) also indicates some creep as a result of the loading. This effect is also shown in Figure 12(b) which shows the deflection as a function of time under the sustained load. This figure clearly demonstrates that the panel central deflection progressively increases with no further increase in load, and having a resultant deformation of approximately 2.0 mm after Test No. 1 and 2.4 mm after Test No. 2. It is not apparent if this permanent deformation is a realistic expectation in real world use, since the variability and reversibility of the wind load means these deflections could cancel each other out.

The deflections measured at various points on the panel under loading were compared to ascertain the shape of the deflection and the similarity to the assumed one way loading in the analytical calculations. This comparison is made in Figure 13(a). The deflection curves for 'Def-L-Cen', 'Def-L-E', and 'Def-W' are the deflections for the long middle, and long edge at the top and bottom of the panel, respectively. The deflection curves for 'Def-S' and 'Def-N' are at the quarter points of the long middle member. Due to the close similarity of the deflections across the width of the panel (Def-W, Def-L-E, and Def-L-Cen), it is observed that the panel behaved as a single unit spanning between the supports.

Test No. 3, shown in Figure 13(b) shows the central deflection of the panel through to failure under negative pressure. In this test, elastic behaviour of the panel is shown under applied loading approaching 2.5 kPa, at which point cracking of the panel notably reduces the panel stiffness, indicated by the reduced slope of the graph. Ultimately, this panel failed at an applied load of approximately 8.4 kPa, which equals approximately 8.8 kPa including the self-weight of the panel, at a deflection of approximately 146 mm.

As expected for this panel, the ultimate failure occurred as a crack propagating across the short direction of the panel, located predominantly within the decorative ribs, as these act to reduce the effective section of the panel. The final failure crack is shown in Figure 13(b).

## 2.7 Static Tests Comparison and Validation

The primary criteria for acceptability of the wall panels is the deflection under serviceability load conditions. In this section, a comparison of all static test results is presented including the Short Panel [6], Long Panel #1, and Long Panel #2 [6]. A comparison of the deflection values obtained through the analytical calculations, the finite element model, and the static testing is shown in Table 3. It is noted that the analytical calculations predicted the highest deflections, most likely due to the number of simplifying assumptions made, including ignoring the contribution of the surface ribs to the panel strength, analyzing the panels as a one-way and two-way slab and beam system, and ignoring the contribution of the 'T' and 'L' sections to the member strength. For the short panel, the actual deflection at the SLS load level was significantly less, nearly half as much, as that calculated in the finite element model. This could be due to the additional stiffness offered by the textured rib surface, which was not accounted for in the modelling, but was shown to have a significant impact. The short panel static testing displayed deflections significantly below the established deflection limit for both the positive and negative pressures.

For the Long Panel #1, the average deflection of the panel agreed well with the analytical calculations, but was higher than the finite element analysis calculations. However, there was a substantial disparity in the performance of the two panels, for which there appears to be little explanation. Here, Long Panel #1 deflects less under load than both the analytical calculations and the finite element analysis predict and is within the acceptable deflection limit, while Long Panel #2 had measured deflections greater than expectations and limitations. Given that the performance of the Long Panel #2 continues the trend of deflecting less than the predicted deflection, similar to the Short Panel, it is theorized that Long Panel 1 is an anomaly and may not be representative of the typical panel behaviour. However, since only two Long Panels were tested, this could not be confirmed. When the average of the two long panels is considered, the maximum of 4.00 mm under negative SLS pressure results in a deflection of span/400, which is deemed to be acceptable given the established limit is based on masonry construction, and these Ductal® concrete panels exhibit much greater ductility than would be expected with masonry.

Based on the Short Panel and the Long Panel #2, the spandrel panels as designed satisfy the deflection design requirements.

**Table 3. Comparison of predicted and measured panel deflections**

Analysis Method	SLS Positive Pressure Deflection (mm)		SLS Negative Pressure Deflection (mm)	
	Short Panel [6]	Long Panel	Short Panel [6]	Long Panel
Established Limit: L/600	1.95	2.73	1.95	2.73
Analytical Calculations	2.03	3.02	2.53	3.96
Finite Element Analysis	1.41	2.43	1.75	3.02
Static Load Testing <sup>Note 1</sup>	0.84	<i>Panel 1</i>	1.24	<i>Panel 1</i>
		<i>Panel 2 [6]</i>		<i>Panel 2 [6]</i>
		4.38		1.71
		3.05 (average)		4.00 (average)

Note 1: The measured deflection from the static load testing does not account for the deflection caused in the panel under self-weight in the horizontal position.

In fact, the short panel cracked at a loading higher than the ultimate load condition, and as such would not be expected to crack at all through the life cycle of the panel. In general, the cracking loads predicted through analytical calculations were approximately three to four times less than the static test loads.

The measured failure load of the panel during the static testing was also notably higher than the load predicted through analytical calculations. This can likely be attributed to the simplifications made in the analytical calculations and the material reduction factors applied to the UHPFRC and GFRP reinforcing bars.

Given the fact that the panel was able to resist forces much higher than the ultimate limit states design loads and did not exhibit cracking under serviceability load conditions, it is determined that the panel is acceptable for the intended use as spandrel cladding panels. All of the panels demonstrated large deflection prior to the failure of the panels, thus a ductile failure mode was exhibited.

**Table 4. Comparison of calculated and measured cracking and failure pressure**

Panel	Analytical Calculations		Static Load Testing	
	Cracking Pressure (kPa)	Failure Pressure (kPa)	Cracking Pressure (kPa)	Failure Pressure (kPa)
Short Panel [6]	1.05	3.97	5.19	12.03
Long Panel #1	0.68	2.15	2.02	8.80
Long Panel #2 [6]			2.16	14.75

### 3. Conclusions

The UHPFRC spandrel cladding panels with GFRP reinforcing bars as designed and tested are sufficient to withstand the positive and negative wind pressures for the intended application in Victoria, British Columbia. The prototype panels proved to exceed expectations from both the analytical calculations and the FEA. Better realism in the FEA could have been achieved by developing a model that included the tension and compression properties of the UHPFRC by inputting the stress-strain relationship of the material, as opposed to the linear-elastic model that was used. Additionally, while the analytical calculation method undertaken proved to provide a reasonable approximation for the deflections, it was shown to estimate a failure load approximately three times lower than the failure load established through testing. It was also concluded that the textured rib surface did have a beneficial impact on the performance of the panel, contrary to the assumptions made in the initial analysis.

# Upgrading the Dundas Point Boardwalk, Applecross with the use of GFRP Bar Reinforced Concrete Columns and Footings

Joel Brown B.Eng GradIEAust  
Structural Engineer, Airey Taylor Consulting

**Abstract:** The use of Glass Fibre-Reinforced Polymer (GFRP) bars for internally reinforcing concrete structures has been growing to overcome common problems of steel reinforcement, such as corrosion. Areas for application are dominated by bridge decks where de-icing salts are used, although other applications include coastal structures or structures aiming for an extended design life.

The Dundas Point Boardwalk in Applecross, Western Australia is subject to a harsh marine environment and remedial works to the foundation system which included corroded steel piles were focused on achieving an extended design life and addressing the ongoing corrosion issues encountered in marine environments.

In stage one of the boardwalk repair, sixteen concrete columns and eight concrete footings were constructed, all internally reinforced with GFRP bars. The design of the footings and columns was performed using Canadian Code CAN CSA S806-12 (1) and ISIS Canada's guide 'ISIS Educational Module 3: An Introduction to FRP-Reinforced Concrete' (2).

As the boardwalk decking was constructed using steel supporting members, attention was paid to detailing the concrete to steel connections in order to avoid moisture ingress and bimetallic corrosion. This connection was designed using GFRP threaded bolts embedded into the concrete piles and connecting the supporting steel members.

Contractor feedback highlighted the ease of workability with the GFRP bars and all research suggests that there is no reason that a design life in excess of 75 years for the concrete elements cannot be achieved.

**Keywords:** GFRP, Reinforcement, Columns, Marine, Corrosion.

## 1. Introduction

### 1.1 Background of Dundas Point Boardwalk

Dundas Point Boardwalk is approximately 250 metres long, between 2.5 and 7 metres in width, and is located on the southern side of the Swan River Estuary near the north and western sides of Dundas Point in the City of Melville, Western Australia. The majority of the boardwalk is in the tidal zone of the Swan River and receives constant wetting and drying of its support structure. The boardwalk is used for foot and bike traffic only.

The boardwalk was designed and constructed in the 1990's utilising steel universal column (UC) piles encased in concrete a minimum of 200mm below ground level at the time of construction. This supported steel framing on which a timber deck was laid. All steel members including piles and steel framing were hot-dipped galvanised.

**Figure 1.**Left: Steel UC Connecting to Steel Framing. Right: Steel UC Below Concrete Encasing.

Steel thickness measurements were performed on a selection of the steel piles. They were assessed in accordance with AS 1627.0-1997: 'Metal finishing - Preparation and Pretreatment of Surfaces (3). All piles were classified as suffering from Grade H corrosion –'Large portion of surface is covered with rust, pits, rust nodules and non-adherent paint, pitting is visible.' The results of the thickness measurements were extrapolated through a detailed non-destructive visual inspection to give an assessment of all 76 of the boardwalk piles, Table 1 summarises these results.

**Table 1. Steel Pile Mass Loss Summary.**

<b>Steel Mass Loss Range</b>	<b>No.</b>	<b>%</b>
Not Inspected	1.0	1.3
No Assessed Loss	0.0	0.0
0 - 10% loss	0.0	0.0
10 - 20% loss	9.0	11.8
20 - 30% loss	36.5	48.0
30 - 40% loss	26.0	34.2
40 + % loss	3.5	4.6
<b>Total</b>	<b>76.0</b>	<b>100.0</b>

Due to funding limitations, it was decided to only remediate a 41 metre section of the boardwalk at the southwestern corner with the remainder of the required works programmed into the City of Melville's future works programme.

## **1.2 Background to GFRP**

Fibre Reinforced Polymers (FRP) are composite materials that can be used to strengthen concrete structures. They are made of fibres of a particular material selected, embedded in a polymeric resin. The most common fibres used in FRPs are glass, carbon or aramid. FRPs can come in woven sheets, which attach to the outside of reinforced concrete structures to offer strengthening, usually for remediation purposes. FRPs are less commonly produced as reinforcing bars.

Advantages of GFRP bars include; having high tensile strength, being corrosion resistant, nonmagnetic and lightweight with low thermal and electrical conductivity. This suite of characteristics is useful in many situations. GFRP bars are well suited for use in corrosive environments, in structures required to have a very long design life, in hospitals near MRI machines, for example, and provide easy workability because they are lightweight.

Disadvantages of GFRP bars include; no yielding before failure, low transverse strength compared to steel, low modulus of elasticity and possible durability issues of glass fibres in high alkaline environments. These characteristics need to be understood with guidelines to manage risk associated with these properties in concrete.

In 2001, the American Concrete Institute (ACI) released their first standard detailing recommendations of the use of FRP bars in reinforced concrete (RC). "Guide for the Design and Construction of Structural Concrete Reinforced with FRP Bars" (4) is the most current standard and was published in February 2006. ACI Committee 440 has chosen not to offer recommendations on the use of FRP bars in compression members due to the lack of experimental data at that time. The Canadian Code CAN CSA S806-12 (1) does include the use of GFRP in concrete compression members but ignores the contribution of GFRP when considering axial capacity.

## **1.3 Objectives**

Experimental research at University of Western Australia was undertaken by the writer in 2012 who compared the performance of axially loaded concrete columns reinforced with GFRP bars to traditional steel reinforcement "The Study of FRP Strengthening of Concrete Structures to Increase the Serviceable Design Life in Corrosive Environments" (5). The results concluded that the same axial capacity could be achieved using the same area of reinforcement providing the GFRP transverse reinforcement spacing

was lowered to approximately half that of the steel equivalent. That study led to the decision to construct concrete columns in an active project not only to achieve a corrosion resistant solution which would be economically beneficial, but to also monitor the performance of the columns, validating the findings of previous research.

**Figure 2. Existing Boardwalk in Tidal Zone.**

## **2. Initial Design Phase**

### **2.1 Constraints**

The project brief stipulated that remedial works undertaken must yield a similar appearance as the existing boardwalk. This therefore set column sizes at 300mm in diameter and required them to have a black exterior. The same size and arrangement of steel framing was to be used to support the decking. Whilst keeping to these aesthetic requirements, the Client required a design life of over 25 years. The portion of boardwalk being replaced was 23 years old.

**Figure 3. Typical Arrangement of Two Piles and Cross Beam.**

In the existing northeastern section of the boardwalk, there is pile support for the riverside of the boardwalk, with the steel cross beam which connects being supported in a recess into the limestone retaining wall on the land side. This connection was unstable as the retaining wall was rotating due to erosion issues below the boardwalk. This meant that new supports were needed to avoid reliance on the retaining wall for support.

**Figure 4. Steel Cross Beam Embedded in Retaining Wall.**

## 2.2 Proposed Solution

The proposed solution included the replacement of pile supports whilst keeping a portion of the embedded steel UC pile to provide added anchorage of the element into the ground. The existing concrete encasement to piles was to be fully removed and replaced with a durable GFRP reinforced concrete solution. Whilst the existing steel UC pile was engaged, its requirement was designed out in the final design. This meant that a new footing would be required to support the concrete columns.

It was proposed that to eliminate the corrosion vulnerable column to superstructure connection, GFRP bolts would be cast into the new columns. This was deemed necessary as the steel framing for the decking was to be replaced and treated with an ultra-high build epoxy painting system so as to achieve a system that could be maintained over time and give a long design life of 20-25 years in a harsh marine environment.

Where the boardwalk cross beams were embedded in the limestone retaining wall adjacent, it was proposed to support them on new GFRP reinforced concrete columns identical to the replacement columns.

**Figure 5. Proposed Column and Footing Design.**

In the original construction there was a 300mm deep layer of sand extending up from the base of the concrete encasement of the steel piles. Over time this had been eroded away, in some cases exposing the limestone base below. This meant that two arrangements of footings were required to be designed, one founding on sand areas of the site and one founding on limestone.

### 3. Final Design

#### 3.1 Columns

The final design of the columns included six 15.88mm GFRP longitudinal bars with ligatures at 100mm centres made from 9.53mm GFRP bars. Although the bars are non-corrosive, it was decided that a pour blocker would be used in a 40MPa concrete mix to minimise concrete degradation. This was used with the intent of achieving a design life of the columns in excess of 75 years.

As there was the requirement for the new columns to look the same as the existing, permanent fibre cement formwork 300mm in diameter was specified and then painted black. This both allowed for easy forming and yielded a neat appearance.

The existing steel piles were nominated to be cut back to leave an 800mm lap to be embedded in the replacement column. Following this they were to be cleaned to a Class 2.5 finish according to AS 1627.4 using grinding to remove the bulk rusted layers followed by wet abrasive blast cleaning or a blasting / washing / blasting sequence to achieve effective removal of soluble salts. Surface chlorides were tested to ensure that they were less than 50 micrograms per square centimeter. Where otherwise, they were to be re-washed with inhibitor solution then re-blasted prior to coating with a corrosion inhibiting priming paint.

Figure 6. Final Column Design.

#### 3.2 Footings

The strip footings were designed to be able to support the loads through the new columns without the need for the engagement of the existing steel pile. One strip footing is used to support a pair of columns. The footing is 2.5 metres long, as required due to the placement of the columns, 600mm wide and minimum 250mm deep. The footing has bottom reinforcement, with six, 15.88mm GFRP bars equally spaced over the long span and four, 15.88mm GFRP bars over the short span. Six starter bars extend from the footings which would lap onto the main column reinforcement.

Due to the variable site conditions, the strip footing could be slightly altered for each case. Where sand is present, the footing and column are to be constructed with 500mm of sand above the top of the footing to allow for future erosion, or until bedrock is encountered. Where bedrock is exposed, the footing is to be recessed 250mm into the bedrock. These arrangements are shown in Figure 7.

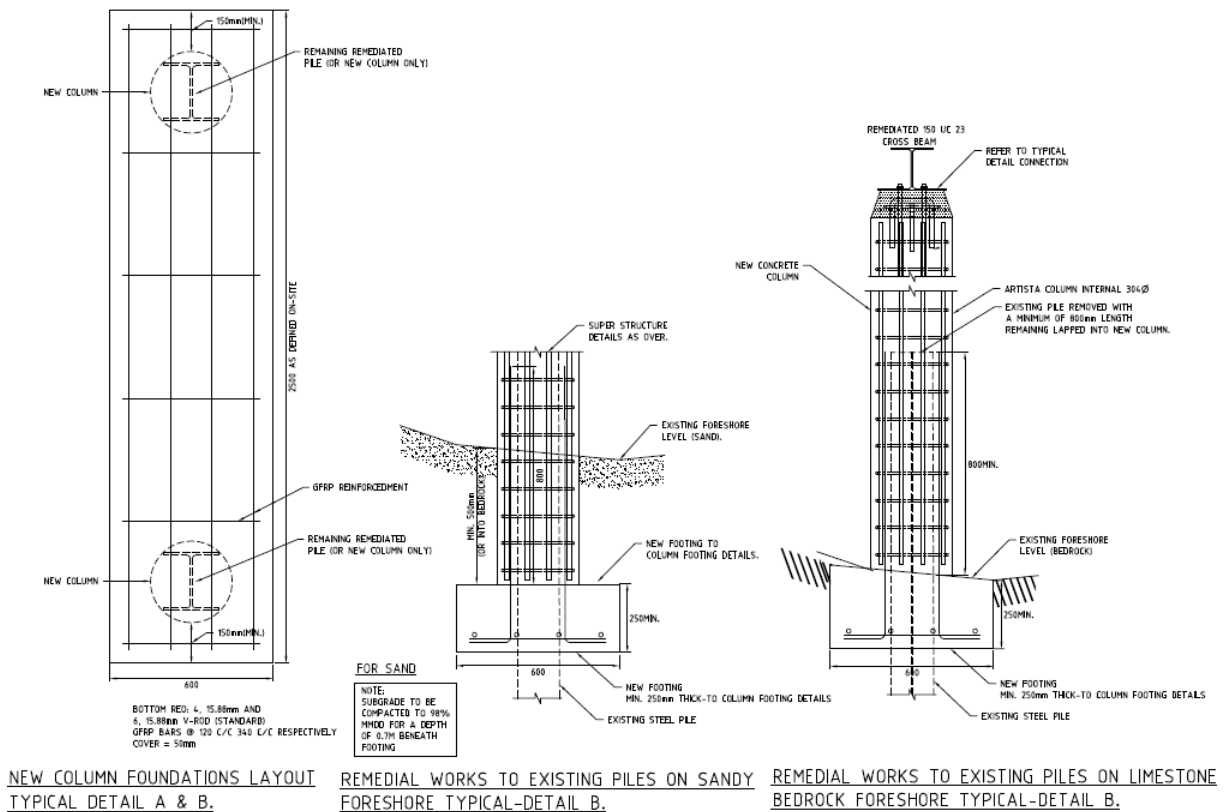

Figure 7. Final Footing Design.

### 3.3 Connection to Steel Framing

The connection detail between the new columns and the steel cross beams which support the decking is critical. As this zone was prone to the deposition of salts, GFRP bolts were assessed as the best material for fixing the columns to the steel. Four 24mm diameter GFRP threaded rods were anchored 1 metre into the new concrete column. The new steel UC cross beams which were fabricated had additional plates welded to the bottom flanges in order to allow for these bolts to be accommodated. Due to the high grade paint specification used, EPDM washers were used to protect the steel from the nut and washer fixings.

As there was a gap between the top of column and the underside of the steel cross beam, two 'U-bars' were fabricated from 15.88mm GFRP and cast into the top of the column. This allowed for a non-shrink structural epoxy grout to be used to infill the gap and be engaged by the remainder of the concrete column. The grout could then be tapered to the steel cross beam to minimise pooling of any moisture.

Figure 8. Final Column to Beam Connection.

## 4. Construction Phase

### 4.1 Footings

The existing steel UC piles were successfully cut back and cleaned via abrasive blasting and thorough wire brushing. Chloride tests were performed on five of the sixteen steel sections with all tests yielding results under the allowable 50 micrograms per square centimeter. The steel was then painted with the appropriate corrosion inhibitor within four hours of the chloride tests being undertaken. This ensured that no excess chloride deposition took place between the testing and painting phases.

The footings were formed and GFRP reinforcement and starter bars laid as per Airey Taylor Consulting drawings and specifications. All footings encountered bedrock and therefore all footings were recessed into the bedrock. Rock boulders would be placed at the base of the footings to assist in limiting erosion, protecting the retaining wall structure adjacent to the boardwalk. The Contractors noted the ease of laying the reinforcement due to its light weight. Plastic zip ties were used to tie bars together.

Figure 9. Forming and Pouring of Footings.

### 4.2 Columns

Once the footings were cast and cured, the column reinforcement cages, which were assembled on site, could be installed and the permanent formwork positioned and propped correctly. Timber plates were used to position the GFRP threaded rods at the correct height whilst the columns were poured.

The installation of GFRP reinforcement was completed in the same way that traditional steel reinforcement is. Contractor feedback focused on the lightweight material and the easy with which it was positioned.

Figure 10. Forming and Pouring of Columns.

### 4.3 Connection to Steel Framing

The steel cross beams were installed over the concrete columns and timber was used to hold the members at a slightly elevated level. The non-shrink structural epoxy grout was then placed and the steel lowered onto the grout to ensure there were no gaps between grout and steel. The grout was then tapered to give a rounded finish.

Once the cross beams were in place over the threaded rods, FRP washers and nuts, usually used for rock bolts, were installed over EPDM washers. This ensured that the paint on the steelwork was not damaged by the tightening of the nuts.

Figure 11. Column and Steel Connection.

### 4.4 Finished Boardwalk

Following installation of the steel framing, a composite decking was installed and the original hardwood handrails were reinstalled. After the remediation of the boardwalk reclaimed beach sand was placed over the top of the footings with a geotextile placed on top of that with additional rock armouring and beach re-nourishment. This was to aid in protecting the surrounding structures.

The construction phase was carried out in line with the final design and construction administration was performed by the writer throughout to ensure this was the case. The Client was very pleased with the outcome and the fact that the remediated portion of the boardwalk looked very similar to the existing, although now with a design life of 75 years for the columns and footings, minimizing their future maintenance costs in a very inaccessible area. The Contractor had no issues with the placement of GFRP and advised that it was similar to working with steel reinforcement but lighter.

Figure 12. New (left) vs Old Boardwalk (right).

## 5. Cost Analysis

Cost estimates were gathered from steel reinforcing suppliers in Perth for the fabrication and delivery of equal volumes of steel reinforcement compared to the GFRP bars specified. The steel estimates were approximately \$4,000 whereas the fabrication and delivery (via air freight) of GFRP came in at \$7,866. The price supplied for the same amount of GFRP but delivered via sea was \$6,810.

The difference of approximately \$4,000 is less than 1.5% of the total project cost which tendered for the amount of \$275,772.28 + GST. This was considered to be negligible, whilst the advantages in corrosion resistance and extended time prior to first maintenance are significantly increased.

## **6. Conclusion**

Previous experimental research performed by the writer in 2012 (5) concluded that concrete compression members reinforced with GFRP bars gave comparable capacities to concrete columns reinforced with traditional steel. This research was the basis of the design of the Dundas Point Boardwalk.

The use of GFRP reinforcement in compression members is not recommended by current guidelines and the Dundas Point Boardwalk is the first project in Australia known to have used the technique. This is considered a big step in the acceptance of GFRP as reinforcement not only in compression members but in all concrete structures in Australia. Whilst there are many projects overseas which utilize this material, Australia has been slow to adopt it, and as all things new, people want to see it used in projects before confidence can grow.

The additional 1.5% of the total project cost was assessed as a negligible outlay in order to achieve concrete members which are expected to give good in service duty for over 75 years. The lack of maintenance required will allow for this slight start-up price increase to be recouped multiple times over the life of the structure.

The Client was receptive to the use of GFRP reinforcement at the concept design phase of the project, and the Contractor had no negative feedback whilst using the material and commended the workability of the product. This project, the ease with which it was executed, and the attenuated durability expected will give confidence to others to adopt the material

## **7. Acknowledgements**

The writer would like to acknowledge the support provided by Mr John Clancy, Mr Peter Airey, Dr Anthea Airey and all Airey Taylor Consulting staff for their hard work and support in delivering this project. MMM WA Pty Ltd were crucial in ensuring the construction of the project went smoothly and were willing to learn and work with GFRP bars without any prior knowledge of the material. Thanks to the City of Melville team who were forward thinking and proactive in ensuring their public structure was designed and built to last, giving a very good return for the community they represent.

# A design methodology for fibre reinforced concrete slabs-on-grade

Ravindra Gettu<sup>1</sup> and Sunitha K Nayar<sup>2</sup>

<sup>1</sup>Professor of Civil Engineering, <sup>2</sup>Doctoral Research Scholar  
Indian Institute of Technology Madras, Chennai, India

**Abstract:** Slab-on-grade applications of fibre reinforced concrete have been widespread in the recent past. Design strategies based on inelastic analyses have been accepted for slabs-on-grade and utilized in many guidelines. Some of these have shortcomings due to the limitations of the material parameters adopted or due to the exclusion of critical failure modes, shrinkage and thermal stresses. This paper discusses a design methodology based on yield line analysis incorporating the equivalent flexural strength as the design material parameter, which can be used to choose a combination of fibre type and dosage, for a given concrete strength grade and slab thickness. All critical failure modes have been included in the analysis. The method also addresses the incorporation of thermal and shrinkage stresses systematically in the design. The outcomes of the method are compared with those of other guidelines in terms of slab thickness and fibre dosage.

**Keywords:** Fibre reinforced concrete, Slabs-on-grade, yield-line analysis, inelastic design, toughness.

## 1 Introduction

The effective exploitation of the crack resisting potential of fibre reinforced concrete (FRC) by the inclusion of appropriate material parameters in design methodologies is a necessity for applications such as slabs-on-grade, where FRC with relatively low dosages of fibres may be employed as "stand-alone" primary reinforcement. Many design guidelines are available in this area, in addition to those provided by manufacturers [1-7]. A detailed review of these methods brings out the following shortcomings:

- Most design methods use expressions from solutions of analysis done on large slabs, without considering the actual dimensions and behaviour of the slab [1-3], where the cracks interact with the boundaries. The consequent design solutions may underestimate the stresses generated since the failure mode is different in smaller slabs.
- Many methods use material parameters that may not appropriately represent the material in the slab systems. For example, the use of a constant multiplier (e.g., 0.7) for obtaining characteristic value from the mean value of toughness disregards the variations in the fibres due to differences in their production [1-3, 5]; and the use of an equivalent flexural strength ratio (instead of the absolute value) leads to the misinterpretation that the toughness is a multiple of the modulus of rupture (often calculated empirically from the compressive strength) [7-9].
- Thermal and shrinkage stresses are not dealt with, in detail, but could be significant when the slab is exposed to environmental changes and/or the joint spacing is large.

The present approach attempts to address the above mentioned limitations, as illustrated in the following sections.

## 2 Design philosophy

Incorporating fibres in concrete is expected to impart sufficient rotation capacity to the slab-on-grade during cracking so that the plastic moment capacity of the slab is fully mobilized. The ultimate load may then be estimated with the yield lines forming a mechanism and the regions bounded by the yield lines behaving as rigid-plastic sections. However, the yield line patterns and the corresponding ultimate loads are dependent upon the type of loading, slab dimensions and end conditions, as well as the soil pressure distribution [10-15].

### 2.1 Failure pattern

Based on the various possible cases, the following critical yield line patterns may be envisaged to occur in slabs-on-grade.

### Case 1: Circular fan type failure – for interior loading

Such failure has been typically considered in most design documents for FRC flooring, where radial cracks initially appear at the bottom of the slab and widen followed by circumferential cracking (Figure 1a). The moments along the radial yield lines equal the plastic moment capacity ( $M_p$ ) of the concrete and the negative moment ( $M_n$ ) at the top of the slab reaches the flexural capacity [1-3, 11-15]. The appearance of crack at the top is considered as the failure state. Such failure can occur only when the slab dimensions are large enough to allow the radial yield lines to develop followed by the circumferential yield lines. Meyerhof's solution [11], used by many design guidelines, for the ultimate collapse load is based on the large slab assumption; the condition is that the load should be at least at a distance of  $5l$  from where  $M_n/M_p = 1$ , with  $l$  being the radius of relative stiffness. This implies that such failure will occur only when the slab width is at least  $10l$ . Another possibility for this type of failure to occur is when the stress or load transfer mechanism between slabs is efficient enough for the adjacent slabs to behave monolithically as a large slab, which cannot normally be expected to happen, especially due to degradation of the concrete and shrinkage.

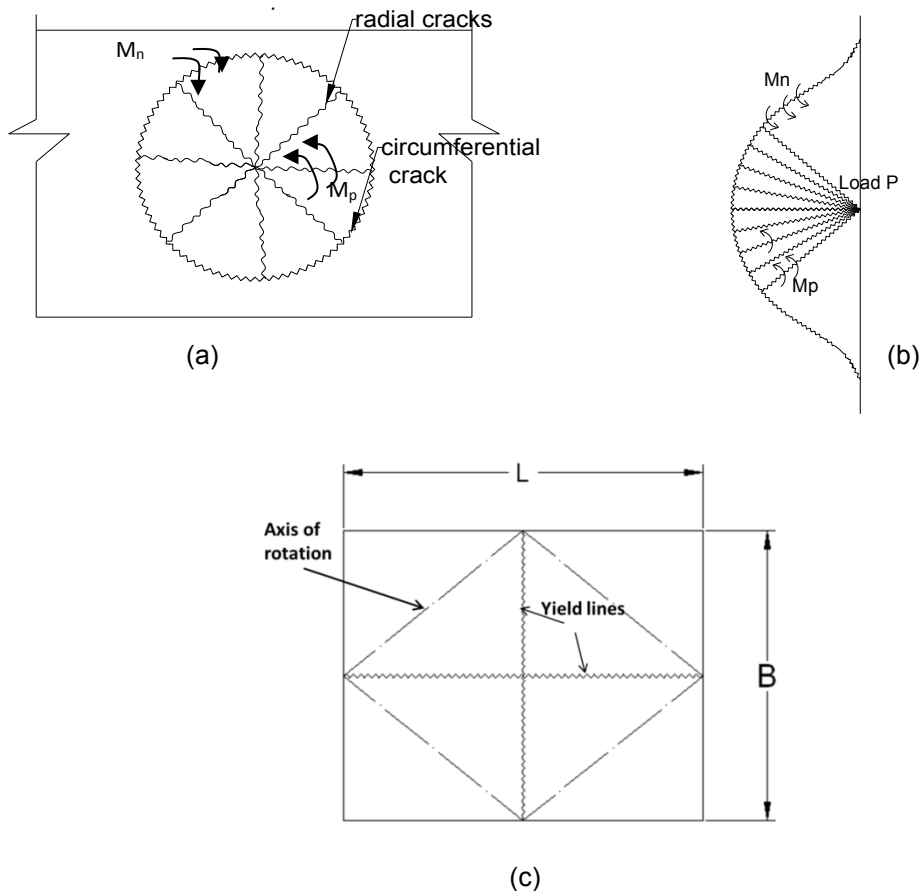

Figure 1. Yield lines: (a) Case 1, large slab; (b) Case 2, dominant edge load; (c) Case 3, free edges

### Case 2: D-cracking at the edges

In cases where the dimensions of the slabs are not large but more than 50% load transfer can be expected at the joints (i.e., enough to prevent free lifting of slab edges) or the loading is on or near the edge of the slab, the D-shaped failure pattern will govern [10, 11, 15]. Radial cracks start from under the load location followed by circumferential cracking, delimited by the edges of the slab (Figure 1b). As in the previous case, the radial yield lines are taken to have fully plastic moments and the circumferential yield lines are subjected to negative moments.

### Case 3: Centre line cracking – load in the interior of slab with free edges

Centre line cracking, as shown in **Figure 1c**, occurs when the slab is of finite dimensions and the edges are free to lift. The moment along all the yield lines may be assumed to be plastic as the slab rotates about the yield lines simultaneously; collapse is governed only by the plastic moment capacity [10].

#### 2.2 Limiting moment capacity estimate

The plastic moment capacity in the FRC slab is taken as the post-cracking moment carrying capacity, which is a function of the post-cracking flexural strength, such as the equivalent flexural strength specified in JSCE SF4 [16] or ICI/TC 01.1 [17]. Consequently, the plastic moment capacity per unit length of the slab is estimated as:

$$M_p = f_{e,nk} \frac{h^2}{6} \quad (1)$$

where  $f_{e,nk}$  is the characteristic equivalent flexural strength of concrete (obtained from the flexural test of an unnotched prism [16, 17]) corresponding to a specified deflection and  $h$  is the thickness of the slab. The equivalent flexural strength is used here instead of the residual strength since the former represents an average response over a range of crack widths rather than at a specific width, and exhibits lower variability than the latter [18-20].

The negative moment capacity is taken as a function of the flexural strength (or modulus of rupture) of the concrete (obtained from the same flexural test) as:

$$M_n = f_{ct,k} \frac{h^2}{6} \quad (2)$$

where  $f_{ct,k}$  is the characteristic value of the flexural strength of the concrete.

The corresponding moment estimates are used in the design equations suited to each yield pattern.

#### 2.3 Design equation and validation

The design equation is formulated to determine the required flexural strength and equivalent flexural strength for each critical loading condition as:

$$f_{e,nkrequired} = \left[ \frac{6M_{applied}}{h^2} - f_{ct,k} \right] \quad (3)$$

for cases where the limiting moments is given by the sum of the plastic positive and negative moment capacities (i.e., the circular and D-cracking cases), as  $M_{limit} = M_n + M_p$ .

For cases where the limiting moment is only the plastic positive moment capacity (i.e., for centre line cracking), the design equation is:

$$f_{e,nkrequired} = \left[ \frac{6M_{applied}}{h^2} \right] \quad (4)$$

$M_{applied}$  is obtained for each loading condition from yield line or other suitable inelastic analysis as:

$$M_{applied} = f\left(P, \frac{c}{l}\right) \quad (5)$$

where  $P$  is the factored applied load,  $c$  is the contact radius of the load application, and  $l$  is the radius of relative stiffness.

In accordance with the Winkler foundation approximation for subgrade, the value of  $l$  is taken as:

$$l = 4 \sqrt[4]{\left[ \frac{Eh^3}{12(1-\mu^2)k} \right]} \quad (6)$$

where  $E$  is the modulus of elasticity,  $\mu$  is the Poisson's ratio of concrete and  $k$  is the subgrade modulus.

In order to assess the validity of the methodology, the failure load obtained following the suggested method has been compared to the results of tests of FRC slabs by Falkner et al. [21]; the details of the test parameters are given in Table 1. The design was done assuming centre-line cracking to occur, since the slab dimensions do not meet requirements for circular cracking and the free edge conditions that permit the uplift of the slab rule out D-cracking. The limiting moment function is taken from the expressions given by Meda 2003 [10] as:

$$f_{e,3,krequired} = \frac{3P}{3h^2} \left[ 1 + \frac{1}{6} \frac{k}{K_s/B^2} \right] \quad (7)$$

where

$$K_s = \frac{86D}{\left( B\sqrt{2}/2 \right)^2} \text{ and } D = kl^4 \quad (8)$$

where  $B$  is the width of the slab = 3 m,  $h = 150$  mm,  $k = 0.025$  N/mm<sup>3</sup>. The terms needed for applying Eqn. (7) can be calculated as  $l = 540$  mm and  $K_s = 129$  kN/mm using the parameters in Table 1. The calculated load capacity is 185 kN, which falls between the reported fracture load of 165 kN and collapse load of 240 kN from the test results.

**Table 1. Parameters from the tests of Falkner et al. (21)**

Parameters	Values
Slab dimension	3.0 m × 3.0 m × 0.15 m
Loading plate dimensions	120 mm × 120 mm
Grade of concrete	C30/37
Fibre type used	Steel fibres, 60 mm long, diameter of 0.75 mm (Dramix RC 80/60 fibres)
Fibre dosage	20 kg/m <sup>3</sup>
Bedding type	Cork with $k = 0.025$ N/mm <sup>3</sup>
Elastic modulus of concrete	23400 N/mm <sup>2</sup>
Flexural strength of concrete $f_{ctk,fi}$	4.52 MPa*
Equivalent flexural strength $f_{e,150k}$	3.19 MPa*

\*Estimated from tests performed on similar FRC with same grade of concrete, fibre type and fibre dosage at IIT Madras

## 2.4 Thermal stresses

In cases where the temperature variations are significant, the design has to account for thermal stresses, especially in regions where the negative moment is critical. Axial tensile forces could occur if the temperature is uniform over the depth (usually occurs for thinner slabs) [22, 23]. A conservative estimate of the axial stresses has been suggested by Ghosh and Dinakaran [23], and Yoder and Witzack [22], as:

$$\sigma_{\Delta T_{axial}} = 24 \frac{wLf}{h} \quad (9)$$

where  $w$  = weight of slab, in N/m<sup>2</sup>,  $L$  = length of slab, in m,  $f$  = coefficient of subgrade restraint (<1.0), and  $h$  = thickness of slab, in m. However, these stresses are generally negligible and are, consequently, not taken into account in practice.

Flexural stresses could be generated when there are substantial temperature gradients [2, 4, 13], which can reduce the negative moment capacity to resist applied loads, affecting failure occurring with circular and D-cracking:

$$M_{limit} = M_p + (M_n - M_{\Delta T}) \quad (10)$$

Therefore, the required equivalent flexural strength value is to be modified to account for this, as:

$$f_{e, n_{krequired}} = \frac{6P}{h^2} f\left(\frac{c}{l}\right) - f_{ctk} + f_{\Delta T} \quad (11)$$

where  $f_{\Delta T}$  is the flexural stress due to the temperature differential ( $\Delta T$ ) in the slab. This could be estimated using the classical Bradbury's equation as:

$$f_{\Delta T} = \frac{E\alpha\Delta T}{2(1-\nu^2)} (C_1 + \nu C_2) \quad (12)$$

where  $\alpha$  is the coefficient of thermal expansion, and  $C_1$  and  $C_2$  are the Bradbury's correction factors for curling in finite slab, which are obtained from charts prepared for various values of  $L/l$ , where  $L$  is the joint spacing [22].

## 2.5 Shrinkage stresses

Proper concrete mix design and good construction practices are key to reducing shrinkage stresses in concrete, especially in the plastic stage. In hardened concrete, shrinkage stresses can be considerably reduced by providing friction relief layers, such as polyethylene sheets, so as to reduce the restraint against shrinkage, and by providing properly-prepared joints at adequate intervals [1-3]. Typically, sawn joints are recommended, with groove widths not less than 3 mm and depths of about 1/3<sup>rd</sup> to 1/4<sup>th</sup> the thickness of the slab [24]. The joint spacing depends on the amount of restraining stress and the tensile strength of concrete, both of which will depend on the composition and quality of concrete, and the length-to-width ratio of the slab. The following recommendations, compiled from existing standards, may be adopted:

- Joints may be located along the column lines with intermediate joints located at equal spacing between column lines (ACI 360R [3]).
- Maximum limit on length/width ratio = 1.5 (TR34 2003, TR34 2013 [1-2])
- Largest dimension between joints can be restricted to 4.5-6 m depending upon the thickness. (with smaller values for higher thicknesses) (TR34 2003, TR34 2013, IRC 15 [1-2,24])
- ACI 360R charts for joint spacing in unreinforced slabs or slabs with reinforcement for temperature or shrinkage stresses, obtained based on shrinkage measurements on concrete as per ASTM C157/ C157M, may be adopted in design [3].

Since the stress levels in concrete due to shrinkage could be considerable, an approach similar to that used for curling stresses is recommended in line with the method suggested in TR 34 2003 [1]. Thereby, the shrinkage stresses estimated from the ultimate (free) shrinkage strain values ( $\epsilon_{sh}$ ) may be reduced from the total negative moment capacity, as:

$$M_{limit} = M_p + (M_n - M_{\Delta T} - M_{sh}) \quad (13)$$

and the flexural stress associated with the moment due to shrinkage strain is calculated as:

$$f_{sh} = E \varepsilon_{sh} \quad (14)$$

where  $E$  is the modulus of elasticity of concrete and  $\varepsilon_{sh}$  is the ultimate shrinkage strain.

In the absence of data, a value between 300–500 microstrains may be assumed as the ultimate shrinkage strain of concrete. Further, a restraint factor of 0.2 may be assumed when a friction release layer is used, following TR34 (2003) [1], and the reduced shrinkage stresses may be computed as

$$f_{sh} = 0.2 E_{cm} \varepsilon_{sh} \quad (15)$$

## 2.6 Final design equations

Incorporating thermal and shrinkage stress in Eqn. (3), the final design equation for circular or D-cracking becomes:

$$f_{e, nkr} = \frac{6P}{h^2} f(c/l) - f_{ctk} + f_{\Delta T} + f_{sh} \quad (16)$$

Once the critical equivalent flexural strength value is determined by considering all possible loading and failure patterns, this can be specified as the performance requirement for choosing the fibre type, dosage and concrete mix, for the specified slab thickness. The choice can be made using any existing material database or test data.

From the actual parameters corresponding to the fibre type, dosage and concrete mix, preferably from test data, a design check has to be performed by calculating the allowable load, using the inelastic design equations (e.g., Eqn. 16), and ensuring that the following is satisfied:

$$P_{allowable} > P_{actual} \quad (17)$$

## 3 Comparison of design guidelines

The suggested method is compared in this section with design solutions obtained from various existing guidelines in terms of slab thickness and fibre dosage; comparisons were made with TR34 2003, TR34 2013, ACI 360 R-10 and the Losberg yield line method [1-3, 12]. The parameters that are significant for each method are shown in **Table 2**.

TR34:2003 uses the Meyerhof's equation wherein the equivalent flexural strength ratio is used to calculate the plastic moment capacity and the flexural strength for the negative moment capacity estimate to arrive at the allowable load. The TR34:2013 method uses the residual flexural strength (from a notched beam test) as the material parameter and neglects thermal and shrinkage stresses in the design equations, which results in an underestimation of stresses resulting in a less conservative design. ACI 360R uses the approximate equations suggested in Meyerhof's analysis for a slab on elastic foundation, with the assumption that the contact radius of the load ( $c$ ) is equal to or greater than the thickness of the slab, which leads to severe underestimation of the stresses. In Losberg's yield line analysis, the soil pressure distribution curves developed based on the elastic theories for the infinite elastic slab lead to more conservative estimates than the Meyerhof's analysis.

Allowable loads were obtained here, using the above-mentioned methods, for different slab thicknesses, for an M35 grade concrete having 20 kg/m<sup>3</sup> hooked ended steel fibres of length 60 mm and aspect ratio of 80. The material parameters for this combination were obtained from tests performed on notched and unnotched prism specimens, as listed in

**Table 3.** The stress due to thermal and shrinkage strains was taken as 1.5 MPa, based on TR34:2003 recommendations.

**Table 2 Details of parameters used in each method**

Design method	Input variables	Input material parameters	Dependent material parameters	Output variable
TR 34:2003 [2]	Load (P) Subgrade modulus (k) Thickness (h)	$R_{e,150}$ Grade of concrete	Type of fibre Dosage of fibre $f_{ctk}$	$P_{all}$
Losberg [12]	Load (P) Subgrade modulus (k) Thickness (h)	$f_{e,150mean}$ Grade of concrete	Type of fibre Dosage of fibre $f_{ctk}$	$P_{all}$
ACI 360 [3]	Load (P) Subgrade modulus (k) Thickness (h)	Grade of concrete	Type of fibre Dosage of fibre $f_{ctk}$	$R_{e,150}$ $P_{all}$
TR34:2013 [1]	Load (P) Subgrade modulus (k) Thickness (h)	$f_{r1}/f_{r4}$ Grade of concrete	Type of fibre Dosage of fibre $f_{ctk}$	$P_{all}$
Suggested method	Load (P) Subgrade modulus (k) Thickness (h)	Grade of concrete	$f_{ctk}$	$f_{ek,150}$ $f_{ctk actual}$ $P_{all}$

**Table 3 Material parameters used in the design comparison**

$f_{ct}$ , MPa		$f_{e,150n}$ MPa		$f_{r1}$ MPa		$f_{r4}$ MPa		$R_{e,150}$ %		Assumed stress due to thermal and shrinkage strains, MPa
Mean	Char	Mean	Char	Mean	Char	Mean	Char	Mean	Char	
5.80	4.87	3.72	2.8	3.96	2.86	4.17	3.26	64	64	1.50

Char: characteristics value

From **Figure 2**, it can be seen that the allowable load calculated as per the suggested method is higher than those obtained from the Losberg's yield line method and TR 34:2003 while it is lower than the allowable load as per TR34:2013 and ACI-360 R. For the case considered, the suggested method gives a higher capacity than TR34:2003 and Losberg yield line methods since it takes into account the characteristic value of the mechanical parameters from actual test results rather than taking the characteristic value as  $0.7 \times$  mean value; in this case, the actual characteristic strengths are higher than those obtained with the factor of 0.7. However, the suggested design method would give a lower estimate than TR34 2003 and Losberg's methods if the characteristic values were lower. It is, therefore, more realistic to take the actual characteristic values in the design rather than factored mean values.

**Figure 2 Comparison of allowable loads for different slab thickness**

Since the TR34:2013 and the ACI 360R methods are consistently less conservative than the other three methods, the next comparison only considers the suggested method, and the TR34:2003 and Losberg's yield line methods. The minimum required fibre dosage (for the same fibre type considered earlier) for a tyre load = 80kN, slab thickness = 120 mm and  $k = 0.02 \text{ N/mm}^3$  is calculated, assuming that the failure occurs by D-cracking, and reported in Table 4. The results suggest that for the same design parameters, the dosage of fibres required as per the suggested method is lowest thus providing the most economical design.

**Table 4. Minimum fibre dosage**

Design method	Minimum required $f_{e,150k}$ , MPa	Corresponding minimum dosage of the fibre considered, $\text{kg/m}^3$
TR34:2003	1.7	16
Losberg method	2.5	27
Suggested method	1.5	10

For the same combination of load and  $k$ , if the design by suggested method is done by assuming failure to be governed by centre line cracking (assuming a slab of  $3.0 \text{ m} \times 3.0 \text{ m}$  dimensions), then the design requires a minimum thickness of 150 mm (as opposed to 120 mm for D cracking) and a dosage of  $30 \text{ kg/m}^3$  of same fibres. Thus, it can be seen that the suggested method provides solutions that account for critical failure situations encountered in practice (normal size slabs without sufficient load transfer), and can be more conservative than other methods, such as the TR34:2003 method.

## 4 Conclusions

The prominent conclusions brought out in this study are

- A design methodology, for fibre reinforced concrete slabs-on-grade, based on yield line analysis is proposed wherein the material parameter adopted is equivalent flexural strength. The equivalent flexural strength has been taken as the basis since it gives a more realistic estimate of the post cracking capacity of the slabs-on-grade. The design equation estimates the required equivalent flexural strength for the given loading condition leading to a performance requirement for concrete.

- The governing design equations are dependent on the yield pattern that occurs based on the dimensions and end conditions of the slab. The design solutions of the suggested method are compared with existing design methods. It is seen that the current method can account for differences in the quality of concrete by the explicit use of the characteristic flexural strength and toughness parameter, instead of generic factors, and failure in small slabs by centre-line cracking.

**Abstract:** The application of anchorage devices to externally bonded fibre-reinforced polymer (FRP) strengthening systems for concrete structures is an intuitive solution to the debonding problem. While there have been experimental investigations of FRP anchors in FRP-concrete bonded interfaces to date, there has been decidedly less numerical modelling research. This paper presents the details of a finite element analysis of FRP-concrete joints anchored with FRP anchors. The finite element model as well as test results are also used to calibrate a constitutive model for the FRP anchor. The numerical simulations are shown to compare favourably with test results, and the simulations allow insights to be gained about the various components of FRP-concrete bonded interfaces anchored with FRP anchors.

**Keywords:** Finite elements, FRP, modelling, strengthening.

## 1. Introduction

Reinforced concrete (RC) structures can be strengthened with externally bonded fibre-reinforced polymer (FRP) composites. There have been numerous experimental studies conducted to date on FRP-strengthened RC members and a commonly observed failure mode has been premature debonding of the FRP [1, 2]. In order to delay or even prevent debonding failure, anchorage devices can be installed onto the FRP strengthening. The effectiveness of anchorage devices has been experimentally verified and quantified in a recent study by Kalfat et al. [3]. There have, however, been limited finite element investigations on anchorage devices and their use in FRP-strengthened structures thus far. Of central importance to such modelling are constitutive models for the anchorage devices. There has been limited development of such models to date.

Anchors made solely from FRP are referred to as FRP anchors. They are suitable for anchoring a wide variety of FRP strengthening applications ranging from beams to slabs. A convenient means to investigate the influence of FRP anchors is to incorporate them into FRP-concrete joints [e.g. 4, 5]. Figure 1 shows a typical joint as well as a FRP anchor hand-made from carbon fibre sheet and epoxy. A noticeable relationship between the position of the anchor relative to the loaded plate end has been observed from tests [6]. As the length  $L_{anc}$  is decreased, the load carrying capacity of the joint is increased. In addition, as the length  $L_{end}$  is increased past a threshold value, the load carrying capacity of the joint reaches a plateau. Other relationships between various geometrical parameters have been found to exist through experimentation, however, the trends concerned with anchor position and plate length are of most relevance to this paper.

A means to quantify the joint behaviour is to monitor the relationship between load applied to the free-end of the plate,  $P$ , versus the relative movement between the FRP and the adjacent concrete substrate at point A (i.e. slip,  $s$ ). Figure 2a is a generic load-slip relationship that has been compiled from numerous tests on FRP-concrete joints anchored with FRP anchors [6]. The anchor is activated once the load to initiate debonding  $P_{db}$  has been reached and the debonding crack has propagated to the anchor position. The peak load carrying capacity of the joint is reached at load  $P_{max,1}$ . At this stage the debonding crack has reached the unloaded plate end upon which the plate completely debonds at slip  $s_{max,1}$  and the load is reduced. A post-peak reserve of strength of load  $P_{max,2}$  is then maintained until anchor failure at slip  $s_{max,2}$ .

This paper presents the details of a constitutive model for FRP anchors that is derived from finite element analysis and calibrated with experimental results of FRP-concrete joints anchored with FRP anchors. ABAQUS [7] is utilised to perform the numerical simulations. An earlier paper has also developed a constitutive model for the FRP anchor using the same tests considered herein by Zhang and Smith [8]. This earlier model differed in that it utilised a partial interaction method of analysis with which to perform the numerical simulations.

**Figure 2. Summary of results of FRP-concrete joints anchored with FRP anchors.**

## 2. Test results

Twenty five test results of FRP-concrete joints anchored with FRP anchors are utilised to calibrate the FRP anchor constitutive model. A detailed account of the test joints is provided in Zhang [6] although a brief overview is provided herein in relation to the features most relevant to this paper. For all joints, the anchor was located 75 mm from the loaded bonded plate end (i.e.  $L_{anc} = 75$  mm). The length of the plate between the anchor and the unloaded plate end ( $L_{end}$ ) was varied from 25 mm to 275 mm in 25 mm increments, and hence the total plate length was varied from 100 mm to 350 mm. The average concrete compressive cube strength was 55.1 MPa and the elastic modulus was 30.2 GPa. The FRP plate, which was made from three layers of carbon fibre sheet in a wet lay-up manner, had a tested tensile strength of 2978 MPa and elastic modulus of 227.5 GPa. Each FRP anchor was hand-made from a 200 mm wide carbon fibre sheet of the same type of fibre used to make the FRP plates. The cross-sectional dimensions of the concrete blocks were 200×200 mm<sup>2</sup> while the length of each block was 200 mm. In addition, a 20 mm unbonded zone was maintained at the loaded end of the joint. Figure 2a shows the test relationship between  $P_{max,1}$  and  $L_{end}$ . The load reaches a plateau at an  $L_{end}$  of about 175 mm.

### 3. Finite Element Model

#### 3.1 Element and mesh details

ABAQUS [7] was utilised to construct a two-dimensional finite element model of the generic joint shown in Figure 1a with the geometric and materials properties provided in Section 2. The model, along with the boundary conditions and element details, is shown in Figure 3.

A two-node truss element of ABAQUS designation T2D2 was utilised to model the FRP plate and concrete block components. In addition, a 4-node cohesive element designated as COH2D4 by ABAQUS was used to model the FRP-concrete interface as well as the FRP anchor. A single element was used to model the FRP anchor. The thickness of the cohesive elements was set to 1 mm in order to maintain a proportional relationship between the shear stress and the slip between the concrete and FRP nodes.

Mesh convergence studies yielded no significant variation on results and hence a 1 mm element size in the longitudinal direction was adopted. A linear-elastic analysis was utilised owing to the low stress level experienced in the concrete and the linear-elastic behaviour of the FRP and epoxy.

Figure 3. Finite element model and boundary conditions.

#### 3.2 Constitutive models

A linear-elastic relationship was used to define the response of the concrete block and FRP plate. Lu et al.'s [9] simplified bond-slip model was used for the cohesive FRP-concrete elements. The relationship for the cohesive element of the FRP anchor is derived from the P-s response of the anchor. In order to establish such a relationship, the FRP anchor can be idealised as a mechanical connector. Figure 4 shows a generic anchor response that is based on the response of mechanical shear connectors in steel-concrete composite structures [e.g. 10]. The response can be expressed algebraically as follows in Equation 1. Other relationships are provided in Reference [6] although the model shown in Figure 4 is satisfactory for its intended use.

$$P = (s/s_1) P_{anc} \quad 0 < s \leq s_1 \quad (1a)$$

$$P = P_{anc} \quad s_1 < s \leq s_2 \quad (1b)$$

$$P = 0 \quad s > s_2 \quad (1c)$$

The maximum shear force that the anchor can sustain is  $P_{anc}$  and this occurs at slip  $s_1$ . Afterwards, the load reaches a plateau. Anchor failure at slip  $s_2$  causes the load carrying capacity of the anchor to be lost. Note that tests have shown the slip  $s_2$  typically to be several times greater than the slip at debonding initiation and subsequent anchor activation.

**Figure 4. Constitutive model of FRP anchor.**

The force that is applied to the plate is assumed to be resisted by the intact (non-debonded) FRP-concrete bond, as well as the frictional resistance arising from the debonded plate. Measured responses of Figure 2a for selected test joints can therefore be used to extract these two components of resistance and hence such responses can be used to calibrate a constitutive model for the FRP anchor.

### **3.2.1 Calibration of $P_1$**

The anchor force capacity is denoted as  $P_1$  and it is equal to  $P_{\max,2}$  arising from the load-slip response of each test joint. The value of  $P_{\max,2}$  of each of the 25 test joints is reasonably consistent and the average value arising is 12.92 kN. This consistency means that the force capacity of the anchor depends more on the anchor properties than the geometric and material properties of the test joint.

### **3.2.2 Calibration of $s_2$**

The slip capacity of the anchor,  $s_2$ , is equal to  $s_{\max,2}$  arising from the test load-slip responses. The average of the measured values is equal to 4.11 mm.

### **3.2.2 Calibration of $s_1$**

The anchor first reaches  $P_1$  at slip  $s_1$  (i.e. the anchor yields). As  $s_1$  cannot be directly extracted from the measured load-slip responses, recourse is therefore made to finite element analysis. According to the test results contained in Figure 2b,  $P_{\max,1}$  peaks when  $L_{\text{end}} = 175$  mm. This corresponds to a test joint of 250 mm bond length (i.e.  $L_{\text{anc}} = 75$  mm, plate length =  $L_{\text{anc}} + L_{\text{end}}$ ). Values of  $s_2$  are varied in the analysis of the test joint until  $P_{\max,1}$  coincides with yield of the anchor. Note that the value of  $P_{\max,1}$  is obtained from the simulated stress and the simulated value of  $s_1$  is determined to be equal to 0.1 mm.

## **4. Results**

The simulated results of several joints of varying bond length are provided in Zhang [6]. The load-slip responses of one joint of long bond length (i.e. 325 mm) are presented herein in Figure 5. The long bond length ensures that the full load capacity (i.e.  $P_1$ ) of the anchor is able to be developed.

(a) Load-slip: prediction versus tests

(b) Load-slip: generic simulated behaviour

(c) Shear-stress distribution along plate length

**Figure 5. Simulation and test results.**

Figure 5a contains the simulated load-slip response as well as three test results for nominally identical specimens. The agreement between prediction and test is acceptable and hence gives confidence in the accuracy of the numerical technique.

Figure 5b contains an enlarged view of the simulated load-slip response up to a slip just in excess of  $s_{\max,1}$ . The load-slip responses for the anchored joint, as well as the anchor and an unanchored joint are provided. The anchor load is derived from the stress contained in the anchor cohesive element. It is evident that the plate completely debonds after the anchor has yielded (i.e. slip  $s_1$  has been reached) but before the anchor fails (i.e. slip  $s_2$  has not been reached). This results in a load plateau between points d and e. The existence of a load plateau is therefore of importance as it provides ductility to the FRP-concrete bond. Finally, the existence of a load plateau for the FRP anchor is evident and this occurs when  $P_1$  is reached.

Figure 5c contains the simulated distribution of shear stress at the FRP-concrete interface along the whole length of the bonded plate. Note that the shear stresses correspond to different levels of slip as indicated in Figure 5b by letters a to e. These five levels of stress correspond to:

- (i) Point a: The slip positioned midway between zero and point b.
- (ii) Point b: Initiation of debonding (i.e.  $P_{db}$ ) and it corresponds to zero shear stress at the loaded end of the plate.
- (iii) Point c: The slip corresponding to the peak shear stress occurring past the FRP anchor.
- (iv) Point d: Corresponds to  $P_{\max,1}$  and  $s_1$ .
- (v) Point e: Corresponds to complete plate debonding.

## 5. Conclusions

A constitutive model for FRP anchors has been provided in this paper. The model, which has been calibrated from tests on FRP-concrete joints anchored with FRP anchors, has then been incorporated into a finite element model. The model is shown to produce results consistent with experimental measurements. The finite element model results also reveal insights about the distribution of bond stress as well as the level of anchor activation in the test joints. Of particular importance, joints containing a long bond length have been shown to produce desirable ductile behavior.

Future studies can revolve around utilisation of the finite element model to conduct parametric studies. Such studies can then be used to develop design rules applicable to the design of FRP anchors in FRP strengthening applications.

# Joint Free Restrained Slabs – SFRC combined with mesh

Alan Ross CPEng IntPE(NZ)  
General Manager, BOSFA

**Abstract:** Controlling cracking to acceptable levels in concrete structures requires accurate detailing and good construction practices. This is more prevalent in ground supported slabs that are typically detailed to avoid cracks occurring under service stresses. Detailing the slab to avoid these cracks puts a number of limitations on the floor design and construction. There is an upper limit on panel size and shape, restraint should be limited as much as possible and of course joints are required, which can be expensive and may require on-going maintenance. And even with all this effort, cracks can still occur, and when they do they tend to be large and can have an adverse effect on the serviceability of the floor.

Recent Standards from Europe<sup>(5,6,7)</sup> enable the engineer to design using steel fibre reinforced concrete (SFRC) combined with conventional reinforcing. For floor slabs this means any panel size or shape can be considered, even when the floor is fully restrained, and importantly these solutions can be joint free. Using combined reinforcing also enables the design of economical liquid retaining structures, such as containment bunds, dangerous goods store floors, tank base slabs, watertight basement slabs.

This paper discusses the theory behind this design approach and provides a number of local and overseas project examples.

**Keywords:** CombiSlab, combined reinforcement, crack width calculation, SFRC, steel fibres, serviceability design

## Introduction

Concrete is a brittle material and cracking is normal. In fact, in order to take account of the reinforcing effect of bar or mesh, cracked section material properties and design capacities are used in the design of concrete structures. If these cracks are controlled within specified levels they are not detrimental to the integrity of the structure and do not affect its serviceability. This control is generally met by providing a minimum percentage of steel reinforcing and/or appropriate joint detailing.

With this in mind, a major design consideration for any concrete structure is the location and detailing of joints. This can become paramount for concrete pavements or slabs where joints have traditionally been the Achilles' heel of this form of construction. Being able to minimise or eliminate joints is an attractive proposition in terms of on-going maintenance costs.

This is one of the main reasons continuously reinforced concrete (CRCP) pavements, which are designed to eliminate the need for joints, are often preferred over jointed pavements with large numbers of closely centred crack control joints. CRCP are designed with enough steel reinforcing to keep the inevitable cracking within acceptable limits - by typically utilising 16mm or 20mm reinforcing bars at close (< 200mm) centres, the requirement for crack control jointing, such as saw cuts, is removed.

On the other hand, jointed pavements/slabs are detailed and designed in such a way as to limit the stresses in the slab due to restrained, temperature and shrinkage deformations to be less than the tensile capacity of the concrete, i.e. the design is based on the slab remaining uncracked in its serviceability limit state (SLS).

Innovation in this field of concrete design has led to the development of design rules that enable the use of steel fibre reinforced concrete (SFRC) in combination with conventional reinforcing. This makes it possible to design economic solutions for controlled cracking under service stresses. For floor slabs this means any panel size or shape can be considered, even when the floor is fully restrained, and importantly these solutions can be joint free.

## Say NO to Joints

Designing for controlled cracking in concrete elements is common practice, to suggest that this is a good idea for a ground supported slab requires quite a shift in thinking. A warehouse slab or external pavement is arguably the most important part of the tenanted space; it has to remain operational and serviceable with preferably as little maintenance as possible; and this maintenance typically involves joints.

There are flooring solutions that can reduce the number of joints, but as mentioned earlier, these put a number of limitations on design and construction. Particularly post tensioned slabs where wall block outs and pour strips may be required, joints over large distances open significantly and it's common for the slab to curl at joints and free edges. To avoid cracking a slab is normally tensioned incrementally as the concrete gains strength; this can put it on the critical path for construction. Importantly, limiting restraint is of paramount importance and the construction and design/detailing of these floors types is a specialist field.

Joints can work well, if detailed and constructed properly, but almost always require maintenance, as shown in figure 1. This dowelled movement joint will require a maintenance programme to reseal it possibly many times over the life of the floor. They can also perform poorly, as shown in figures 2 and 3. This costs the building owner and has a detrimental effect on the serviceability of the floor.

**Figure 1**  
**Figure 2**

**Figure 3**

The photographs in figures 4 and 5 show controlled fine cracking in a slab containing steel fibres and mesh. Figure 4, a close up and figure 5 showing two controlled cracks running parallel to each other, taken from head height, they are quite difficult to see.

**Figure 4**

**Figure 5**

So, instead of trying to detail and construct the slab with joints to avoid cracking under service stresses, another approach is to assume the slab will crack under services stresses but to design with enough tensile capacity at the cracked section to ensure any cracks are controlled and hence small enough not to affect the serviceability of the floor. To do this efficiently and economically you can use a 'CombiSlab' solution; steel fibres combined with mesh or bar.

This approach is particularly beneficial where there is unavoidable restraint in the floor. Rather than trying to detail round this restraint, by the judicious design and construction of a suitable arrangement of joints, the approach entails designing a suitable combination of mesh and steel fibre reinforcement to ensure an acceptable level of crack width whilst eliminating or minimising the need for either movement (dowel) or crack control (saw cut) joints.. Restraint may result from precast concrete panels being tied into the slab, pads or plinths that are poured integrally with the slab, or non-symmetrical shapes to the floor etc. etc.

It is worth noting, that in floors where restraint can be limited, joints are acceptable, the serviceability demands on the floor are small and there is no requirement for a crack width calculation, steel fibre only solutions can still be the most economically attractive option.

## Quantifying SFRC

Most current standards for design of SFRC provide guidance on how to quantify the reinforcing properties based on the measured post crack tensile strength of SFRC. The universally adopted approach is to measure the post crack performance in a flexural beam test, performed in the laboratory (Fig 5) and by means of suitable conversion factors, convert the laboratory measured flexural performance in terms of a load versus deflection or crack width curve into a tensile stress/crack width as shown in Figure 6 and hence into a stress/strain relationship that can then be used for design as shown in Figure 7.

Figure 5 Typical Beam test setup in the laboratory

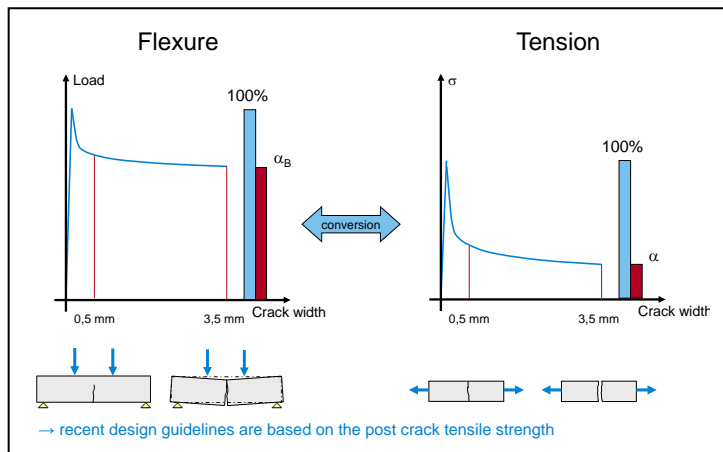

Figure 6 Converting Test results for SFRC

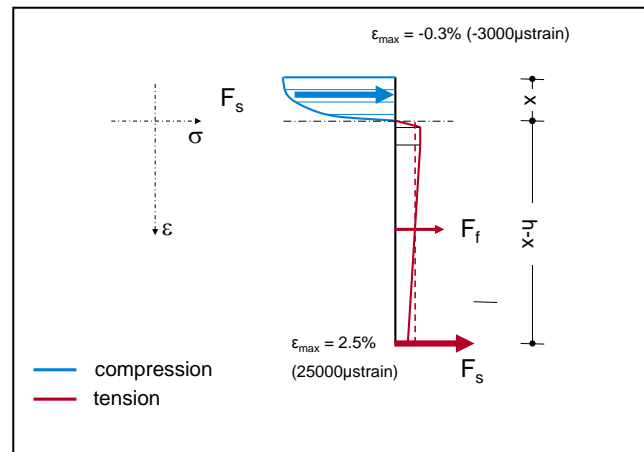

Figure 7 Stress/Strain for RC

There are a number of important points to be noticed about Figure 7 as follows:-

1. The stress strain diagram is exactly what is expected for conventionally reinforced concrete with the addition of a tensile stress block (dashed red line in figure 7) to model the effect of individual fibres crossing the crack that develops below a sections neutral axis. For more accurate modeling a refined stress-strain diagram should be applied (continuous red line in figure 7).
2. The strain nominated at the main reinforcing bar or wire can be chosen such that the steel will have yielded, as shown, or not. The nominated stress strain diagram is therefore suitable for determining either a sections Ultimate Moment Capacity or the tensile stresses that will exist in the section under working or service loads.

3. The compressive stress in the concrete and the tensile stress in the cracked fibre reinforced concrete (c.f. Figure 6) will in reality be curvilinear in shape. However, for simplicity it is acceptable to assume a stress block for both.
4. The value used for the magnitude of the steel fibre stress block varies with the section capacity that is to be determined. For the ultimate limit state moment capacity the tensile stress value used is the residual stress value shown in Figure 6 for a crack width of 3.5mm. For the serviceability limit state (e.g. for a crack width calculation) the tensile stress value used is the residual stress value shown in Figure 6 for a crack width of 0.5mm

Point 4 above brings into play an important concept for fibre reinforced concrete, namely the interplay between the stress in the reinforcement and the width of cracks. For conventionally reinforced concrete the lower the stress and hence strain in the steel the smaller will be the crack width. Conversely, for SFRC exhibiting strain softening behavior as shown in Figure 6, the lower the crack width the higher will be the residual stress value provided by the steel fibres. For this reason, to incorporate the effects of steel fibres in a combined reinforcement solution, it is critical that the stress values used in design for both the fibres and conventional reinforcement are those that will occur for the same, or at least consistent, values of strain.

As strain is a nebulous concept for SFRC, the fibres are actually pulled out rather than being strained over some imaginary fixed length that varies with a fibres orientation in 3-dimensions, it is more practical to fall back on crack widths. The difficulty of effectively and consistently relating crack widths to strain has been addressed in the DAfStb<sup>(4)</sup> guideline on SFRC, where crack width is defined as:

$w = \epsilon_{ct} \times 140\text{mm}$ , where  $\epsilon_{ct}$  is the concrete strain in the tensile zone.

The fixed value of 140mm is due to defining a crack opening of 3.5mm as being equivalent to a strain of 2.5% or 25000 $\mu$ strain.

This fixed relationship between strain and crack opening means that the defined stress/strain relationship applies to any depth of section, even when the material properties are derived from different sized beam tests; the same strain always gives the same crack width irrespective of the size of an actual element. This means the strain, crack width and design strength are the same irrespective of how deep your section is. RILEM (and NZS3101) on the other hand links design strength to section thickness, which means that they require a size factor to compensate. This latter approach is not being used in the recent design rules from Fib and DafStb; they have used the constant relationship between strain and crack width.

With the stress strain properties of SFRC, as well as concrete reinforced with combined reinforcement effectively defined, it is possible to determine, the tensile and ultimate moment capacity of a section reinforced with SFRC and/or SFRC combined with conventional reinforcing.

## The Importance of Crack Control

A crack width calculation is based on empirical guidelines and requires an understanding of the strains and stresses in the concrete section prior to cracking as well as a number of other assumptions in regards to the strength the concrete will be when cracking actually occurs. It is therefore not an easy calculation to perform and thus not often carried out in engineering design offices. The ability to avoid performing crack width calculations is typically addressed in Concrete Standards by the provision of guideline criteria that will indirectly provide a suitable level of serviceability/durability as well as strength in the finished structure, usually built around the service stress in reinforcing steel as well as the quality and amount of concrete cover in different environments.

As concrete standards are being revised and rewritten, both in Australasia and overseas, durability and serviceability of concrete structures is becoming more and more important. Typically this is done by means of additional requirements on material properties, detailing and minimum reinforcement. In fact what these concrete standards are typically achieving with their recommendations on durability and serviceability is to impose limits on crack widths i.e. higher durability and serviceability can very often be interpreted to mean the use of more reinforcement to effectively control crack widths.

Concrete Standards typically do a good job with these guidelines when it comes to cracking caused under load. However, when it comes to cracking caused by the restraint of shrinkage and thermal movements these recommendations become much less tangible. For instance in AS3600<sup>(1)</sup> there are

two recommendations for the minimum secondary reinforcement required in restrained slabs based on the degree of control over cracking that is required and a third level is added for slabs fully enclosed in a building. It is up to the engineer to decide what level of restraint is present.

The important parameters to judge if a crack is still acceptable or not will vary with the type of element, how the element is used and to what environment it is exposed. The owner of a concrete element or structure is really only interested in whether or not the element “works” and how long it lasts. It is therefore necessary that “works” is translated into an acceptable design crack width, which is the role of the designing engineer with guidance from suitable standards and technical recommendations.

An indicative example related to acceptable crack widths in reinforced concrete slabs on grade comes from DafStb<sup>(4,6)</sup> and DIN<sup>(5)</sup> as follows:

- Dry environment            0.5mm
- Soil or moisture            0.3mm
- Chlorides                    0.1 – 0.3mm (+possibly coated)
- Coated                        0.2mm
- Water tight                 0.1 – 0.2mm (+ possibly coated)
- Environmental              0.1 – 0.2mm (+ possibly coated)
- Chemical                    0.1 – 0.2mm (+ possibly coated)
- Heavily trafficked         0.2 – 0.3mm

A local example for designing concrete pavements can be taken from Austroads<sup>(2)</sup>, where continuously reinforced pavements are designed for a nominal crack width of 0.3mm.

It is obvious that the usefulness of such recommendations makes it essential that a crack width calculation be performed. Fortunately spread sheets can be developed that not only perform these calculations quickly and easily but can be used to investigate the sensitivity of the assumptions an engineer needs to make when using them. As an example, BOSFA can provide Dramix 4D CombiSlab designs to engineers, contractors and the like using a design tool based on relevant European Standards.

### **SFRC with No Conventional Reinforcement**

The strain softening behavior of SFRC is problematic in terms of calculating crack widths. Although it is theoretically possible to calculate a crack width in a section that has a permanent compression zone, the fact is that the tensile strength of the **uncracked** fibre reinforced concrete is higher than the tensile strength of the **cracked** fibre reinforced concrete. This means that for a concrete element where the full section is in tension, for example due to restraint of shrinkage and temperature stresses in a ground slab, the cracked section is the weakest section and it's not possible to determine accurately if and where the concrete section will crack again i.e. it is impossible to determine a theoretical spacing between cracks and without a crack spacing it is also impossible to determine a crack width using current crack width calculation theory. The determination of crack spacing and hence crack widths is discussed more in the next section.

This situation can be likened to the determination of crack widths for conventional reinforcement where the tensile capacity of the reinforcement is less than that of the concrete. At a cracked section that is under reinforced it is possible for the steel to yield giving the possibility of uncontrolled and hence very large localized crack widths.

It should not be forgotten that steel fibres are effective in “locking off” or arresting the development of cracks at their earliest stage of development i.e. micro cracking. They effectively reduce the tendency of these cracks to propagate and as such fibre only saw cut free slabs on grade and rafts have been constructed successfully for many years. But it's not possible to effectively calculate a precise crack width, making it necessary to rely on experience when nominating joint centers, fibre type and dosage.

### **Combined Reinforcement, the synergies**

When conventional and steel fibre reinforcement are combined the strain softening behavior of SFRC does not change. However, the post cracking tensile capacity of the SFRC can be taken into account when calculating crack widths for the conventional reinforcement.

In conventionally reinforced concrete the width of a crack is a function of the distance between cracks and the distance between cracks is determined by the bond length of the reinforcing bars, this is shown graphically in figure 8 and explained below:

**Figure 8. Initial state of cracking**

At a crack the tensile force in the concrete is zero with all the tensile force being carried by the reinforcing steel. Away from the crack the reinforcing bars, being effectively bonded into the concrete matrix, transfer this tensile force into the concrete, with all the force being transferred into the concrete a distance from the crack equal to the reinforcing bars development length. This means that the minimum spacing between cracks is one development length and the maximum spacing is two development lengths. The maximum crack width will therefore result when the cracks are spaced at the maximum spacing of two development lengths. In practice, it may be somewhere in-between.

The effect of steel fibres is to increase the tensile force in the concrete at a crack from zero to the tensile capacity of the cracked SFRC. The result of this is that the tensile force in the conventional reinforcement at the crack is reduced and the development length of the steel is consequently reduced. The same holds for the strain in the steel. Reducing the development length and the strain of the reinforcement reduces the maximum distance between cracks and thus results in more but narrower cracks. This has a significant effect on the amount of bars or mesh required for a particular crack width design, using a SFRC with a residual tensile strength  $> 1.0 \text{ N/mm}^2$  can reduce the conventional reinforcing by about 50% for the same level of crack control.

As a simplification of this concept the crack width  $w_k$  may be seen as a function of the concrete tensile strength  $f_{ct}$  in the case of reinforced concrete and a function of the concrete tensile strength minus the cracked tensile strength of SFRC  $f_{ct,SFRC}$  in the case of combined reinforcement, this is shown in equation (1):

$$w_k = \text{function} [f_{ct} - f_{ct,SFRC}] \quad (1)$$

A number of related test programs <sup>(3,8,10,12)</sup> have been carried out and a number of design methods have been proposed. These approaches differ in some points but more or less follow the same principle, namely the reduction of the concrete tensile strength by the post crack tensile strength of SFRC.

Apart from serviceability and the determination of crack widths, the post crack strength of SFRC may also be taken into account for the ultimate limit state, where significant contributions to the load bearing capacity are possible. In joint free slabs there is also no requirement to model the floor loads on a joint, this leads to more efficient use of concrete – thinner slabs.

## Practical Experiences

Over 1m m<sup>2</sup> projects have been constructed utilising combined reinforcement in countries all over the world. A few examples are given to explain why combined reinforcement was used and what benefits were achieved.

### ***NZ, Container handling pavement***

Pavements designed for the handling and storage of containers need to accommodate high loads and constant wear and tear which invariably damages joints, resulting in expensive maintenance programs. Reducing or eliminating these joints is an attractive proposition to the asset owner. This project is about 13,000m<sup>2</sup>, the pavement winds its way round corners and up slopes, has been designed to accommodate stacked containers and is completely joint free. The SFRC was used in the ULS design, resulting in a thinner slab compared to PT and conventional reinforcing, AND it was used for SLS crack control in combination with one layer of mesh. Design crack width 0.25mm.

### ***Belgium, E17 motorway***

The E17, a major Belgian highway was constructed with a lane using SFRC in combination with 20mm reinforcing bars. Crack width is an important parameter for the long term performance of CRCP, particularly the development of punch outs (pavement failure). Using a CombiSlab enabled a reduction in calculated crack width, allowed a reduction in longitudinal reinforcing and improved the risk associated with punch out failure.

### ***NZ, Commercial building, restrained joint free floor***

The building is 95m x 45m and has full restraint along one 95m length from tied in precast panel walls. Using conventional methods of construction, this level of restraint would have required jointing in the floor. Taking this restraint into account in the design through combining SFRC with one layer of 441 mesh (7.5mm wires at 100c/c) enabled the construction of the floor without any joints. Eliminating construction, and importantly, maintenance costs associated with saw cuts and movement joints. The increase in load carrying capacity provided by the SFRC resulted in a slab thickness of 130mm. Design crack width of 0.25mm.

***NZ, Containment bund, joint free water tight***

Leakage of containment bunds can be an issue and costly to put right. Typical design and construction has sealed joints and expensive water stops. However, if the bund cracks outside these control points then there commonly isn't enough reinforcing to control them to acceptable levels. Combining SFRC with one layer of mesh enabled the design of a water tight layer and construction of the bund without any joints. 120mm thick, design crack width 0.2mm.

***NZ, Bulk Storage facility, restrained joint free floor***

This building is approximately 10,000m<sup>2</sup>, split into four rooms. The precast panel walls required large foundations due to the storage of bulk materials, and these were cast monolithically with the slab, fully restraining the floor. The whole building was constructed completely joint free using SFRC plus one layer of mesh. Design crack width 0.3mm.

***Australia, 15,000m<sup>2</sup> seamless floor***

The main challenge with this project was being able to accommodate 25t post loads, re-entrant corners, the slab being tied into the perimeter and tight time constraints. All this was taken into account in the design and a completely joint free floor was constructed using SFRC plus one layer of mesh. Design crack width 0.25mm.

***NZ, external saw cut free yard slabs***

Sealing of external saw cuts is time consuming, expensive and requires maintenance. Saw cut free panels approximately 30 x 30m, constructed using SFRC plus one layer of light mesh. Design crack width 0.25mm.

***Australia, dam spillway***

This joint free watertight spillway is approximately 700m long. The conventional design used 2 layers of bars plus mesh and very expensive jointing. The SFRC option was used in combination with one layer of heavy mesh. This resulted in a solution that was cost effective, joint free, more durable and quicker and easier to build, Design crack width 0.2mm.

## Conclusions

Combining SFRC with mesh or bar provides the engineer and contractor greater flexibility in slab construction; restraint, panel size and shape, as well as joint location are no longer a constraint on design. Importantly, designing for controlled cracking under service stresses and the elimination of joints will result in a floor that is more durable, serviceable and maintenance free, a very attractive proposition for the building owner. The CombiSlab solution also provides an economic option for liquid retaining structures such as containment bunds, dangerous goods store floors, tank base slabs and watertight basement rafts/slabs.

# Neutron Pair Distribution Function Analysis of Synthetic Calcium-Silicate-Hydrate Gels

Claire E. White<sup>1</sup>

<sup>1</sup>Department of Civil & Environmental Engineering and Andlinger Center for Energy and the Environment, Princeton University, Princeton, USA

**Abstract:** The atomic structural arrangements in calcium-silicate-hydrate (C-S-H) gel in ordinary Portland cement-based pastes and blended pastes have been the subject of rigorous debate in recent years. Standard characterization techniques fail to fully capture the complex structure and morphology of C-S-H gel, primarily due to the nanocrystallinity of this important binder phase combined with the variability in calcium-to-silicon ratio and incorporation of aluminium in the structure for certain blended systems. Nevertheless, local structural tools such as X-ray and/or neutron pair distribution function (PDF) analysis are increasingly being employed to analyse the atomic structure of disordered materials. Here, for the first time, neutron PDF analysis is applied to a range of deuterated C-S-H gels with varying Ca/Si ratios (denoted C-S-D), including the in situ analysis of a C-S-D gel exposed to elevated temperature. The results highlight the water-containing bonding environments present in the gels, particularly through the use of deuterated samples. The in situ temperature study reveals that the local atomic bonding environments in C-S-D gel undergo large structural rearrangements due to exposure to elevated temperature, and sheds light on the non-crystalline structural transitions that cannot be accessed using standard crystallographic techniques.

**Keywords:** Calcium-silicate-hydrate, neutron diffraction, pair distribution function, temperature, dehydration.

## Introduction

Ordinary Portland cement (OPC)-based concrete has been used in the construction industry for more than 175 years, however, the main phase that controls strength and durability, calcium-silicate-hydrate (C-S-H) gel, remains a topic of significant debate since conventional characterization methods are ill-suited for elucidating the complex atomic structure of this important cementitious phase (1). C-S-H gel co-exists with multiple other phases in OPC concrete, including portlandite, ettringite and various sulphates phases, which makes isolation of the gel extremely difficult. The atomic structure of C-S-H gel has been debated rigorously in the literature, with new structural models derived from quantum chemistry failing to capture the known bonding environment existing in these gels (2,3). Experimentally-driven structural representations have been developed using techniques such as reverse Monte Carlo (4), with additional research required to fully-validate these models from a thermodynamics viewpoint to ensure that the models are chemically-reasonable (5).

Although the structure of C-S-H gel has been actively pursued in recent decades, little information is available regarding the atomic structural changes that occur when the gel is exposed to moderate (~ 100 °C) and high (> 100 °C) temperatures. These changes are extremely important for understanding how OPC concrete performs at high temperatures, especially in fire conditions (6,7). Some progress has been made in understanding the temperature-induced structural transitions in C-S-H gel analogues such as 11 Å tobermorite, which has been seen to decrease in interlayer spacing from 11.3 to 9.3 Å when heated to 300 °C (and remains intact with the interlayer spacing at 9.3 Å past 700 °C) (8). The thermal behaviour of C-S-H gel in OPC paste has been investigated using neutron diffraction (9), however, due to the existence of multiple phases in the sample the exact behaviour of the C-S-H gel remains unclear as studied using neutron diffraction.

Here, neutron total scattering measurements and subsequent pair distribution function (PDF) analysis is used to investigate the atomic structure of C-S-H gels together with the structural changes that occur due to dehydration and exposure to high temperatures (up to 650 °C). By using the high-flux available at the Spallation Neutron Source, Oak Ridge National Laboratory, it is possible to study the dehydration and high temperature reactions in situ (in real time) using neutrons, and therefore obtain information on the exact local structural changes that occur during exposure to these elevated temperature. Furthermore, the use of neutrons as opposed to X-rays enables the water-containing correlations to be measured and analysed.

## Materials and Methods

Calcium-silicate-deuterate (C-S-D) gels of varying Ca/Si ratios (0.83, 1.2, 1.5, 1.7 and 3.0) were synthesised using triclinc tricalcium silicate ( $C_3S$  in cement notation, CTLGroup) and amorphous fumed silica ( $SiO_2$ , Alfa Aesar, 325 mesh). The synthesis method used to produce these samples was previously outlined in detail in reference (10). The samples were measured on the Nanoscale-Ordered Materials Diffractometer (NOMAD) instrument at the Spallation Neutron Source, Oak Ridge National Laboratory (11). In order to produce each total scattering function and associated PDF, the measured intensities were normalised by scattering from a vanadium rod and then subjected to a background subtraction from the empty container. Prior to calculation of the PDF, the total scattering function was multiplied by a Lorch function in order to improve the signal/noise at the expense of real-space resolution. The PDF ( $G(r)$ ), was obtained via a sine Fourier transform of the total scattering function ( $S(Q)$ ) using a  $Q_{max}$  of  $20 \text{ \AA}^{-1}$ , as outlined in Eq. 1, where  $Q$  is the momentum transfer as defined in Eq. 2.

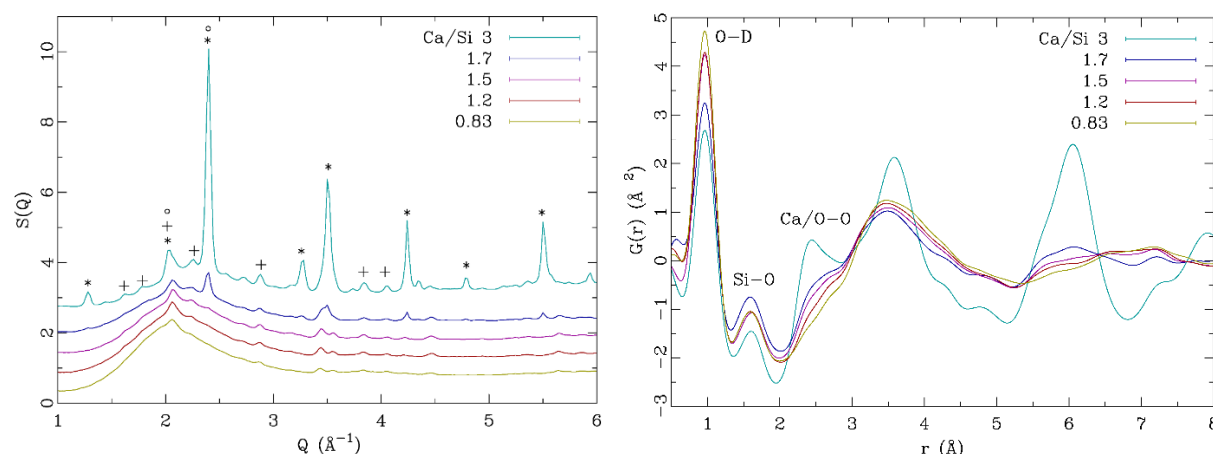

$$G(r) = \frac{2}{\pi} \int_{Q=Q_{min}}^{Q=Q_{max}} Q[S(Q) - 1] \sin(Qr) dQ \quad (1)$$

$$Q = \frac{4\pi \sin \theta}{\lambda} \quad (2)$$

## Results and Discussion

### Atomic Ordering at Ambient Temperature in Calcium-Silicate-Deuterate Gels

Figure 1 displays the neutron scattering data for the C-S-D gels, where Figure 1a provides the total scattering functions of the gels (in reciprocal space) and Figure 1b the neutron PDFs. It is clear that for increasing Ca/Si ratio the amount of crystalline portlandite dramatically increases (Figure 1a). However, the tricalcium silicate ( $C_3S$ ) peaks remain relatively small irrespective of the Ca/Si ratio, which is attributed to the smaller neutron coherent scattering length of silicon and calcium compared to oxygen and deuterium. Therefore, as more portlandite precipitates (as the Ca/Si ratio increases), and therefore additional deuteroyl units are associated with this crystal structure, the Bragg peaks associated with this crystalline phase are seen to increase significantly. A qualitative analysis of Figure 1a reveals that portlandite is present in the gels with Ca/Si ratios of 1.7 and 3. Figure 1a also contains information on the amount of water present in the sample in the form of  $D_2O$  or deuteroyl units (OD) via the broad amorphous peak situated between  $1$  and  $3.5 \text{ \AA}^{-1}$

(a) Total scattering functions. Bragg peaks assignments are as follows: C-S-H ( $^{\circ}$ ),  $C_3S$  ( $+$ ) and portlandite ( $*$ ). Offsets have been used to enhance clarity.

(b) Pair distribution functions. Nearest-neighbour atom-atom correlations are labelled.

**Figure 1. Neutron total scattering functions and pair distribution functions of C-S-D gels. The Ca/Si ratios are given based on the synthesis stoichiometry.**

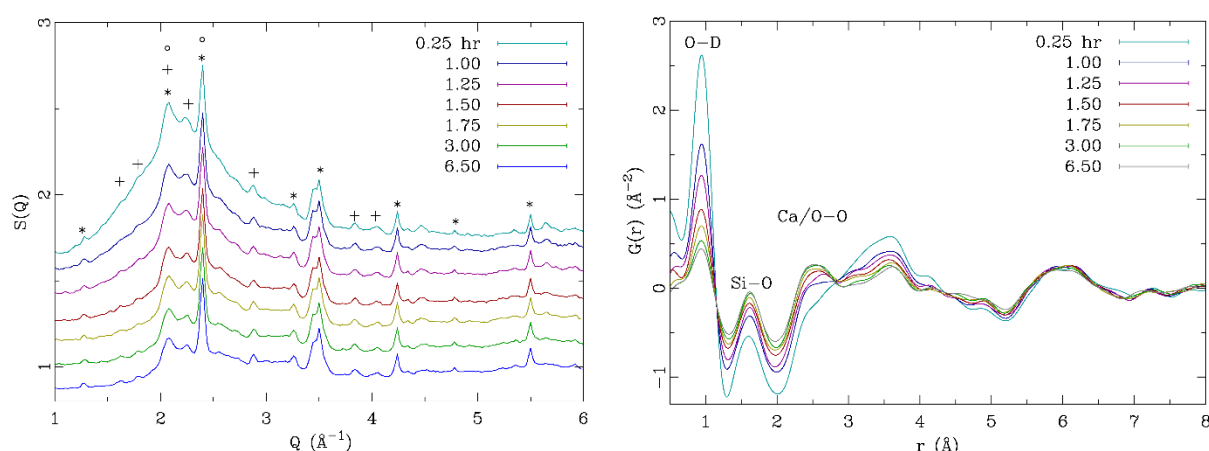

Figure 1b contains the neutron PDFs for the C-S-D gels, where it is apparent that the low Ca/Si ratio samples contain more water (intensity of the O-D correlation at  $0.96 \text{ \AA}$ ). This figure also shows that the Si-O correlation is similar for the gels in terms of overall intensity (taking into account the differences in

the atomic number density, as given by the sloping baseline at low  $r$  (12)). On the other hand, there are significant differences in the Ca-O correlation at  $\sim 2.44$  Å and O-O at  $\sim 2.7$  Å (where an inflection point is located in the data). At higher  $r$  values it becomes more difficult to assign specific atom-atom correlations without a detailed structural model.

### Drying-Induced Structural Changes at 110 °C

The main change seen in the total scattering patterns (Figure 2a) as a C-S-D gel (with Ca/Si ratio of 1.7) is exposed to 110 °C is the loss in intensity of the broad diffuse peak positioned between  $Q$  values of 1 and 3.5 Å<sup>-1</sup>, which is attributed to removal of water from the gel. The neutron PDFs (Figure 2b) directly show this loss of water via the reduction in intensity of the nearest-neighbour correlation (O-D) positioned at 0.95 Å. Although this correlation reduces significantly by 6.5 hrs, there is still a well-defined O-D correlation present. Hence, further drying would likely result in additional changes in the local atomic structure. The other major changes in the local structure due to drying at a temperature of 110 °C are the water-containing correlations (O-D and D-D) between 3 and 4.5 Å (2), which are seen to reduce in intensity, and the Ca-O and O-O correlations between 2 and 3 Å, where the intensity increases.

(a) Total scattering functions. Bragg peaks assignments are as follows: C-S-H (°), C<sub>3</sub>S (+) and portlandite (\*). Offsets have been used to enhance clarity.

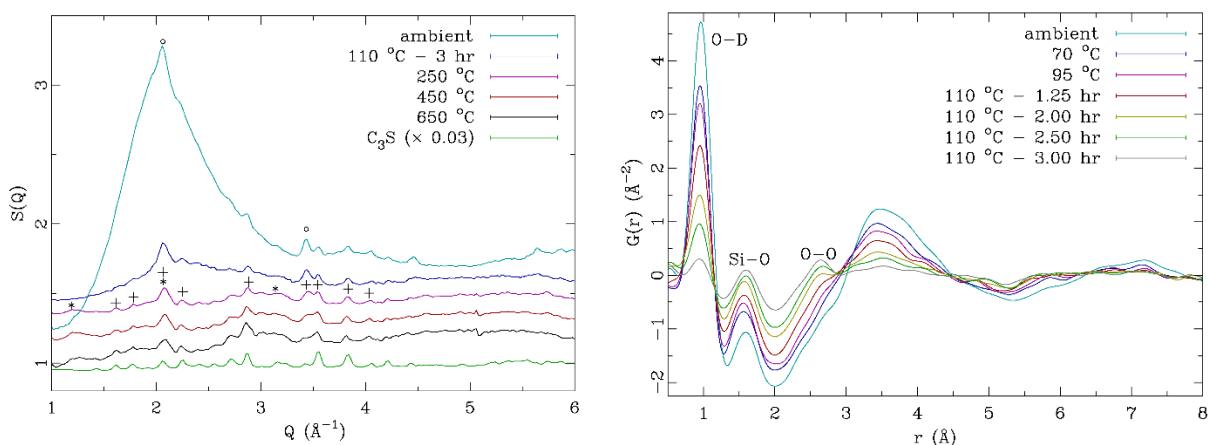

(b) Pair distribution functions. Nearest-neighbour atom-atom correlations are labelled.

**Figure 2. Neutron total scattering functions and pair distribution functions of the C-S-D gel with Ca/Si ratio of 1.7 exposed to drying conditions at 110 °C.**

### High Temperature Behaviour of a Calcium-Silicate-Deuterate Gel

The local structural changes of C-S-D gels in response to exposure to high temperatures ( $> 200$  °C) are important from a macroscopic structural integrity viewpoint (concrete strength degradation), and therefore it is important to have a detailed understanding of the atomic structure of C-S-D gel and changes that occur upon heating. Figure 3 contains the neutron diffraction data for a C-S-D gel with Ca/Si ratio of 0.83 exposed to elevated temperatures (up to 650 °C), with Figure 3a containing the total scattering data (reciprocal space) and Figures 3b and 3c the real-space neutron PDF data. Figure 3a reveals that a significant amount of water is removed from the sample after 3 hrs at 110 °C, which is seen via the reduced intensity of the diffuse scattering attributed to the water correlations (between 1 and 3.5 Å<sup>-1</sup>). An additional reduction in the diffuse scattering is visible between 110 and 250 °C, with higher temperatures (up to 650 °C) revealing little change in the measured scattering patterns. Apart from the significant reduction in diffuse scattering during the in situ temperature measurement due to the removal of water from the sample, there are additional changes visible in Figure 3a, specifically the emergence of weak diffuse scattering located at  $Q$  values of 1.2 and 3.15 Å<sup>-1</sup>. Preliminary analysis of this diffuse scattering in conjunction with the existing Bragg peaks visible in the patterns reveals that this new diffuse scattering can be attributed to either larnite (C<sub>2</sub>S in cement notation) or 9 Å tobermorite. However, from analysis of the Bragg scattering it can be concluded that calcite, lime, wollastonite, and larger spacing tobermorite (11 and 14 Å) are not present in the sample.

(a) Total scattering functions. Bragg peaks assignments are as follows: C-S-H ( $\circ$ ),  $C_3S$  ( $+$ ) and 9.6 Å tobermorite ( $*$ ). Offsets have been used to enhance clarity. (b) Pair distribution functions ranging in temperatures up to 110 °C. Nearest-neighbour atom-atom correlations are labelled.

(c) Pair distribution functions above 110 °C. Nearest-neighbour atom-atom correlations are labelled.

**Figure 3. Neutron total scattering functions and pair distribution functions of the C-S-D gel with Ca/Si ratio of 0.83 exposed to dehydration conditions up to 650 °C.**

As seen in Figure 3b, at a temperature of 110 °C the atomic structure of C-S-D gel with a Ca/Si ratio of 0.83 is seen to go through similar structural transitions to that for a gel with Ca/Si of 1.7 (Figure 2b), where the atomic number density ( $\rho_o$ ) is seen to decrease as water is removed from the gel, and there is a significant reduction in intensity associated with the water-containing correlations (O-D at 0.96 Å, and O-D and D-D between 3 and 4.5 Å). There is also a slight shift in the nearest-neighbour O-D correlation from 0.96 Å at ambient temperature to 0.94 Å after 3 hrs at 110 °C, which may indicate that the remaining deuterium atoms at this stage of the reaction exist mostly as deuteroxyl units (OD) as opposed to  $D_2O$  molecules. Figure 3c shows that all the deuteroxyl units have been removed from the structure by 250 °C as there is no discernible O-D correlation at  $\sim 0.94$  Å in the neutron PDF. Also apparent in Figure 3b is the emergence of the O-O correlation at 2.65 Å, however, the positioning of this peak implies that there is limited contribution from a Ca-O correlation at  $\sim 2.4$  Å, which is attributed to the low calcium content of this C-S-D gel. Nevertheless, the emergence of the O-O correlation in Figure 3b is a strong indication of an increase in ordering of the Si-O-Si linkages, possibly via an increase in degree of polymerisation (conversion from  $Q^1$  to  $Q^2$  sites). Figure 3c contains the neutron PDFs for the C-S-D gel (Ca/Si of 0.83) exposed to higher temperatures (125 to 650 °C), where additional increases in the Si-O and O-O correlation are seen together with decreases in the nearest-neighbour O-D correlation and the water-containing correlations between 3 and 4.5 Å.

## Conclusions

Neutron PDF analysis has been utilised to investigate the local atomic bonding existing in synthetic C-S-D gels with different Ca/Si ratios, together with the changes in local structure of C-S-D gel that occur during (i) drying at 110 °C, and (ii) exposure up to a temperature of 650 °C. The results show that

neutron PDF analysis is extremely sensitive to the water-containing correlations in C-S-D gels, specifically the nearest-neighbour O-D correlation at  $\sim 0.96\text{\AA}$ , and the O-D and D-D correlations between 3 and 4.5  $\text{\AA}$ . Exposure to elevated drying conditions (110 °C) causes a significant loss of water together with an increase in ordering of the Ca-O and O-O correlation. Heating to higher temperatures (up to 650 °C) reveals that all water in the gel (structural and free water) is lost by 250 °C, and that the calcium silicate atomic structure undergoes additional ordering beyond 110 °C. Further analysis is required to assess the evolution of these phases with temperature, and to correlate the diffraction results with complementary spectroscopic analyses.

# USING CONVENTIONAL MATERIALS AS CONCRETE CONFINEMENT

Hua Zhao<sup>1</sup> and Muhammad N.S. Hadi <sup>2</sup>

<sup>2</sup>Associate Professor, the University of Wollongong

**Abstract:** Strengthening concrete members to improve the load carrying capacity and ductility at an economic cost has constantly been a challenge. This study aims to evaluate the effects of the conventional repair materials, mortar and galvanised wire mesh and mortar composite (MGWM) on the overall behaviours of confined concrete columns. The investigation was carried out on medium strength concrete (MSC) and normal strength concrete (NSC), respectively. Two methods were used to install the mesh reinforcement: cast integrally with concrete and wrapped to precast concrete core. The first method was applied to MSC specimens while the second was adopted for NSC cylinders.

The test results indicate that for MSC specimens, MGWM did not improve the load carrying capacity. However, ductility was substantially improved. The test results also show that for NSC specimens, mortar confined specimens outperformed MGWM confined specimens in terms of load carrying capacity, but the latter significantly improved ductility. Finally, the method for estimating the ultimate load of mortar-confined specimens is discussed.

**Keywords:** Mortar, galvanised wire mesh, load carrying capacity, ductility

## 1. Introduction

Due to the low material cost, wire mesh is considered for enhancing the performance of concrete members. The purpose of this series of experiments is to investigate the methods of using mesh to improve the behaviours of concrete columns. Two different methods were adopted: in the first experiment, wire mesh was formed into cage and placed into the steel moulds before medium strength concrete (MSC) cast, while in the second experiment wire mesh was wrapped onto the pre-cast normal strength concrete (NSC) core. In each case the layers of wire mesh (fracture volume) was the parameter.

In the first experiment, ten standard cylindrical specimens ( $\varnothing 150$  mm x 300 mm) cast, including two concrete controls and eight reinforced specimens, as shown in Table 1. In the second experiment, twelve ( $\varnothing 150$  mm x 380 mm) concrete specimens cast, among which were four controls and eight concrete cores, as shown in Table 2. All the specimens were tested under axial compression.

**Table 1 Specimen configuration \_Experiment 1**

Specimen Code	Cage <sup>1</sup> D <sub>m</sub> mm	Diametre D mm	Height H mm	Layer <sup>2</sup> n	Cover t mm
Control1	-	150	300	-	-

1M1	150	153	190	380	1	20
1M2	150	153	190	380	1	20
2M1	150	155	190	380	2	20
2M2	150	155	190	380	2	20

It is noted that in the first experiment the cover thickness was 5 mm and 10 mm, respectively, while in the second experiment the cover was identically 20 mm thick. The diameter of the confined specimens was 190 mm.

## 2. Experimental Program

### 2.1 Specimen Preparation

Due to the difference in applying wire mesh reinforcement, the specimens of the two experiments were prepared differently. In the first experiment timber plates were used to form a mesh cage. Wire mesh was overlapped at a length of 80 mm (6 x 13 mm), approximately, as shown in Figure 1. To ensure that the overlap would not loosen or slide from each other, it was tied with steel wire in two rows through the whole length at a space of every two grids. Additional ties were applied to the middle of the overlap area at every 6 grids. Wires were used to ensure space for 5 mm or 10 mm cover.

(a) Wire mesh cage (b) Wrapping mesh onto the precast core  
**Figure 1. Wire mesh reinforcement installation**

In the second experiment, concrete cores were cured for 28 days and each core was roughened evenly throughout the surface. Wire mesh was wrapped onto the surface in a continuous way. A working table was set up to facilitate installing wire mesh reinforcement. At the overlap area steel wires were used to tie up the mesh in a similar way as introduced in the first experiment.

All the confined specimens were strengthened with two layers of 40 mm wide CFRP strips at both ends and capped with high strength plaster before testing.

## 2.2 Properties of preliminary materials

Locally purchased galvanised wire mesh (12.7 mm x 12.7 mm) was used for this series of study. The tensile strength of single wire in both lateral and vertical directions was investigated, as shown in Table 3. The concrete used for the first experiment was mixed in the laboratory, while read mix concrete with target strength of 32 MPa was adopted for the second experiment. The slump test result and the average compressive strength at 28 days for the first and the second experiment were 150 mm, 55 MPa, 175 mm, 33 MPa, respectively. Due to the equipment constraint, four batches of mortar cast for the second experiment. The mortar compressive strength of each batch at 28 days was 62.4 MPa, 48.5 MPa, 59.5 MPa and 55.6 MPa, respectively.

II	Trans.	1.12	614	620
II	Long.	1.13	584	587

Note: Orient. = Orientation, Trans.=transverse, Long.=longitudinal

## 2.3 Specimens testing

All specimens were tested under concentric loading, which was performed through displacement control. The specimens of the first experiment were tested using MTS 643, at a speed of 0.15 mm/min in the structural laboratory at Hong Kong Polytechnic University. The specimens of the second experiment were tested using the Denison testing machine, at a speed of 0.5 mm/min in the High Bay laboratory at the University of Wollongong.

## 3. Results and discussion

### 3.1 Experiment I: wire mesh cages cast integrally

The results of the first experiment are presented in Table 4 and Figure 2. The ultimate load of mesh confined specimens was less than the controls. The increment in the layer of wire mesh did not ensure the increment in the load capacity. The results also show that 5 mm difference in cover did not make significant difference in terms of load carrying capacity. Plasticity ratio was adopted to investigate ductility, which is defined as  $\beta = \Delta_{0.85} / \Delta_{ult}$ , where  $\Delta_{0.85}$  = the displacement corresponding to the load at 85 percent of the maximum axial load on the descending curve;  $\Delta_{ult}$  = the displacement corresponding to the maximum axial load. The specimens confined with wire mesh had significantly outweighed the controls in terms of ductility. However, the increment was not linear to the increase of wire mesh reinforcement.

**Table 4. Results of Experiment I**

Specimen Code	Ultimate Load kN	Ultimate Load, kN Average	Comp.	Plasticity Ratio $\Delta_{.85}/\Delta_{ult}$	Plasticity Ratio Average	Comp.
Control 1	924.			1.090	1.119	1.00
Control 2	841	883	1	1.148

2L10C2	881	861	0.98	1.497		

Comp. = comparison

**Figure 2. Load and plasticity of Experiment I**

### 3.2 Experiment II: wrapping method

The results of the first experiment are presented in Table 5 and Figure 3. It is noted that the diameter of confined specimens were 190 mm, larger than that of control. In contrast to the first experiment, the load carrying capacity of mortar or MGWM composite confined specimens had been considerably improved. Moreover, the specimens confined with mortar had outperformed the specimens confined with MGWM composite in terms of load carrying capacity, which indicates that the increment in strength was related to the contribution of mortar. However, MGWM composite significantly improved plasticity. The second method, wrapping wire mesh onto precast concrete core combined with mortar, can improve both the load carrying capacity and ductility.

**Table 5. Results of Experiment II**

Code	Ultimate Load kN	Ultimate Load, kN Average	Mortar $f'_m$ MPa	Plasticity Ratio $\Delta_{.85}/\Delta_{ult}$	Plasticity Ratio AVE	Plasticity Comp.

**Figure 3 Load and plasticity of Experiment II**

### 3.3 Estimated Load

Following AS 3600 (2009), the lateral confinement to the core was calculated for the MGWM composite confined specimens. Wire mesh was considered as steel reinforcement. The estimated values of the second experiment are shown in Table 6. The variation between the estimated values and the experimental results is large, which indicates that the strength contribution related to the wire mesh was marginal due to low reinforcement ratio. In other words, the contribution by concrete core and mortar are critical. A factor of 0.85 is considered for evaluating the mortar shell and the concrete core contribution to the load carrying capacity, as shown in the following equation:

$$P = 0.85(A_c f'_c + A_m f'_m) \quad (1)$$

where  $A_c$ ,  $f_c$  is the area and the compressive strength of concrete core, respectively;  $A_m$ ,  $f_m$  is the area and the compressive strength of mortar confinement, respectively.

**Table 6. Load estimation**

Specimen Code	$f'_m$ MPa	Layer L	VFR Vr	$f_{r,eff}$ MPa	$f_{c,c}$ MPa	$P_{est}^{**}$ kN	$P_{exp}$ kN	Comparison $(P_{est}-P_{exp})/P_{exp}$	$P^*$ kN	Comparison $(P-P_{exp})/P_{exp}$

#### 4. Conclusions

Based on the series of experiments, the following conclusions are drawn:

At low reinforcement ratio, the contribution of wire mesh to the compressive strength is marginal. However, wire mesh can significantly improve the ductility of confined specimens in both cases. The method of wrapping wire mesh to precast core and compacted with mortar is sufficient to improve both the load carrying capacity and ductility. The contribution by concrete core and mortar is critical to predict the ultimate load. A factor of 0.85 might be adopted for a relatively close estimation for the ultimate load of mortar-confined specimens.

**ABSTRACT:** This paper describes preliminary experimental work conducted to explore the possible use of crumb rubber concrete (CRC) for structural columns. Two reinforced concrete columns with a diameter of 240 mm and shear span of 1500 mm were tested under constant axial compression load and incrementally increasing reversed cyclic loading. One column was constructed out of CRC and the other one was constructed out of conventional concrete. A snap-back test was conducted to evaluate the damping properties of each column. The results indicated that the use of CRC in the column structure increased the hysteretic damping ratio and energy dissipation by 13% and 150% respectively, up to 4% drift. Beyond that the hysteretic damping ratio and energy dissipation slightly decreased by 0.33% and 1.8%, respectively compared to conventional concrete. However, using CRC decreased the viscous damping ratio compared to a conventional concrete. The CRC column was able to sustain a lateral load of about 98.6% of the load sustained by the conventional column. In addition, the CRC column showed an ultimate drift of about 91.5% of the drift shown by the conventional column. This investigation demonstrates that CRC has the potential to provide an environmentally-friendly alternative to conventional concrete in structural applications.

## 1. Introduction

Used tyres that are currently dumped to landfill are a significant problem throughout the world. Every year, one billion tyres reach the end of their useful lives and 0.5 billion more are expected to be discarded each year by 2030 [1]. Scrap tyres are among the largest and most problematic sources of waste of modern societies, due to their durability and the huge volumes of discarded tyres every year [2]. Recycling of used rubber conserves valuable natural resources and reduces the amount of rubber entering landfill [3]. One application where recycled tyres can be used is concrete. Crumb rubber concrete (CRC) is similar to conventional concrete but uses crumbed scrap tyre rubber as a partial substitution for mineral aggregates.

Well designed and detailed reinforced concrete structures under the prevailing capacity design codes will suffer from severe damage at predesigned locations (i. e. plastic hinges). Hence, more energy-dissipative materials and systems are highly desirable to reduce this damage. Experimental studies on rubberised concrete materials have shown that using rubber in concrete as a partial replacement of its mineral aggregates enhances its ductility, toughness, and damping ratio, but reduce its compressive strength, compared to conventional concrete [4-10]. However, limited studies have been carried out on larger scale structural elements and the results to date have been inconsistent [11, 12].

While tests at the material level showed that CRC generally has higher viscous damping compared to its counterpart conventional concrete, tests on structures constructed using CRC are rare and showed conflicting results. Xue and Shinozuka [11] have investigated the potential use of CRC as a structural material. They tested two very small-scale columns having dimensions of 40x40x500 mm on a shaking table with one column made out of conventional concrete and the other one made out of CRC. Their tests showed that the CRC increased the damping ratio by 62% and decreased the peak seismic response acceleration by 27% compared to conventional concrete. On the other hand, Bowland [12] has investigated the damping properties of two large-scale footbridges 9145x2135 mm using an electro-dynamic shaker. One bridge was constructed using conventional concrete, while the other one was constructed using CRC. This investigation showed that the crumb rubber did not significantly affect damping of the bridge and the crumb rubber sometimes reduced the viscous damping. The main differences between these two studies reported in [11] and [12] were the rubber particle size used and the scale of the tested structure as well as the test limit. In [11], the rubber particle size was 6 mm and it was applied on a relatively small scale column. By comparison, Bowland [12] used a smaller rubber particle size (0.25 mm) and applied it to a relatively large scale structure.

In addition, Xue and Shinozuka [11] have tested their columns up to failure. However, in Bowland [12] the footbridges were tested in the elastic range. This could have contributed to the differences in their findings.

Skripkiūnas et al. [8] observed a continuous decrease in damping ratio ( $\zeta$ ) with increasing rubber content up to 30% sand replacement. The rubber particle size in their study [8] was 1-3 mm. Resende et al. [13] used rubber particles of 2.4 mm size and found that there was no increase in  $\zeta$ . However, a significant increase in  $\zeta$  was observed when they used rubber and steel fibre together [13]. Therefore, it could be concluded that the rubber particle size also has a significant effect on structure  $\zeta$ .

The contradiction in the effect of crumb rubber on the dynamic properties of concrete structures indicates the need for future research and provided the motivation to investigate the performance of CRC as a construction material in reinforced columns under lateral cyclic loading simulating seismic loads. This paper provides the first investigation on seismic behaviour of relatively large scale CRC columns which can help explore the possible future use of CRC for structural columns.

## **2. Experimental program**

Two circular reinforced concrete columns with a diameter of 240 mm and shear span of 1500 mm were cast and tested under constant axial compression load and incrementally increasing reversed cyclic loading. One column was made out of CRC (CRC specimen) and the other one was made out of conventional concrete (CC specimen). Each specimen consisted of a 400x400x1200 mm footing, circular column of 240 mm diameter and 1325 mm clear height, and a 350x350x350 mm column head. The column head acted as a load stub through which the actuator for lateral loading was attached. Each column was reinforced by 6N12 (12 mm diameter) longitudinal bars. Shear and confinement reinforcement was provided by a RW10 (10.5 mm diameter) spiral at a pitch of 80 mm. These represent a longitudinal reinforcement ratio of 1.45% and a transverse volumetric reinforcement ratio of 1.42%. The column longitudinal reinforcement was extended into the footing and the column head to provide adequate shear capacity. Each column had a central un-bonded post-tensioned (PT) bar of 20 mm diameter with un-bonded length of 2253 mm that was used to apply an axial load of 110 kN, in conjunction with two disc springs that were used to keep the axial compression load constant during column loading.

### **2.1 Materials and concrete mixes**

General purpose Portland cement, according to AS 3972 [14], was used as the binder material in the concrete mixes. Two sizes of dolomite stone having nominal maximum sizes of 10 mm and 20 mm were used as coarse aggregate (10 mm : 20 mm = 1 : 2.34). River sand with a maximum aggregate size of 5 mm was used as fine aggregate. The crumb rubber used during the course of this study had only two particle sizes of 1.18 and 2.36 mm. The specific gravity, unit weight, and fineness modulus were 2.72, 1570 kg/m<sup>3</sup>, and 6.02 respectively for dolomite; 2.65, 1630 kg/m<sup>3</sup>, and 2.36 respectively for sand; and 0.85, 530 kg/m<sup>3</sup>, and 4.53 respectively for rubber. Polycarboxylic ether type superplasticizer (SP) with a specific gravity of 1.08 was added to the concrete mixtures to achieve the required concrete workability with a concrete slump of 130-150 mm.

The reinforcement in all column specimens consisted of N12 and RW10 for longitudinal and transverse steel bars, respectively. The yield strength, yield strain, ultimate strength, and ultimate strain provided by the supplier were 550 MPa, 0.00275, 698 MPa, and 0.11600, respectively for N12, and 612 MPa, 0.00306, 641 MPa, 0.02680, respectively for RW10. The yield strength and ultimate strength of the PT bar were 901 MPa and 1102 MPa, respectively.

In order to increase the rubber/cement interface adhesion, pre-treatment of the rubber particles with sodium hydroxide (NaOH) solution was used. The process commenced with the rubber particles being washed by tap water to remove any impurities and dust. They were then submerged into 10% NaOH solution for 30 minutes in a container. Finally, the rubber particles were washed again by stirring in water until its pH became 7, and then they were left to air dry. The final washing is essential to remove any existence of NaOH solution and to prevent any negative effect on the concrete durability [15-17].

The specimens were cast using two different concrete mixtures; conventional concrete of 60 MPa target compressive strength, and the corresponding CRC where 20% of the sand volume was

replaced by rubber particles. The concrete mixes were designed according to Australian Standard (AS) AS 1012.2 [18]. Table 1 summarises the different components and properties of the concrete mix used for each specimen.

**Table 1. Proportions of concrete mixes.**

Specimen code	Rs (%)	W/C	Mix proportions (kg/m <sup>3</sup> )							$f'_c$ (MPa)		E (GPa)
			Cement	Sand	Dolomite		Rubber	Water	SP	28 day	Test day	
					10 mm	20 mm						
CC	-	0.5	350	866	311	727	--	175	6.30	58.6	61.9	45.62
CRC	20	0.5	350	693	311	727	55.5	175	6.65	43.0	44.7	43.27

Rs Per cent of sand volume replaced by rubber.

The mixing procedure for the conventional concrete mix was as follows: mix dry sand and gravel for 1 min.; add half of the water and mix for 1 min.; rest for 2 mins; add cement, water, and admixtures, and then mix for 2 mins. The same procedure was followed for the CRC mix; except that the rubber aggregate was first mixed with dry cement for 1 min in an external container, aiming to increase the rubber/cement interface adhesion, which is one of the main factors affecting CRC strength. These are the same procedures previously followed by the authors in earlier work on CRC material properties [17].

## 2.2 Specimen preparation and cyclic test setup

The column reinforcement cage was placed in position during casting of the column footing to avoid using any steel splices in the column longitudinal bars. A PVC-225 stormwater pipe (240 mm inner diameter and 5.5 mm wall thickness) was used as the circular column formwork. A PVC-40 pressure pipe (45.1 mm inner diameter and 1.5 mm wall thickness) was centred along the whole specimen height to become a duct for the PT bar. Figure 1 shows a prepared test specimen. The concrete was cured until 28 days by showering the column specimens two times a day in conjunction with wrapping the specimens in plastic sheet. Ten 100x200 mm concrete cylinders were taken from each mix to record the 7 and 28 day compressive strengths, as well as, the column test day compressive strength according to AS 1012.9 [19].

After 28 days concrete age, the column footing was post tensioned to the lab strong floor. The MTS actuator ram was attached to the column head using two high-strength bolts passing through two horizontal ducts in the column head. The PT bar was loaded and anchored at the footing and head using two 160x160x40 mm steel plates and two 80 mm length hex nuts. The PT bar system was used to apply an initial axial force of 110 kN. This axial force was approximately 4.0-5.6% of the columns axial capacity ( $P_0$ ) calculated as  $P_0 = f'_c A_g$ , where;  $f'_c$  is the concrete compressive strength and  $A_g$  is gross cross-sectional area of the column.

The lateral load was applied using a horizontally aligned 100-kN hydraulic actuator under displacement control. The column specimens were subjected to reverse cyclic lateral loading at 1 mm/sec according to ASTM E2126-11 [20]. The displacement increment started with 0.25% drift ratio until reaching a total of 1% drift. Up to 1% drift, two complete cycles per drift were applied. Then, the displacement increment increased from 1% drift to 10% drift in increments of 1% drift. Each drift level in this stage consisted of three complete cycles. Figure 2 shows the loading pattern used in this study. The forces in the PT bars were measured using a load cell attached at the top of the column. All measurements were recorded using a data acquisition system and computer software (LABVIEW 8.6).

## 2.3 Snap-back test

Snap-back tests were carried out on each column specimen, before the cyclic loading tests, to estimate the structure damping ratio, natural frequency, and stiffness. Figure 3 shows the snap-back test setup. The column head was pulled with an initial displacement of 5 mm towards a reaction frame using steel wire of 16 mm diameter connected to the MTS hydraulic ram. Then, this initial displacement was suddenly released by using a double shear connection designed to fail at 5 mm displacement for each column, see Figure 3(b). The column displacement at the mid-height of the

column head was recorded using linear variable displacement transducers (LVDT). The column acceleration was measured using an accelerometer placed horizontally at the mid-height of the column head. The test was repeated three times for each column and the results were averaged.

(a) Pulling system.

(b) Double shear connection.

(c) Pin double shear failure.

Figure 3. Snap-back test setup.

**3. Test results and discussions**

**3.1 Snap-back test**

Snap-back tests were carried out on the columns to determine their initial stiffness, natural frequencies, and damping ratios. The initial stiffness was determined as the slope of the linear load-displacement relationship recorded during the static pull of the column before the sudden snap failure. To determine the natural frequency for each column, Fast Fourier Transform (FFT) analyses were carried out to convert data from the time domain to the frequency domain. Damping ratios ( $\zeta$ ) were calculated from the recorded accelerations and displacements in time domains using the logarithm decrement method (Eq.1) after five cycles and in frequency domains using the half-power band width method (Eq.2). More details of each method can be found in Chopra 1995 [21].

$$\zeta = \frac{1}{2\pi n} \ln \frac{y_1}{y_n} \tag{Eq.1}$$

Where;  $y_1$  is the initial amplitude of displacement/acceleration in the response decay, and  $y_n$  is the amplitude of displacement/acceleration after n cycles in the time domain.

$$\zeta = \frac{f_b - f_a}{2f_n} \tag{Eq.2}$$

Where;  $f_b$  and  $f_a$  are the frequencies associated with the half power points ( $\frac{A_p}{\sqrt{2}}$ ) on either side of the peak amplitude ( $A_p$ ) in the frequency domain, and  $f_n$  is the natural frequency of the specimen.

Table 2 shows the detailed results of the snap-back tests. The natural frequency of the CRC specimen (18.3 Hz) was higher than that of the CC specimen (12.1 Hz). This was attributed to the higher initial stiffness of the CRC specimen which was 3.8 times the initial stiffness of CC specimen. However, the modulus of elasticity (E) for the CRC was less than that of the CC (see Table 1). The difference in the initial stiffness between the tested columns may be attributed to the casting of columns two days after the footing which can affect the bond at the footing/column interface. As shown in Table 2,  $\zeta$  for the CRC specimen was less than that of the CC specimen. By averaging the results of the two methods, it can be concluded that replacing 20% of the sand aggregate by rubber aggregates (specimen CRC) decreased  $\zeta$  by 56% compared to conventional concrete. This implies that using rubber aggregate in concrete in large scale structure applications is not as promising as what was found by researchers in most of the concrete material level studies [4-6, 22]. The rubber particle size used in this study ranged between 1.18 and 2.36 mm which is in the same range of 0.25-3.0 mm used by some previous researchers [8, 12, 13]. These researchers found that using this relatively small rubber size has no effect on concrete damping or sometimes decreased its damping properties. However, Xue and Shinozuka [11] used a rubber size of 6.0 mm and achieved 62% increase in concrete damping. Therefore, the rubber particle size plays an important role in affecting the concrete damping. More research is clearly required in this area.

**Table 2. Snap-back test results.**

Specimen code	Initial stiffness (kN/mm)	Natural frequency (Hz)			Damping ratio, $\zeta$ Log. dec.(%)			Damping ratio, $\zeta$ Half-power (%)		
		Disp.	Acc.	Average	Disp.	Acc.	Average	Disp.	Acc.	Average
CC	0.62	11.94	12.19	12.1	4.5	9.9	7.2	4.7	8.0	6.3
CRC	2.31	18.16	18.49	18.3	2.7	3.0	2.8	3.6	2.5	3.1

### 3.2 Cyclic test

Table 3 summarises the main results of the static cyclic test conducted in this study. The CC specimen reached an ultimate force of 28.9 kN at a drift of 5% before it reached an ultimate drift of 9.95%. The CRC specimen reached an ultimate force of 28.5 kN at a drift of 4% before it reached an ultimate drift of 9.10%. Thus, using rubber in concrete resulted in a decrease in the ultimate force and ultimate drift by 1.3% and 8.5%, respectively. The CC specimen had an average compressive strength,  $f_c$  of 61.9 MPa in comparison to  $f_c$  of 44.7 MPa for the CRC specimen, which would make it likely that the CRC column would have higher deformability. However, these specimens were tested under the same magnitude of axial load. Thus, the CRC specimen was subjected to a slightly higher percentage of its concentric capacity (5.6%) than the CC specimen (4.0%) which resulted in a reduction of the specimen deformability. The CRC specimen displayed residual drift 20% lower than that displayed by the CC specimen at their ultimate drift cycles, which were 9.10% and 9.95%, respectively. Residual drift is the drift that remains in the specimen at zero force of a given cycle drift.

**Table 3. Cyclic test results.**

Specimen code	Ult. disp. (mm)	Ult. drift (%)	Ult. force (kN)	Drift at ult. force (%)	Residual disp. at ult. drift (mm)	Residual drift (%)	Concrete cover spalling height (mm)
CC	149.3	9.95	28.9	5.0	105.0	7.0	250
CRC	136.5	9.10	28.5	4.0	84.0	5.6	230

#### 3.2.1 Test observations

Figure 4 shows the global damage, horizontal crack extensions, and concrete cover spalling regions of the tested specimens. In the CC specimen, at 3% drift, horizontal cracks began to occur at a height of 100 mm above footing. Spalling of concrete cover started at a drift of 4.5% in the bottom-most 100 mm

of the column above the footing, and then extended to 250 mm height above the footing at the end of the test (10% drift). In the third cycle of 9% drift the northern-most longitudinal bars ruptured. In the CRC specimen, up to 3% drift, only some horizontal cracks at a height of 150 mm above footing occurred without any concrete spalling. At 4% drift, concrete cover spalling started and extended up to 150 mm above the footing until 9.0% drift. Rupture of the most north and most south longitudinal bars occurred in the first cycle of 10% drift with extension of concrete cover spalling up to 230 mm above the footing. In the CRC, horizontal flexural cracks were observed to only 370 mm above the footing compared to observed horizontal flexural cracks to 860 mm above the footing in the CC specimen. These observations indicated that the rubberized concrete columns can behave almost like the conventional concrete columns. However, rubberized concrete can delay and reduce the amount of damage occurring under seismic loading. This is attributed to the higher deformability of rubberized concrete compared to conventional concrete.

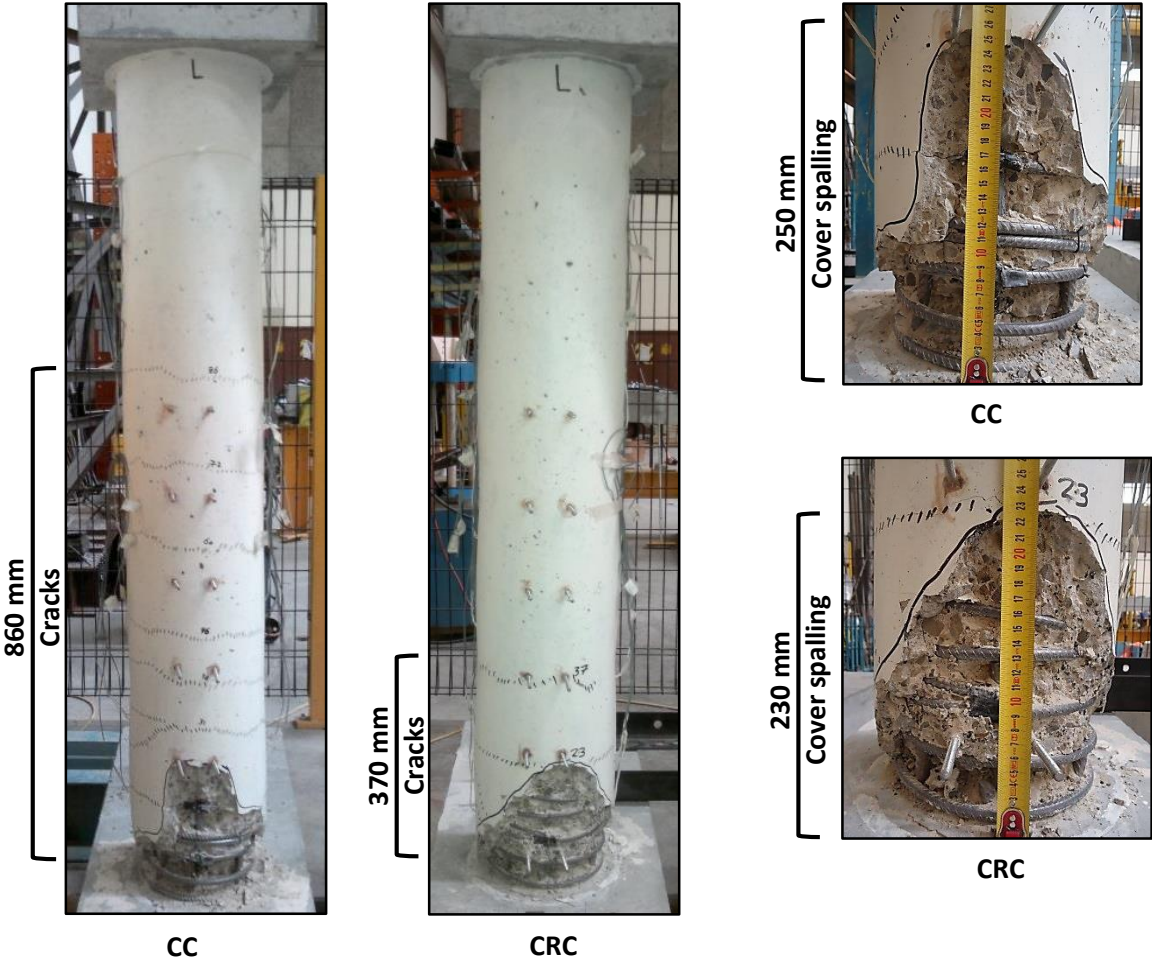

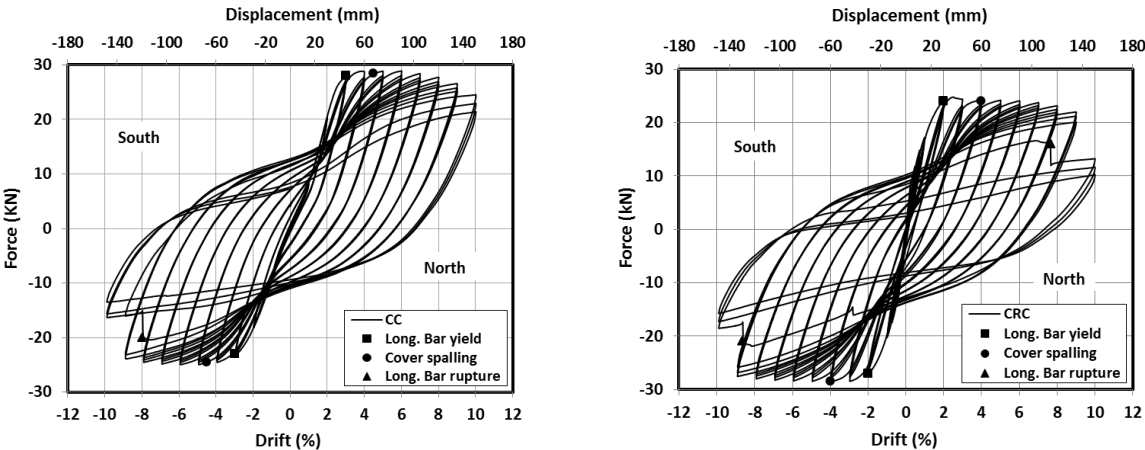

Figure 4. Global damage, horizontal crack extensions, and concrete cover spalling regions of tested columns.

3.2.2 Hysteretic behaviour and backbone curve

The recorded lateral force versus column displacement for each specimen is shown in Figure 5. The CC specimen showed linear behaviour until about 1% drift. However, the CRC specimen showed linear behaviour until only 0.5% drift. This was followed by stable nonlinear hysteretic loops until the end of the test for all specimens. The nonlinearity was attributed to the concrete cover spalling, horizontal flexural cracks, and longitudinal bar yielding. The hysteresis loops initially indicate typical well rounded curves until after a significant deterioration of the concrete has taken place. All specimens resisted the maximum lateral load for several cycles with minor strength degradation until the first rupture of the longitudinal bar that can be observed from the sudden drop in the specimen force at cycles of 9% and 10% drift for specimens CC and CRC, respectively. If a 20% drop in the

lateral force be considered as the point of specimen failure, then columns CC and CRC failed during the second cycle of 10% drift (north direction) and first cycle of 10% drift (south direction), respectively.

The backbone curves (envelopes of the hysteretic loops) of the tested specimens are shown in Figure 5(c). As shown in this figure, the CRC specimen had higher initial stiffness than that of the CC specimen (see Table 2). For all specimens, after the steel yielded the specimens possessed a constant post-yield stiffness until reaching their ultimate strengths of 28.9 kN and 28.5 kN for CC and CRC specimens, respectively. This was followed by strength degradation due to concrete cover spalling, longitudinal bar rupture and longitudinal bar buckling. In Figure 5(c), there is no significant difference in the stiffness degradation rate between the CRC and CC specimens. This indicated that the nonlinear behaviour of rubberized concrete is very similar to that of conventional concrete.

(a) Hysteretic behaviour of CC specimen.

(b) Hysteretic behaviour of CRC specimen

(c) Backbone curve for all specimens.

**Figure 5. Cyclic test results.**

**3.3 Energy dissipation and equivalent viscous damping**

High energy dissipation of structural elements subjected to earthquakes is a very desirable characteristic. The energy dissipation of the tested columns at each % drift can be calculated from the hysteretic behaviour as the area enclosed by the cycle of the lateral load versus displacement curve. Figure 6 shows the amount of energy dissipated at each % drift. The energy at each % drift has been taken as an average energy of all cycles at the same drift. As shown in Figure 6(a), up to 2% drift, there was insignificant energy dissipation due to the elasticity in the specimen’s behaviour (before bar yielding and concrete spalling). Beyond that, there was a significant linear increase in the energy dissipation with increasing applied drift until the specimens were not able to keep their post-yield

stiffness, see Figure 6(b). The CRC specimen dissipated mean energy about 2.5 times the energy that was dissipated by the CC specimen up to 4% drift. Beyond 4% drift, the CRC was not able to keep its post-yield stiffness due to the concrete cover spalling and then the peak force started to decrease. This resulted in a slight reduction in the CRC energy dissipation by 1.8% compared to the CC specimen.

Figure 6. Energy dissipation.

Equivalent viscous damping ( $\zeta_{eq}$ ) is a central task in modern seismic analysis methods [23]. Hysteretic damping in structures can be represented by  $\zeta_{eq}$  as it is the simplest form of damping for numerical analysis [21]. In this study,  $\zeta_{eq}$  was calculated for each specimen using Eq.3 [24]:

$$\zeta_{eq} = \frac{1}{4\pi} \frac{E_d}{E_s} \tag{Eq. 3}$$

Where,  $E_d$  is the energy dissipated in a cycle and  $E_s$  is the stored energy measured at the peak force of the same cycle. The plot of  $\zeta_{eq}$  versus drift ratio for each specimen is shown in Figure 7.

The value of  $\zeta_{eq}$  increased with increasing drift ratio almost linearly up to approximately  $\zeta_{eq}$  of 25% for both specimens. This was due to the continuous increase in concrete spalling and horizontal flexural cracks opening until the specimens reached their failure mode. The  $\zeta_{eq}$  of CRC was about 1.13 times that of CC up to 5% drift, see Figure 7(a). Beyond 5%, drift due to the damage started in the CRC, the  $\zeta_{eq}$  slightly reduced by only 0.33% compared to CC, see Figure 7(b).

Figure 7. Equivalent viscous damping.

#### 4. Summary and conclusions

This paper presents an experimental investigation of the performance of crumb rubber concrete (CRC) in reinforced concrete columns. Two reinforced concrete columns having 240 mm diameter and 1500

mm shear span were tested under constant axial compression load and incrementally increasing reversed cyclic loading. One column was constructed out of CRC and the other one was constructed out of conventional concrete. A snap-back test was conducted to evaluate the damping properties of each column before the cyclic testing. The findings and conclusions of this investigation are summarised in the following points:

- 1) CRC in the column structure increased the hysteretic damping ratio and energy dissipation by 13% and 150%, respectively. However, it decreased the column viscous damping ratio by 56% compared to a conventional concrete column.
- 2) The CRC column was able to sustain a lateral load of 98.6% of the load sustained by the conventional column. In addition, the CRC column showed an ultimate drift of about 91.5% of the ultimate drift shown by the conventional column. This indicated that rubber can be used in concrete columns with no significant effect on its ultimate strength and deformability. However, CRC can delay and reduce the amount of damage occurring under the seismic loading.
- 3) CRC decreased the column residual drift by 20% compared to conventional concrete.
- 4) Using CRC in column structures delayed the concrete cover spalling and minimized the concrete cracks compared to conventional concrete.

Further research is recommended into the effect of rubber particle size and column size on both damping and seismic behaviour of column structures.

<sup>2</sup>Professor, Institute of Building Materials Research, RWTH Aachen University, Germany

**Abstract:** The resistance of concrete to sulfate attack in aqueous solutions is often analysed using test methods on small mortar samples. The procedures are usually accelerated by using highly concentrated sulfate solutions. In this review, results on mortars made of sulfate resistant cement and mixtures of Ordinary Portland Cement (OPC) and fly ash are presented. The focus lies on the variation of the temperature and the sulfate concentration of the attacking artificial solution. The evaluation of the expansion caused by the aggressive solution is supported by the analysis of phase changes caused by the sulfate ingress. Artificial sodium sulfate solution is compared to a natural, sulfate bearing groundwater. These results and the assessment of a database containing previous results lead to the conclusion that an acceleration of the test by using high sulfate concentrations is not just unnecessary, but also leads to a change in the attack mechanism, which is not always suitable.

**Keywords:** Sulfate attack, Test methods, Fly ash

## **1. Introduction**

A major aspect concerning the durability of concrete is the resistance to sulfate attack. When exposed to water containing sulfate ions the formation of ettringite ( $\text{Ca}_6(\text{Al,Fe})_2(\text{SO}_4)_3(\text{OH})_{12}\cdot 26\text{H}_2\text{O}$ ), gypsum ( $\text{CaSO}_4\cdot 2\text{H}_2\text{O}$ ) and/or thaumasite ( $\text{Ca}_3\text{Si}(\text{OH})_6(\text{CO}_3)(\text{SO}_4)\cdot 12\text{H}_2\text{O}$ ) can lead to the deterioration of the cementitious matrix. The formation of ettringite and gypsum comes along with an increase in volume, causing expansive strains in the concrete, and thus leading to cracking. Thaumasite may precipitate when a source of carbonate, e.g. limestone powder or  $\text{CO}_2$  from the air is available. Since thaumasite is a mineral with a very low strength, its formation leads to a complete disintegration of the cement paste.

The intensity of the sulfate attack depends on the chemical composition of the cement, the permeability of the concrete, the temperature and concentration of the sulfate solution as well as the accompanying cation. Typically, sulfate resisting cements with a low content of  $\text{C}_3\text{A}$  are used, preventing the excessive formation of ettringite. The use of supplementary cementitious materials (SCMs) such as ground granulated blastfurnace slag, fly ash or silica fume usually results in a higher sulfate resistance.

Because of the differing environmental conditions and the great variety of binders the subject of sulfate attack on concrete is difficult to compress into one single testing procedure. Internationally a large variety of testing methods exists, trying to simulate and approximate the susceptibility of concrete to sulfate attack in the field using lab methods. A review on international methods can be found in [1].

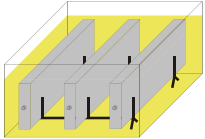

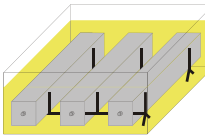

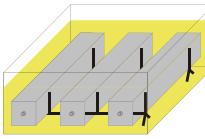

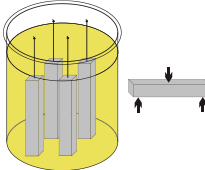

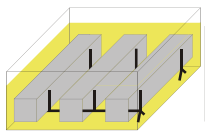

## **2. Test methods for sulfate resistance in Germany**

An overview on the test methods discussed in this paper can be seen in table 1.

The standard test method for sulfate resistance testing in Germany is the so called SVA method, which was developed from the method of Wittekindt [2]. Both methods concentrate on the evaluation of the expansion of flat prisms stored in a highly concentrated sodium sulfate solution. Originally designed to be conducted at ambient temperatures of 20 °C, the SVA method nowadays also includes testing at 5 °C to take the low temperatures usually found in German soils and groundwater into account. Recent findings concerning the attack mechanism and the influence of the concentration of the solution implicated new storage conditions: 3,000 mg  $\text{SO}_4^{2-}/\text{l}$  over a period of at least two years.

The expansions are compared to expansions of samples stored in a reference solution. For both methods (SVA and Wittekindt) a maximum difference between the expansion in sulfate and reference solution was defined: 0.5 mm/m. The assessment times are 91 days (SVA) and 56 days (Wittekindt). However, due to the recent changes in the SVA method, this criterion does no longer apply. Mixtures containing sulfate resistant OPC (CEM I 42.5 R-SR3) and blastfurnace slag cement (CEM III/B 42.5 N-LH/SR/NA) are taken as a reference to ensure the sulfate resistance of the tested binder.

**Table 1. Test methods for sulfate resistance used in Germany**

	SVA method	Wittekindt	CEN	Koch-Steinegger	MNS
Test setup					
Basic principle	Expansion measurement			Visual investigation, relative flexural strength	Relative tensile strength
Samples	Mortar flat prisms (10 x 40 x 160 mm <sup>3</sup> )		Mortar prisms (20 x 20 x 160 mm <sup>3</sup> )	Mortar prisms (10 x 10 x 60 mm <sup>3</sup> )	Concrete prisms (40 x 40 x 160 mm <sup>3</sup> ), cement content 360 kg/m <sup>3</sup>
w/c	0,5	0,6	0,5	0,6	
Storage temperature	20 °C, recently also 5 °C	20 °C	20 °C	20 °C	8 °C
Sulfate solution	Na <sub>2</sub> SO <sub>4</sub> , 30,000 mg SO <sub>4</sub> <sup>2-</sup> /l, recently also 3,000 mg SO <sub>4</sub> <sup>2-</sup> /l	Na <sub>2</sub> SO <sub>4</sub> , originally 14,400 mg SO <sub>4</sub> <sup>2-</sup> /l, later 29,800 mg SO <sub>4</sub> <sup>2-</sup> /l	Na <sub>2</sub> SO <sub>4</sub> , 16,000 mg SO <sub>4</sub> <sup>2-</sup> /l	Na <sub>2</sub> SO <sub>4</sub> , 25,000 mg SO <sub>4</sub> <sup>2-</sup> /l	Na <sub>2</sub> SO <sub>4</sub> , 33,900 mg SO <sub>4</sub> <sup>2-</sup> /l
Solution change	Every 2 weeks	Every month	Every month	-	Every month
Reference storage	Ca(OH) <sub>2</sub> solution	Water	Water	Water	Water
Storage before testing	Until age of 14 days in saturated Ca(OH) <sub>2</sub> solution	Until age of 14 days in water	Until age of 28 days in water	Until the age of 21 days in water	Water storage, Air storage, before immersion vacuum saturation at 150 mbar
Test duration	91 days 2 years for 3,000 mg SO <sub>4</sub> <sup>2-</sup> /l	56 days	Not determined	56 days	84 or 120 days
Criterion	30,000 mg SO <sub>4</sub> <sup>2-</sup> /l: Δε ≤ 0,5 mm/m	Δε ≤ 0,5 mm/m	Not determined	Relative flexural strength ≥ 0,7	Relative tensile strength ≥ 0,8 (84 days) or 0,7 (120 days)

The CEN method has been developed on a European level and is very similar to the SVA and the Wittekindt method, a major difference being the specimen geometry of 20 x 20 x 160 mm<sup>3</sup> and the concentration of the sodium sulfate solution being 16,000 mg SO<sub>4</sub><sup>2-</sup>/l. Extensive research has been carried out using this method in different research projects and round robin tests. However, the comparability between different laboratories has not been satisfying, and the evaluation of mixtures of cement and fly ash did not meet the expectations, since the results were not distinct [3].

Another method developed and applied in Germany is the method according to Koch and Steinegger [4]. Small mortar prisms are immersed into sodium sulfate solution of 25,000 mg SO<sub>4</sub><sup>2-</sup>/l and as a reference in water. In contrast to the three methods using expansion measurements for evaluation, this method

focuses on the relative flexural strength of the specimen after a storage time of 56 days at 20 °C. Publications presenting results achieved using this method are, however, scarce.

A relatively new procedure developed by Mulenga et al. is the MNS method (Mulenga-Nobst-Stark method) [5]. Focus of this method is the analysis of the relative tensile strength of concrete specimen vacuum saturated by and immersed in sodium sulfate solution of 33,900 mg SO<sub>4</sub><sup>2-</sup>/l at 8 °C in relation to water stored specimen. It is stated that the method allows to achieve repeatable results regarding the sulfate resistance of a concrete [5]. However, the application of tensile strength as the basic measurement principle results in a relatively high effort for testing compared to the other test methods. Additionally, the relatively high variance of the tensile strength compromises the validity.

## 2. Materials and Methods

### 2.1 Materials

In this study three different ordinary Portland cements with different composition and fines (CEM I 42.5 R, CEM I 42.5 R-SR, CEM I 52.5 N) are compared. A low calcium fly ash was used. The chemical composition of the materials is shown in table 2. Some of the results were previously presented at the International Conference on Durability of Concrete 2014 (ICDC), [6]. For the convenience of the reader, the material characterisation and the results are repeated in this paper.

**Table 2. Chemical composition of the cements and fly ash, [7]**

Content in wt.-%	CEM I 42.5 R-SR	CEM I 42.5 R	CEM I 52.5 N	fly ash
Loss on ignition	2.1	3.1	2.0	1.94
CaO	60.28	61.56	62.56	3.78
SiO <sub>2</sub>	18.98	19.58	21.10	57.85
Al <sub>2</sub> O <sub>3</sub>	4.12	5.27	5.03	20.07
Fe <sub>2</sub> O <sub>3</sub>	7.03	2.66	2.53	7.77
SO <sub>3</sub>	3.73	3.83	3.97	0.94
MgO	2.55	2.17	1.72	1.87
CO <sub>2</sub>	1.65	2.30	1.19	-
Na <sub>2</sub> O	0.16	0.23	0.22	2.05
K <sub>2</sub> O	0.95	1.03	0.73	1.88
Cl <sup>-</sup>	0.018	0.017	0.022	0.009

According to EN 196-1 five standard mortars with 450 g binder, 1350 g CEN reference sand and varying equivalent water cement ratio were produced. The high sulfate resistance cement was used for the reference mixture (SR). In mixtures M1 and M2 40 wt.-% of the cement were substituted by fly ash. In mixtures M3 and M4 30 wt.-% of fly ash were used as cement replacement. All five mixtures are summarized in table 3.

**Table 3. Mixture composition [7]**

Content in g	SR	M1	M2	M3	M4
CEM I 42.5 R-SR	450	-	-	-	-
CEM I 42.5 R	-	270	-	-	-
CEM I 52.5 N	-	-	270	317.6	317.6
fly ash	-	180	180	132.4	132.4
water	225	225	225	198.5	166.8
w/C <sub>eq</sub> <sup>1)</sup>	0.5	0.74	0.74	0.55	0.46
sand	1350	1350	1350	1350	1350

1) w/C<sub>eq</sub> according to DIN 1045-2

## 2.2 Methods

### 2.2.1 Sulfate resistance testing

For each mixture samples with dimensions of 10 x 40 x 400 mm<sup>3</sup> were produced. The flat prisms were stored for two days at 20 °C and > 95 % r. h.. Afterwards the framework was stripped. Subsequently the samples were pre-stored in a saturated solution of calcium hydroxide at 20°C until an age of 28 days.

Samples of each mixture then were stored in three different solutions: saturated calcium hydroxide solution, sulfate solution with 30,000 and sulfate solution with 3,000 mg/l. Four different temperatures were investigated: 5, 8, 12 and 20 °C. To remain a constant sulfate concentration, the sulfate solutions were exchanged every two weeks during the first three month and every four weeks afterwards.

Groundwater obtained in southern Germany was used for storage of specimen at 5 °C. The groundwater had an elevated sulfate concentration of approximately 1,500 mg/l and an ion composition according to table 4.

**Table 4. Ion concentrations (in mg/l) and pH of the groundwater**

Na <sup>+</sup>	K <sup>+</sup>	Ca <sup>2+</sup>	Mg <sup>2+</sup>	Cl <sup>-</sup>	NO <sub>3</sub> <sup>-</sup>	SO <sub>4</sub> <sup>2-</sup>	pH
22,0	5,7	597,0	74,5	123,98	55,53	1452	7,62

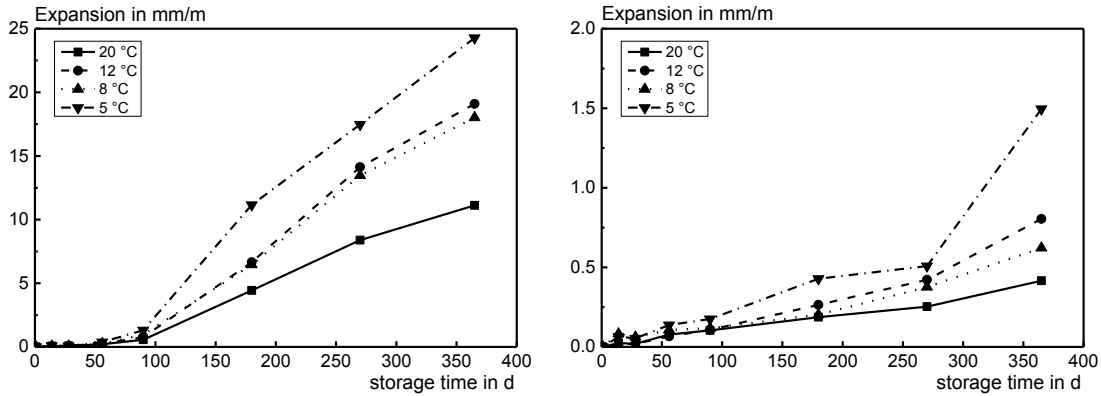

The samples were probed for their deformation and for their change of the modulus of elasticity. The measurements were performed after 0, 14, 56, 91, 180, 270 and 365 days of storage. The deformation was defined by their change of length measured with a digital indicator Mahr Millitast 1070. The dynamic modulus of elasticity was assessed by measuring the resonance frequency at the same dates.

### 2.2.2 X-ray diffraction

After 365 days of storage the sulfate intrusion was determined by means of X-ray diffraction. Therefore samples of 40 x 40 x 10 mm<sup>3</sup> were cut from the flat prisms. These samples were dried via solution exchange in isopropanol for 24 hours, followed by drying at 40 °C. The samples then were ground in steps of 0.5 mm until the middle of the sample. The powder of each step was collected and analysed with an X-ray powder diffractometer Panalytical X'Pert Pro with an X'Celerator detector in a 2θ range of 5 to 70 °2θ with a step size of 0.0167 °2θ. The samples were analysed qualitatively, followed by quantification using the Rietveld method [7].

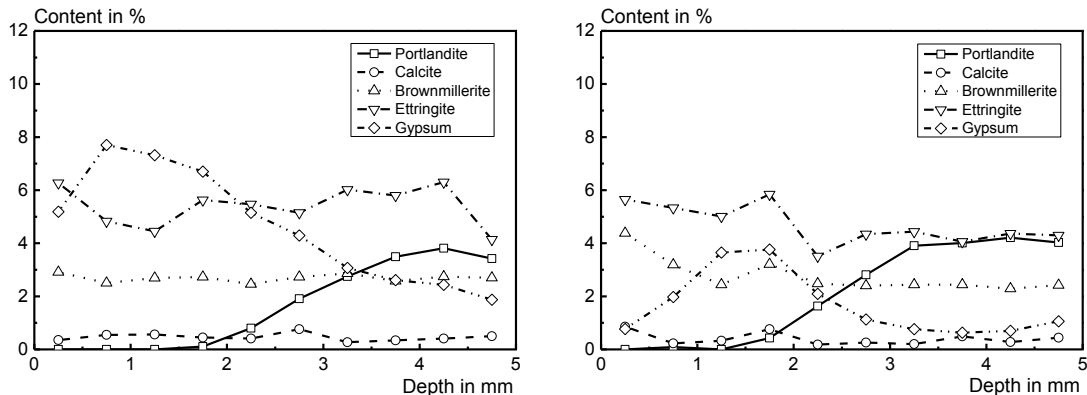

### 3 Experimental Results

The reference sample containing sulfate resisting cement shows a temperature dependence of the expansion rate (see Figure 1). A lower storage temperature leads to higher deformation. After one year of storage the highest deformation is 25 mm/m (30,000 mg/l at 5 °C). Despite the high deformation the samples are still intact. No spalling could be observed. The lower sulfate concentration (3,000 mg/l) results in a smaller expansion of only 1.5 mm/m at same temperature.

**Figure 1. Expansion of mixture SR stored in sulfate solution at 30,000 mg/l (left) and 3,000 mg/l (right), [6]**

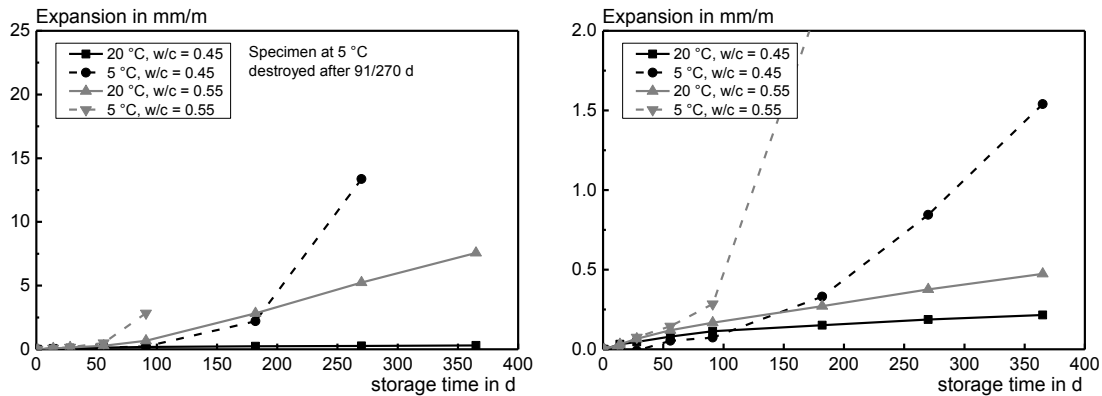

The results of XRD and Rietveld analyses are shown in figure 2. Inert phases like quartz and feldspars were disregarded in the graphs. Two variations of the reference mortar were investigated.

**Figure 2. Phase composition of mixture SR stored in sulfate solution at 30,000 mg/l and 20 °C (left) and at 3,000 mg/l and 5 °C (right), [6]**

The figure shows that there is a relatively high amount of brownmillerite ( $C_4AF$ ) remaining after one year whose content is constant over the depth of the sample. The amount of ettringite is essentially constant and is similar for both the 30,000 mg/l and 3,000 mg/l sulfate solutions. Probably it is primary ettringite formed during hydration. Due to the low alumina content of the cement this ettringite was not converted to monosulfate. In both solutions gypsum is formed. The use of the highly concentrated sulfate solution (30,000 mg/l) results in a doubled amount of gypsum throughout the sample in comparison to the lower concentrated solution. At sample depth of 1 to 2 mm the gypsum concentration reaches a maximum and decreases towards the middle. The lower gypsum content in the outer sample part might be caused by leaching of calcium caused by the deionised water that was used for the sulfate solution. That might be confirmed by the absence of portlandite up to depth of 2 mm.

Figure 3 shows expansions of the mixtures M3 and M4 with fly ash. The reduction of the equivalent water cement ratio of the fly ash containing mortars results in a higher sulfate resistance.

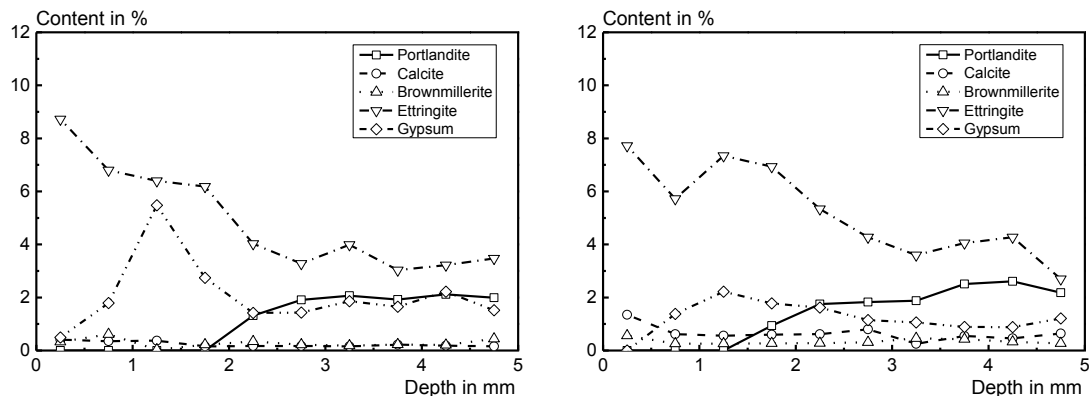

**Figure 3. Expansion of mixture M3 and M4 stored in sulfate solution at 30,000 mg/l (left) and 3,000 mg/l (right), [6]**

Compared to the sulfate resisting cement the fly ash containing mortars contain less  $C_4AF$ . Due to the pozzolanic reaction of the fly ash, the amount of portlandite is lower as well (cf. figure 4).

It is observed that the trend of the gypsum content over the depth of the sample is similar to the reference mortar. Yet, the amount of gypsum is far lower for the fly ash mixture for both sulfate solutions.

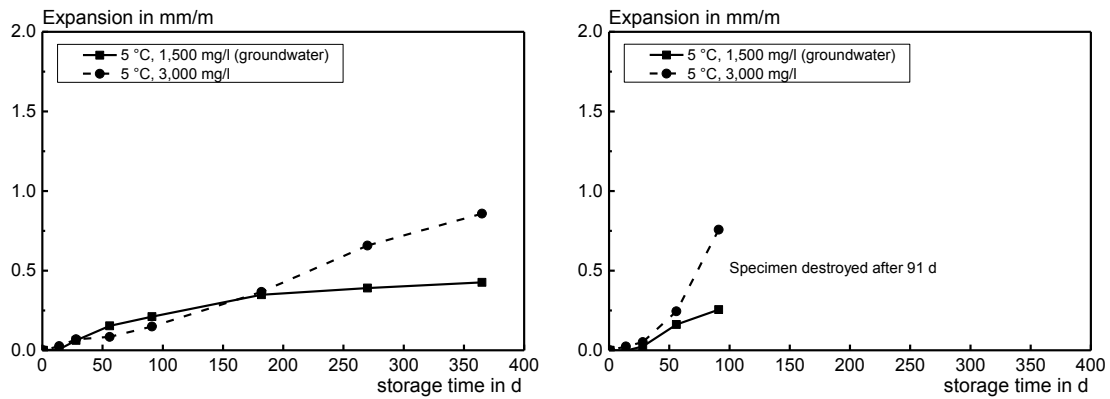

The lower cement content leads to a lower ettringite content in the center of the specimen compared to the reference sample. Close to the surface the amount of ettringite is much higher than in the middle and exceeds the one of the reference mortar. In these mixtures secondary ettringite has formed causing expansion and cracking.

**Figure 4. Phase composition of mixture M4 stored in sulfate solution at 30,000 mg/l and 20 °C (left) and 3,000 mg/l and 5 °C (right), [6]**

Storage of specimen in groundwater with a sulfate concentration of roundabout 1,500 mg/l (cf. table 4) has been conducted to investigate the influence of the artificial sulfate solution prepared with deionised water. Figure 5 compares the expansion of the samples stored in the artificial solution with 3,000 mg  $SO_4^{2-}$ /l with the groundwater storage. The tests were performed at 5 °C to increase the severity of the attack. The liquids have been renewed every 14 days to ensure constant conditions. In Figure 5 the results of the experiments on sulfate resistant cement and on a mixture of OPC and 40 % fly ash are illustrated.

**Figure 5. Expansion of a mixture containing CEM I 52.5 N-SR cement (left) and CEM I 52.5 N + 40 % fly ash (right) stored in sulfate solution at 3,000 mg/l and groundwater (w/b = 0.5)**

The expansion of the samples of both mixtures is lower when stored in the groundwater. This might on one hand be due to the lower sulfate concentration, on the other hand the availability of calcium in the groundwater reduces leaching of the specimens. Nevertheless severe damage was found for the samples with CEM I 52.5 and fly ash even in groundwater. In general, in natural groundwater the reactions are more complex because of a larger variety of ions available. Further analysis of the microstructure would be necessary to characterise the interaction between cement paste and groundwater.

The experimental data presented in this section has been added to a database of experimental results to achieve a more general view of the influence of different binders on the sulfate attack. The evaluation of this database is subject of the following paragraph.

#### 4. Database analysis

Experimental data of sulfate resistance testing on flat prisms executed at the Institute for Building Materials Research has been collected in a database. The collected data includes the storage conditions, the composition of the particular mixture, the results of the determination of expansion and modulus of elasticity and the chemical composition of the constituents of the binder. Results from literature have been added to the database. The database consists of 580 data records, 519 records deal with the storage in pure sodium sulfate solution.

In a first step mixtures of OPC and fly ash (a total of 259 data records) and sulfate resistant OPC (overall 40 data records) were compared. The water-binder-ratio was 0.5, the concentration of the sodium sulfate solution was 30,000 mg  $\text{SO}_4^{2-}/\text{l}$ , and the storing temperature was 20 °C.

For the combinations of OPC and fly ash two groups of mixtures were distinguished: a group with a fly ash content of 20 % related to the binder (cement + fly ash) and one with 40 %.

In figure 6 the expansion after 90 days of storage in sulfate solution is shown. (4 data records for 20 % fly ash, one record for 40 % fly ash and one record for the SR cement mixtures were excluded by a statistical outlier test). It becomes apparent, that on average mixtures with 40 % fly ash and SR cement have the same expansion after 90 days. That speaks for the general applicability of such binder combinations to produce sulfate resistant concrete. In both cases the upper quartile of the data is above the criterion of 0.5 mm/m, which has been used in the SVA test until recently. That is the reason why the limit value was abolished.

**Figure 6. Boxplot of the expansion at 30,000 mg/l and 20 °C for  $f/c = 0,25$ ,  $f/c = 0,67$  and sulfate resistant cement (SR)**

In contradiction to literature figure 6 shows increasing expansion with increasing fly ash content. Looking at the data in more detail it becomes apparent, that the mixtures with 20 % fly ash have always been produced with CEM I 32.5 R, the mixtures with 40 % fly ash were mostly prepared using cement of a strength class of 42.5 and 52.5. Results on the influence of the fineness of cement on the expansion of the mortar prove, that the expansion caused by sulfate attack increases with increasing fineness of the cement (cf. figure 7). Therefore, the apparent lower expansion of the mixtures with 20 % fly ash should not be overvalued.

**Figure 7. Expansion caused by sulfate attack after 90 days in correlation with the specific surface area of the cement of two mortars containing 40 % fly ash at 30,000 mg/l and 20 °C (left) and 3,000 mg/l and 5 °C (right)**

The results presented in section 3 indicate, that even at rather low sulfate concentration (3,000 mg  $SO_4^{2-}/l$ ) considerable expansion can be observed. In Figure 8 the expansion of mortar bars stored in 30,000 mg  $SO_4^{2-}/l$  at 20 °C is compared to that of specimen stored in 3,000 mg  $SO_4^{2-}/l$  at 5 °C. The results of 21 mixtures with different compositions with and without SCMs, and varying w/b ratios are included in the picture. An age of 56 days has been selected, because the results at 90 days had an increased variance due to partial damaging of the specimen.

**Figure 8. Correlation between the expansion after 56 days at 3,000 mg/l and 5 °C and 30,000 mg/l and 20 °C (Corrected  $R^2 = 0.47$ )**

The resulting  $R^2$  of 0.47 for the regression of the data points indicates a weak correlation. The expansion at 3,000 mg  $\text{SO}_4^{2-}/\text{l}$  and 5 °C is roundabout half of the expansion at 30,000 mg  $\text{SO}_4^{2-}/\text{l}$  and 20 °C.

#### 4. Conclusions and outlook

In this work the sulfate resistance of mortars containing OPC and fly ash were compared to mortars containing sulfate resistant cement by using the SVA method that is used to get a technical approval in Germany. The influence of storage temperature was tested, showing that a lower temperature leads to a more severe attack. The gypsum formation is boosted by higher sulfate concentrations in the attacking liquid. The correlation between more realistic concentrations (3,000 mg/l) at low temperatures and the accelerated test at 30,000 mg/l is poor. In conclusion the test method for determining the sulfate resistance of a binder should focus on lower and realistic sulfate concentrations at low temperatures. Depending on the exposure conditions (e. g. sea water or groundwater) other ions like magnesium or chloride have to be taken into account. Magnesium ions may lead to the formation of brucite or magnesium silicate hydrates (MSH). The latter have very low strength. This damage will not be recognised by expansion tests. Therefore other test methods will be needed [8].

By substituting OPC with fly ash a level of sulfate resistance comparable to that of sulfate resistant cement can be achieved, provided that adequate equivalent water cement ratios are used.

**Abstract:** The long awaited Australian Standard test methods to detect alkali-silica reactivity (ASR) of aggregates - AS 1141.60.1 accelerated mortar bar test (AMBT) and AS 1141.60.2 concrete prism test (CPT) - were published in September 2014. Both test methods were adopted correspondently from the ASTM 1260 and ASTM C1294 test methods but with different performance limits leading to a new class of slowly reactive aggregates. This paper reviews international and Australian research which supported these new performance limits. It also reviews and examines the value of these testing methods in predicting the ASR of aggregates in field-exposed large concrete blocks and a limited number of concrete structures. The outcomes may lead to a consideration of the hierarchy of these two test methods.

**Keywords:** AMBT, ASR, CPT, ASR performance limits,

## 1. Introduction

There main types of tests for evaluating the alkali-silica reactivity (ASR) of aggregates are accelerated mortar bar test (AMBT), concrete prism test (CPT) and field testing. Recently, Standards Australia CE-012 Aggregate and Rock for Engineering Purposes Committee has published two new standard test methods to detect potential ASR:

AS 1141.60.1-2014 Potential alkali-silica reactivity - Accelerated mortar bar method (AMBT) [1] and AS 1141.60.2-2014 Potential alkali-silica reactivity - Concrete prism method (CPT) [2]

**Accelerated mortar bar test (AMBT)** is a rapid test method applied to determine the potential alkali-silica reactivity of aggregates by testing mortar specimens. In general, the procedure of mortar bar testing involves casting mortar bars (normally in the size of 25 x 25 x 285 mm) and curing for 24 hours in a relative humidity of at least 95%. Afterwards, mortar samples are kept in potable water and heated to 80°C and then mortar bars are put in the solution of 1N NaOH that is already at 80°C for 24 hours. After that, the initial length of mortar bars is measured as the zero reading. Until the next reading, samples remain in 1N NaOH for a period of time which can be 10, 14, 21 or 28 days according to the different standards and test methods.

During the development of the Standard AS 1141.60.1, three alternative AMBT methods namely the fixed flow (RMS T363 [3] or VicRoads CR376.03 [4]), fixed water-to-cement ratio (ASTM C1260 [5]) and fixed free water-to-cement ratio (RILEM AAR-2 [6]) were considered. The committee finally agreed to adopt the fixed water-to-cement ratio method because of the more conservative mortar mix composition in ASTM C1260 compared to the fixed flow method [7,8], reduced variability due to difficulty in determining the surface saturated dry condition (SSD) of crushed aggregates or flow measurement [9], and the possible benchmarking to international research data [10] and international proficiency program [11].

The procedure of Australian Standard AS 1141.60.1 is adopted from the ASTM C1260. In a recent study, Fournier et al [11] investigated the proficiency of different AMBT test procedures, including the American ASTM, Canadian CSA and the European RILEM test methods. It should be noted that the test procedure for ASTM and CSA tests are similar. As can be seen from **Table 1** coefficients of variation of AMBT methods showed a lower variation in the 14 days expansion for the ASTM and CSA methods compared to the RILEM test results. However, similar variations in the 28 days expansion were observed for all three test methods. By considering the 10 and 21 days limits for measuring the

expansion of mortar samples in AS 1141.60.1, the outcome of Fournier et al investigation provides support for the adoption of ASTM procedure.

**Table 1: Statistical analysis of different accelerated mortar bar test [11]**

Test age	Method of testing	Number of results	Mean [%]	Standard deviation	Coefficient of variation [%]	Min [%]	Max [%]
14 days	ASTM	26	0.375	0.043	11.6	0.307	0.486
	CSA	24	0.374	0.055	14.8	0.206	0.451
	ASTM + CSA	50	0.375	0.049	13.1	0.206	0.486
	RILEM	3	0.291	0.071	24.5	0.230	0.369
28 days	ASTM	26	0.591	0.067	11.3	0.450	0.725
	CSA	24	0.571	0.064	11.2	0.470	0.700
	ASTM + CSA	50	0.582	0.066	11.3	0.450	0.725
	RILEM	3	0.547	0.065	11.9	0.500	0.621

In addition, Thomas and Innis [12] stressed that the usefulness of various tests may be judged on the basis of the ease of testing, the repeatability or precision of the outcomes, the time taken to complete the test and, ultimately, the ability of the test to predict behaviour in the field.

**Concrete prism test (CPT)** is considered a more reliable test method than the accelerated mortar bar tests in the literature. The reason that the CPT test may provide a better measure for determining ASR compared to the AMBT test is that the CPT test samples are prepared using a concrete mix, and kept in less aggressive conditioning and lower temperature for a longer period of time. Moreover, CPT samples are larger in size (normally in the size of 75 x 75 x 285 mm). Another difference between CPT and AMBT test is related to the procedure of providing the available alkali for ASR reaction. While in the AMBT test mortar bars are kept in NaOH solution whereas in the CPT test the alkali content in the concrete was arbitrarily raised during mixing. For example the ASTM C1293 test measures the expansion of concrete prisms with a cement content of  $420 \pm 10 \text{ kg/m}^3$  and a dry mass of coarse aggregate per unit volume of concrete equal to  $0.70 \pm 0.02$  of its dry-rodded bulk density with a water to cementitious material ratio (w/cm) of 0.42 to 0.45 by mass. The cement has a total alkali content of 1.25% of  $\text{Na}_2\text{O}_{\text{eq}}$  equivalent by mass of cement. Specimens are placed in a container stored in a  $38.0 \pm 2^\circ\text{C}$ . Expansion measurements are performed up to 52 weeks for CPT samples. In addition, for samples prepared with supplementary cementitious materials (SCMs) to mitigate potential ASR, it is recommended in the CSA method to extend the test duration up to 104 weeks. Standard AS 1141.60.2 is adopted from ASTM C 1293 [13] procedure however there are differences in the interpretation of test results between both standards.

**Field testing (Outdoor exposure)** provides the most realistic condition for ASR testing. Outdoor exposure can simulate the temperature and moisture cycling. In addition, by conducting field tests, samples with larger dimensions can be casted that are closer to the scale of real structures. In addition, outdoor samples can be evaluated for longer periods of time (5 to 20 years).

It is implied by the literature [14] that the best method to determine whether an aggregate is potentially reactive or innocuous is to study the history of aggregates field performance. An aggregate can be used in concrete provided that satisfactory field performance was achieved and the cement content (the total alkali content of the cement) should be the same or higher in the field concrete than that proposed in the new structure. The outdoor field exposed concrete should be at least 10 years old. In addition, the exposure conditions of the field concrete should be at least as severe as those in the proposed structure [14].

## 2. Performance Limits

In both the AMBT and CPT methods, expansion limits after a particular period are used to indicate/classify the potential reactivity of aggregates tested. These expansion performance limits were derived from research and field experiences with the use of a wide range of aggregates.

## 2.1. Accelerated Mortar Bar Test (AMBT)

Shayan and Morris [7] compared the accelerated mortar bar expansion of 18 aggregates of known service record, based on the RMS T363 and ASTM C1260, and found lower expansion of the RMS mortars than the corresponding ASTM mortars for reactive aggregates. The lower expansion of the RMS mortars may be due to the lower water/cement ratio in the range of 0.40-0.42 in RMS T363 compared to 0.47 used in the ASTM method. The mortar bar expansions are similar for the less reactive aggregates possibly because they consume less alkali and are not affected by the differences in supply of alkali in the two methods. They found both test methods and their corresponding expansion limits to be capable of assessing the alkali reactivity of non-reactive or very reactive aggregates. However for slowly reactive aggregates, both methods can be used provided that the RMS expansion limits, reproduced in **Table 2**, are used to interpret the reactivity of the aggregates.

It was also found that the two methods would produce similar assessments for the effectiveness of fly ash in controlling ASR expansion for all except the very reactive aggregates. For such reactive aggregates, both methods could be used to obtain expansion curves but the RTA limits were recommended for the interpretation of the adequacy of the amount of fly ash used in controlling the expansion.

**Table 2: Aggregate reactivity classification in accordance with RTA T363 [7]**

Mortar Bar Expansion in 1M NaOH (80°C) [%]		Classification
10 days	21 days	
< 0.10*	< 0.10*	Non-reactive
< 0.10*	≥ 0.10*	Slowly reactive
≥ 0.10*	(much greater than) >> 0.10*	Reactive

\* For naturally occurring fine aggregates the limit is 0.15%

The non-mandatory appendix in ASTM C1260 provides guidance to the interpretation of test results with the following expansion limits: 14-day expansions of less than 0.10% to be indicative of “innocuous” behaviour whereas 14-day expansions of more than 0.20% are indicative of “potentially deleterious” expansion. Aggregates with 14-day expansion between 0.10% and 0.20% are known to be either innocuous or deleterious in field performance, and supplemental information in the form of petrographic examination or identification of alkali reaction products in specimens after tests, or field service record can be used in the assessment of the performance. It is noted in the same appendix that some granitic gneisses and metabasalts have been found to be deleteriously expansive in field performance, even though, their expansion in the test was less than 0.10%.

**Table 3 Comparison of ASTM and AS mortar bar expansion limits**

Interpretation	ASTM C1260		AS 1141.60.1	
	14 days	Classification	10 days	21 days
Innocuous	< 0.10%	Non-reactive	-	< 0.10%
Uncertain	0.10 to 0.20%	Slowly reactive	< 0.10%	< 0.30%
Potential deleterious	≥ 0.2*%	Reactive	≥ 0.10% or	≥ 0.30%

ASTM C1260 performance limits are compared with the Australian Standard AS 1141.1 limits in **Table 3**. The AS 1141.60.1 classifies aggregates with 21-day expansion below a lower limit of 0.10% to be non-reactive, and those with 10-day expansion equal or greater than the lower limit of 0.10% or 21-day expansion equal or greater than the upper limit of 0.30% to be reactive. For aggregates with 10-day expansion below the lower limit of 0.10% but 21-day expansion equal to or exceeding the lower limit of 0.10% but not exceeding the upper limit of 0.30% to be a “slowly reactive” aggregate. Note that the lower limit applicable to natural sand is 0.15%.

## 2.2 Concrete prism method (CPT)

The non-mandatory ASTM appendix states that an aggregate might reasonably be classified as potentially deleteriously reactive if the average expansion of three concrete specimens is equal to or

greater than 0.04% at one year. CSA indicated similar 0.04% expansion for determining ASR however, compared to the non-mandatory ASTM approach CSA has a more definitive approach (ASTM C1293 [13], CSA A23.2-27A-02 [15]). It is also suggested in CSA A23.2-28A-02 that the amount of pozzolan or slag used in combination with an aggregate is at least the minimum needed to prevent excessive expansion in field concrete if the average expansion is less than 0.04% at two years [16]. Similarly, the Standard ASTM C1293 confirmed the two years test duration.

In Australia, AS 1141.60.2 uses essentially the same concrete mix proportion and test method as the ASTM C1293 but classifies an aggregate with a prism expansion of less than 0.03% at 52 weeks as “non-reactive” and an aggregate with a prism expansion equal to or greater than 0.03% at 52 weeks as “potentially reactive”. The lower expansion limit is considered more conservative as it was adopted from the RMS T364 which tests concrete with a higher adjusted cement alkali of 1.38% of Na<sub>2</sub>Oeq equivalent. For mitigation, the standard does not state any particular limit but refer to classification contained in the supply agreement.

### 2.3 Hierarchy of test methods

There has been no agreed hierarchy of the two Australian Standard test methods. RMS T363 noted that some glassy basalt may cause excessive mortar bar expansion, due to the production of fine glassy particles in the fine aggregate grading required for mortar bars. The reactivity of coarse aggregate of the same source needs to be verified, because the glassy phase within compact coarse basalt aggregates may not be accessible to alkali and may not cause excessive concrete expansion. Concrete prism tests in accordance with RMS T364 or concrete block tests may be required for this purpose.

## 3. Australian and International Research

### 3.1 Consistency of AMBT & CPT reactivity classification

#### 3.1.1 Improved AMBT performance limits in AS 1141.60.1

**Table 4** presents alkali-silica reaction data from the investigation conducted by Stark [17]. ASTM C1260 limits were applied to check the potential alkali-silica reactivity of aggregates within two weeks. According to the ASTM C1260 limits, aggregates showing 14-day expansions exceeding 0.1% should be classified as being potentially deleterious aggregates and were labelled “reactive” in **Table 4**. Moreover, aggregates that showed 14-day expansions lower than 0.1% were classified as “innocuous”.

**Table 4 Comparison of ASTM and AS mortar bar expansion**

ID	Rock type	Field Performance	Expansion			ASTM 1260	AS 1141.60.1
			10 Days	14 Days	21 Days		
1	Granitic Volcanic	Reactive	0.713	0.867	1.035	Reactive	Reactive
2	Granitic Volcanic	Reactive	0.375	0.424	0.5	Reactive	Reactive
3	Argillite	Reactive	0.354	0.418	0.511	Reactive	Reactive
4	Chert, Quartzite	Reactive	0.328	0.409	0.515	Reactive	Reactive
5	Chert, Quartzite	Reactive	0.246	0.314	0.416	Reactive	Reactive
6	Granitic Gneiss	Reactive	0.239	0.309	0.385	Reactive	Reactive
7	Quartzite	Reactive	0.17	0.225	0.312	Reactive	Reactive
8	Chert, Quartzite	Reactive	0.116	0.177	0.27	Uncertain	Reactive
9	Chert, Quartzite	Reactive	0.073	0.106	0.142	Uncertain	Slow-Reactive
10	Granitic Gneiss	Reactive	0.065	0.096	0.132	Innocuous	Slow-Reactive
11	Granitic Gneiss	Reactive	0.064	0.086	0.124	Innocuous	Slow-Reactive
12	Metavolcanics	Reactive	0.052	0.082	0.115	Innocuous	Slow-Reactive
13	Limestone	Innocuous	0.029	0.026	0.035	Innocuous	Innocuous
14	Dolomite	Innocuous	0.066	0.066	0.077	Innocuous	Innocuous
15	Gabbro	Innocuous	0.029	0.044	0.066	Innocuous	Innocuous
16	Mixed Siliceous	Innocuous	0.181	0.278	0.329	Reactive	Reactive
17	Gabbro	Innocuous	0.061	0.075	0.157	Innocuous	Slow-Reactive

The last column demonstrates the interpretation of the results based on the Australian Standard criteria. As can be seen, the AS 1141.60.1 limits provided a significantly better understanding of the

aggregate performance. ASTM C1260 failed to provide the correct interpretation for the performance of aggregates No 8 to 12. However, the Australian Standard criteria showed the reactivity of those aggregates and classified them as “reactive” or “slow-reactive”. Overall, the ASTM C1260 limit failed to classify 6 aggregates correctly out of the total 17 tested aggregates (aggregate identification 8-12 and 16). On the contrary, the Australian limits failed to provide a correct performance only for two aggregates (identification 16 and 17). From the given data, it can be seen that the Australian limits provided a more accurate understanding of the aggregates ASR performance.

**Table 5** presents another set of data from the research conducted by Touma in The University of Texas at Austin [14]. Datasets presented in **Table 5** includes mortar and concrete expansion test in accordance with the ASTM C1260 and C1293, respectively. Tests were conducted to evaluate 15 types of aggregates while the field performances of aggregates were known. As can be seen from **Table 5** the ASTM C1260 (mortar test) failed to provide the correct interpretation for the performance of aggregates (8, 9, 10, 12 and 14). However, the Australian Standard criteria indicated a correct reactivity performance for some of those aggregates and classified them as “reactive” or “slowly-reactive”. Overall, the ASTM C1260 limit failed to classify 6 aggregates correctly out of the total 15 tested aggregates. In contrast, the Australian limits failed to provide a correct performance for only two aggregates (12 and 14). From the given data it is concluded that the Australian limits for mortar test provide a more reliable understanding of aggregates ASR performance.

**Table 5 Comparison of ASTM and AS mortar bar and concrete prism expansion**

ID	Aggregate	Expansion [%]				Field Performance	Classification			
		Mortar		Concrete			ASTM C1260	AS 1141.60.1	ASTM C1293	AS 1141.60.2
		11-day	14-day	21-day	52-week					
1	Rhyolite	0.21	0.24	0.31	0.073	Reactive	Reactive	Reactive	Reactive	Reactive
2	Rhyolite	0.27	0.29	0.34	0.107	Reactive	Reactive	Reactive	Reactive	Reactive
3	Quartzite, sandstone, limestone	0.75	0.79	0.89	0.379	Reactive	Reactive	Reactive	Reactive	Reactive
4	Rhyolite, andesite	0.83	0.91	1.04	0.411	Reactive	Reactive	Reactive	Reactive	Reactive
5	Argillite	0.28	0.31	0.39	0.085	Reactive	Reactive	Reactive	Reactive	Reactive
6	Pink granite, quartz, chert	0.23	0.28	0.39	0.051	Reactive	Reactive	Reactive	Reactive	Reactive
7	Quartz, chert	0.19	0.26	0.40	0.043	Reactive	Reactive	Reactive	Reactive	Reactive
8	Feldspar, quartz, chlorite	0.09	0.11	0.16	0.046	Reactive	Uncertain	Slowly-Reactive	Reactive	Reactive
9	Quartz, granitic rock	0.11	0.15	0.25	0.040	Reactive	Uncertain	Reactive	Reactive	Reactive
10	Quartzite, pyroxene, sericite	0.14	0.17	0.24	0.053	Reactive	Uncertain	Reactive	Reactive	Reactive
11	Dolomite	0.02	0.02	0.03	0.022	Innocuous	Innocuous	Innocuous	Innocuous	Innocuous
12	Glacial deposit, shale	0.38	0.25	0.44	0.025	Innocuous	Reactive	Reactive	Innocuous	Innocuous
13	Natural siliceous and glassy	0.18	0.25	0.34	0.060	Reactive	Reactive	Reactive	Reactive	Reactive
14	Natural siliceous	0.20	0.42	0.53	0.022	Innocuous	Reactive	Reactive	Innocuous	Innocuous
15	Rhyolite, andesite	0.33	0.36	0.46	0.064	Reactive	Reactive	Reactive	Reactive	Reactive

### 3.1.2 Consistency of both CPT classifications with field performance

The concrete prism test results for expansion of prisms in 52 weeks showed the ASTM C1293 criterion could accurately decide on the reactivity performance of aggregates. Using the ASTM C1293 0.04% expansion limit, all 15 aggregates were classified correctly regarding their performance. Similarly, the Australian Standard AS 1141.60.2 limit provided correct reactivity performance for all the aggregates. Results showed that there is no difference in the outcome of using the AS 1141.60.2 expansion limit (0.03 expansion over 52 weeks) and the ASTM C1293 expansion limit (0.04 expansion over 52 weeks). In addition, the assessment of data indicated a more reliable outcome for concrete prism test compared to the mortar bar test for both ASTM and the Australian test methods.

### 3.1.3 Relative value of AMBT and CPT methods

It is reported by Lane [18] that alkali-silica reaction has been a major cause of the deterioration for several concrete structures in Virginia. Lane examined the occurrence of the reaction in several Virginian structures. **Table 6** summarised the reactivity performance for the 13 aggregates. As can be

seen the aggregate evaluation based on the ASTM C1260 provided a correct decision on reactivity of some of the aggregates.

**Table 6 Comparison of ASTM mortar bar expansion and field performance**

ID	Rock Type	Field Performance	Expansion 14 Days	ASTM 1260
1	Dolomitic Limestone	Undetermined	0.23	Reactive
2	Argillaceous Dolomite	Innocuous	0.09	Innocuous
3	Diabase	Innocuous	0.13	Reactive
4	Quartzose Sand	Undetermined	0.09	Reactive
5	Quartzose Gravel	Undetermined	0.12	Reactive
6	Quartzose Sand	Reactive	0.19	Reactive
7	Quartzose Gravel	Reactive	0.32	Reactive
8	Metarhyolite	Reactive	0.39	Reactive
9	Qartzite	Undetermined	0.30	Reactive
10	Acrch Marble Calc Chist	Reactive	0.17	Reactive
11	Granite Gneiss	Suspected	0.17	Reactive
12	Granite Gneiss	Reactive	0.07	Reactive
13	Greenstone Metabasalt	Reactive	0.08	Reactive

Except for aggregate No 3 there is no disagreement between the field performance and ASTM C1260 mortar test results. For some aggregates with unknown field performance, ASTM C1260 classified them as “reactive”. However, the only notable drawback from the ASTM C1260 test is that it is significantly conservative and as can be seen from **Table 6** ASTM C1260 labelled performance of the most unknown aggregates as “reactive”.

The National Aggregate Association (NAA) performed the ASTM C1293 and ASTM C1260 tests on several aggregates. Results of this testing program was reported by Touma [14]. As can be seen from the listed results in **Table 7** there is no strong correlation between the outcome of ASTM C1260 and C1293. For 12 aggregates, results of ASTM C1260 test could not confirm the evaluation of ASTM C1293. In addition, for 8 aggregates there is a conflict between ASTM C1260 and C1293 interpretation. It is noted that the interpretation of test results at 14 days resulted in a conservative interpretation and led to labelling several aggregates as “reactive”. In addition, except for one aggregate (aggregate No 14), all other results showed that there is no difference in the outcome of using the AS 1141.60.2 expansion limit (0.03% expansion over 52 weeks) and the ASTM C1293 expansion limit (0.04% expansion over 52 weeks). It can be noted that the lower expansion limit based on the Australian CPT method did not make difference in the interpretation of the test results.

**Table 7 Comparison of ASTM and AS mortar bar and concrete prism expansion**

ID	Rock type	Expansion [%]		Classification		
		Mortar 14 days	Concrete 1year	ASTM C1260	ASTM C1293	AS 1141.60.2
1	Limestone	0.252	0.083	Reactive	Reactive	Reactive
2	Siliceous, Dolomite	0.227	0.009	Reactive	Innocuous	Innocuous
3	Dolomite, Siliceous	0.159	0.020	Uncertain	Innocuous	Innocuous
4	Limestone	0.285	0.015	Reactive	Innocuous	Innocuous
5	Limestone	0.335	0.070	Reactive	Reactive	Reactive
6	Siliceous	1.061	0.196	Reactive	Reactive	Reactive
7	Limestone	0.041	0.016	Innocuous	Innocuous	Innocuous
8	Siliceous	0.210	0.012	Reactive	Innocuous	Innocuous
9	Siliceous	0.139	0.018	Uncertain	Innocuous	Innocuous
10	Siliceous	0.250	0.012	Reactive	Innocuous	Innocuous
11	Siliceous	0.678	0.026	Reactive	Innocuous	Innocuous
12	Siliceous	1.072	0.016	Reactive	Innocuous	Innocuous
13	Siliceous	0.080	0.008	Innocuous	Innocuous	Innocuous
14	Dolomite, Limestone, Siliceous	0.154	0.038	Uncertain	Innocuous	Reactive
15	Siliceous	0.279	0.007	Reactive	Innocuous	Innocuous
16	Siliceous	0.316	0.005	Reactive	Innocuous	Innocuous

A research conducted by Berube [19] showed that even though the AMBT test was capable of detecting numerous of reactive aggregates, it was too severe for many aggregates that have performed well when tested using the concrete prism method and that have performed well in the field. Accordingly, it is stated that the ASTM C1260 should not be applied for rejecting aggregates.

### 3.1.4 Effect of different performance limits in AS 1141.60.2 and ASTM C1293

Test results from Berube [19] investigation are presented in **Table 8**. It can be seen that the ASTM C1293 CPT could accurately predict the field performance of reactive aggregates. In addition, except for one aggregate (aggregate identification 9) there is no conflict between the interpretation of AS 1141.60.2 and ASTM 1293. This outcome confirm the fact that the AS 1141.60.2 lower limit provides no difference in the interpretation of test results.

**Table 8 Comparison of ASTM (CSA) and AS mortar bar and concrete prism expansion**

ID	Aggregate type	Field performance	Expansion [%]		Classification		
			AMBT 14 days	CPT 52 weeks	ASTM 1260	ASTM 1293	AS 1141.60.2
1	Andesite	Innocuous	0.26	0.02	Reactive	Innocuous	Innocuous
2	Anorthosite	Innocuous	0.04	0.02	Innocuous	Innocuous	Innocuous
3	Basalt	Innocuous	0.03	0.01	Innocuous	Innocuous	Innocuous
4	Charnockite	Innocuous	0.02	0.01	Innocuous	Innocuous	Innocuous
5	Hornfel	Innocuous	0.22	0.02	Reactive	Innocuous	Innocuous
6	Hornfel	Innocuous	0.23	0.01	Reactive	Innocuous	Innocuous
7	Diorite	Innocuous	0.02	0.01	Innocuous	Innocuous	Innocuous
8	Gabbro	Innocuous	0.20	0.02	Uncertain	Innocuous	Innocuous
9	Granitic gneiss	Innocuous	0.05	0.03	Innocuous	Innocuous	Reactive
10	Granite	Innocuous	0.02	0.01	Innocuous	Innocuous	Innocuous
11	Greywacke	Innocuous	0.19	0.02	Uncertain	Innocuous	Innocuous
12	Greywacke	Innocuous	0.20	0.01	Uncertain	Innocuous	Innocuous
13	Potsdam sandst	Reactive	0.07	0.07	Innocuous	Reactive	Reactive
14	Phonolite	Innocuous	0.02	0.02	Innocuous	Innocuous	Innocuous
15	Quartzite	Innocuous	0.01	0.01	Innocuous	Innocuous	Innocuous
16	Chloritic schist	Reactive	0.19	0.05	Uncertain	Reactive	Reactive
17	Siliceous shale	Reactive	0.34	0.09	Reactive	Reactive	Reactive
18	Syenite	Innocuous	0.01	0.01	Innocuous	Innocuous	Innocuous
19	Rhyolitic tuff	Reactive	0.35	0.25	Reactive	Reactive	Reactive
20	Rhyolitic tuff	Reactive	0.25	0.09	Reactive	Reactive	Reactive
21	Rhyolitic tuff	Reactive	0.27	0.05	Reactive	Reactive	Reactive
22	Granitic sand	Innocuous	0.02	0.01	Innocuous	Innocuous	Innocuous
23	Lithic gravel/sand	Innocuous	0.26	0.02	Reactive	Innocuous	Innocuous
24	Carb sandstone	Innocuous	0.12	0.02	Uncertain	Innocuous	Innocuous

**Figure 1** is plotted based on the shown data in **Table 8**. It shows the effectiveness of the CPT results compared to AMBT results. CPT recognised most of the known reactive aggregates (aggregates 13, 16, 17, 19, 20 and 21 are reactive based on field performance), however, it did not misclassify other “innocuous” aggregates as “reactive”.

it can be seen that the AMBT has a conservative and incorrect interpretation for some aggregates such as No 1, 5, 6 and 23 which resulted in classifying these aggregates as “reactive”, while they are not reactive. On the other hand, the grey highlighted area of **Figure1** implies that most of the aggregates classified “uncertain” were “innocuous”, except for aggregate 16. Moreover, aggregate 13 labelled innocuous by AMBT test while it is a reactive aggregate based on field performance and CPT results. Although AMBT is not a time-consuming test compared to the CPT, it is a good measure only for highlighting the innocuous aggregates. AMBT is conservative and due to the aggressive nature that this test has, it labels some innocuous aggregates as “reactive” or “uncertain”, accordingly, no aggregate is suggested to be rejected by this test. It is suggested that the complementary CPT data

could provide a more reliable understanding of aggregates reactivity. Another shortcoming of the ASTM AMBT test is the 14-day limits. These limits could not provide any clear classification for several numbers of aggregates. In that case, other testing methods such as CPT or field data would be required for a reliable decision-making.

**Figure1: CPT vs AMBT test results [19]**

Ideker et al. [10] recently reported expansion data of ASTM C1260, ASTM C1293 and exposure concrete blocks made from 8 fine aggregates and 17 coarse aggregates as presented in **Table 9**. The mortar bar and concrete prism results were calibrated to those obtained from the large 710x380x380 mm concrete blocks exposed outdoor at the University of Texas in Austin.

**Table 9 Comparison of ASTM, AS, and exposure block results**

ID	Mineralogy	Expansion [%]			Classification			
		AMBT 14-day	CPT 1-year	Field block Exposure <sup>2</sup>	ASTM 1260	ASTM 1293	AS 1141.60.2	Field Exposure
F1'	Mixed quartz/chert/feldspar	0.64	0.586	1.239	Reactive	Reactive	Reactive	Reactive

<sup>1</sup> F= Fine aggregates and C= Coarse aggregates, <sup>2</sup> Na<sub>2</sub>O<sub>eq</sub>=1.25%

It was found that the AMBT was a good indicator of reactivity of some aggregates. However, the concrete prism test could provide a more reliable evaluation of the most aggregates. In some cases, the results from the CPT disagreed with those from the AMBT. Ideker indicated that in no reported cases of deleterious expansion in the field, concretes containing aggregates that have passed the ASTM C1293 [10]. This evidence supports the better correlation between the reactivity diagnosed by CPT and reactivity in field exposure.

It is possible to re-evaluate the expansion data based on the performance criteria recommended in AS1141.60.2. It was found that except for aggregate F5, the proposed AS1141.60.2 would have classified all aggregate in a similar classification. However, the lowering of the CPT limit from 0.04% to 0.03% would have made no difference to the prediction. The results do not support the use of the lower 0.03% limit in the draft AS1141.60.2. They also show the exposure blocks to be a very useful calibration tool for the laboratory test methods.

### 3.2 Australian (AS) classification

In Australia, Shayan [20] tested five Australian aggregates with field evidence to be slowly-reactive using two accelerated mortar bar test methods. The ASTM C1260 classes them as non-reactive or uncertain while the RTA T363 correctly classified such aggregates as slowly-reactive aggregates. It was suggested that the Australian acceptance limit of <0.1% expansion at 21 days of storage in 1 M NaOH solution at 80°C be adopted by ASTM C1260 or that its 14-day expansion limit be lowered from 0.10% to 0.08%. The 300mm cube blocks showed large expansion or map-cracking usually after more than 1 year of exposure.

**Table 10** Summary of data from Shayan [20]

Structure	Prism Expansion after 1 year	Comments
Australian Railway sleepers. Gneissic granite rocks which produced about 0.10% expansion at 21 days in the AMBT	Prism in 50°C in water 0.06% with 1.4% alkali 0.09% with 1.9% alkali	300mm cube Block in 50°C in water 0.12% with 1.4% alkali 0.18% with 1.9% alkali
Canning dam, WA. Gneissic granite rocks	Just >0.05%	Blended cements: 44%HVFA, 42%FA/4.2%SF triple blend shown to reduce expansion below 0.04%.
Dam 1 gneissic quartz gravel. Tests conducted on 3 reactive quartz gravels No 1-3	No 1 just < 0.03% No 2 & 3 well < 0.03% RTA T363 classified aggregate No 1-3 as reactive.	Aggregate No 1 blocks in 38°C in water showed low expansion at 1 year but increased significantly at 2 years.
Dam 2 gneissic granite containing strained and microcrystalline quartz.	No CPT results.	Reactive aggregate as tested by RTA T363.
Dam 3 phyllite aggregate UY	Prism 0.019% at 1 year	410kg/m <sup>3</sup> cement with 1.76% alkali Block 0.117% at 1 year

Accordingly, the one-year concrete prisms test duration might not be enough for classifying the aggregates and may need to be extended. Results of the prism tests and field performance are summarised in **Table 10**. Using supplementary cementitious materials (SCMs) in mix designs is a common practice nowadays. It is important to take into account that the ASTM C1293 recommended the extension of the CPT duration to two years when SCMs are applied for mitigating the ASR. The two years test duration provides a more reliable time framework for evaluating the effect of the mitigation on slowly-reactive or reactive aggregates. This duration is supported by the observations of Shayan [20].

### 3.3 Slowly reactive aggregates

The term “slowly-reactive aggregate” has been introduced since 90s and is extensively used through literature [7,17,19–26]. However, lack of an existing appropriate test method or test limits for detecting ASR is observed throughout previous studies. It is significantly important to apply a reliable ASR test method, which can provide expansion limits for classification of aggregates as “non-reactive”, “slowly reactive” or “reactive” [20].

Some studies have shown the field evidence regarding the inability of ASTM 1260 14-day limit (expansion greater than 0.10%) for detecting slowly-reactive aggregates [27]. The failure in detecting slowly-reactive aggregate could cause serious damage to concrete structures in the long-term. In Australia, it is reported that meta-basalts or granitic gneisses cause serious damage to major structures [20]. In addition, studies in the United States showed that the slowly reactive aggregates could pass the existing AMBT tests but result in failure in field structures. These aggregate mostly included quartzites, gneisses, and schists [17]. For this reason, the AMBT test needs to be revised when slowly reactive aggregates are tested [28].

The proposed procedure should be rapid, requiring preferably not more than 28 days. Also the procedure should reliably discriminate between innocuous and slowly reactive as well as highly reactive aggregates [17]. In one study, it is recommended to extend the AMBT test duration up to 90 days and with the expansion limit of 0.20% to correctly classify the slowly-reactive aggregates [28]. Another suggested method is amongst the RILEM methods particularly the AAR-4 reactor method, which claimed to be as the proper method for identifying the reactivity of the slowly-reactive aggregate [23].

The Standard AS 1141.60.1 applies new limits to detect the “slowly-reactive” aggregates. The current CCAA research found a number of aggregates as “slowly-reactive”. The clear limits of AS 1041.60.1 classified these aggregate “slowly-reacted” instead of classifying them as “uncertain”. The slowly reacted aggregates can be utilised in concrete production while the proper ASR mitigation such as addition of SCMs to mix design is selected. In the case of slowly-reacted detection, it is suggested by this paper that the mitigation solution be tested by conduction the AS 1141.60.2 over the period of 2 years. This suggestion is supported by literature as it shown the CPT test could provide a more reliable indication of the performance of aggregates and the two years duration of testing will determine if the applied mitigation is effective to control the prism expansion to lower than 0.03%.

The test results proved that the proposed limits could distinguish between some innocuous and slowly-reactive aggregates. The Australian test method limits will enable the designer and concrete producer to distinguish slowly-reactive aggregates and safely use them in mix design by including the appropriate mitigation strategy. This approach is more efficient in term of asset management and provides a wider access to resources (local aggregates), which guarantees the more sustainable production of concrete. It is suggested by this research that the Australian test framework needs to provide an agreed hierarchy of the two Australian Standard test methods. This can help resolving issues when there is a conflict between the test results AS 1141.60.1 AMBT and AS 1141.60.2 CPT classifications.

#### **4. Conclusions**

Evaluation of the international and Australian test results by the Australian mortar bar (AS 1141.60.1) and concrete prism (AS 1141.60.2) tests support the reliability of both tests for determining the alkali-silica reactivity (ASR) of most aggregates and can be actively used by local industry.

Both the Australian and the ASTM mortar bar tests are quick and reliable means for determining non-reactive (innocuous) aggregates. However, the evaluation procedures of these test methods were found to be conservative and should not be applied for rejecting aggregates. In addition, international data for aggregates with known field reactivity showed that the Australian 1141.60.1 AMBT evaluation procedure is more reliable compared to the ASTM 1260 14-day limits.

Literature showed that the concrete prism test (CPT) has a better correlation with the performance of aggregates in field. The majority of international data showed that for cases which there are conflicts between AMBT and CPT classifications, the recommended approach was to accept the CPT test results. In addition, literature indicated that the 1-year expansion duration may not be sufficient, especially if supplementary cementitious materials (SCMs) are used for mitigating the ASR. In this case, it is suggested to extend the duration concrete prism testing up to two years in AS 1141.60.2

CPT test results indicated that there is no conflict between the Australian and ASTM CPT classifications. Although the Australian test procedure applies the lower 1-year expansion limit of 0.03%, however, there is no significant change observed in the outcomes of the both procedure. For this reason, it is suggested that the selected 1-year expansion limit of 0.03% may be increased to 0.04%.

There is a need for an extensive examination of available Australian and International data so that an agreement can be reached on the hierarchy of the two Australian Standard test methods. This can help resolving issues when there is a conflict between the AS 1141.60.1 AMBT and AS 1141.60.2 CPT classifications.

# Mechanical properties of mortar with oil contaminated sand

Rajab M. Abousnina\*, Allan Manalo, Weena Lokuge

Faculty of Health, Engineering and Sciences, University of Southern Queensland, Toowoomba, QLD  
4350, Australia

**Abstract:** The use of oil-contaminated sand in construction is now being considered as an alternative and cost effective remediation method to minimize its adverse effect in the environment. In this study, the effect of oil contamination on the mechanical properties of mortar under two different mixing methods and three different w/c ratios 0.4, 0.5 and 0.6 were investigated. Three different percentages of crude oil contamination (0, 2 and 10%) were considered. Similarly, the mortar was prepared using two mixing methods, i.e (i) cement is mixed with water first before sand is added (CWS) and (ii) cement and sand was mixed first before adding water (CSW) to examine its effect on the compressive strength. The results indicated that the oil contamination affects the compressive strength of mortar. While the compressive strength of 0 and 2% oil contamination is almost the same, a 25% of compressive strength reduction was obtained for 10% crude oil contamination. On the other hand, CWS provided higher compressive strength than the CSW mixing method under different crude oil content. These results show the importance of mixing method especially for mortar with sand with high percentage of crude oil contamination. While the optimum compressive strength was observed with w/c of 0.5 compared to 0.4 and 0.6. Furthermore, the results indicated that oil contaminated sand has the potential for use in construction application.

**Keywords:** Mixing, Compressive strength, Mortar, Contamination and Crude oil

## 1. Introduction

Oil contamination can adversely affect the ecosystem and contaminate ground water resources [1]. Moreover, the physical and chemical properties of the surrounding sand change as soon as they come into contact with crude oil [2]. To minimize its effect to the environment, a range of remediation methods for sand contaminated with oil have been implemented but the cost of these methods is prohibitive especially in developing countries [3]. Hence, a better and more cost-effective way of remediating oil contaminated sand is warranted. Several researchers [4-8] mixed the oil contaminated sand with cement and then use this mixture in construction as an alternative and cheap remediation method. While this approach is considered to be a clever and successful civil engineering solution in terms of cost and reducing the environmental impact; very limited studies have been conducted to investigate the properties of contaminated sand and its concrete in order to substantiate their beneficial use in construction.

The compressive strength of hardened concrete which is generally considered to be an index of its important mechanical properties, depends upon many factors, e.g. quality and quantity of cement, water cement (wc) ratio and aggregates; batching and mixing; placing, compaction and curing. Out of these factors mixing and wc ratios are considered as one of the most important factors that affects the compressive strength of concrete [9]. The workability of freshly mixed concrete is required for proper in practice and the hardened concrete needs to be durable in order to obtain a specific compressive strength [10]. The main purpose of a concrete mix design is to attain a workable concrete that meets a specific strength. Jézéquel and Collin [11] indicated that the compressive strength of concrete varies much based on the consistency achieved through mixing. Therefore, inability to achieve the design or required strength in concrete will have adverse effect on the structural behavior of the member that it will be used in.

Generally for any type of concrete, most literature recommends mixing the concrete until the mix is consistent and uniform in nature based on physical observation. For instance, ASTM C305 – 14 [12] and AS 2350 12-2006 [13] gives fine details on the procedure for preparation of mortar which includes “pouring water into bowl and, with the mixer in the operating position, add the cement to the middle of the

bowel then add the entire quantity of sand slowly". Based on ASTM C305 – 14 and AS 2350 12-2006 standards, cement needs to be mixed with water before sand is introduced, whereas, AS 1012.2:2014 [14] and ASTM C192/C192M-14 [15] give the details on the preparation of concrete mixes and curing concrete respectively. AS 1012.2:2014 and ASTM C192/C192M-14 standards recommend mixing the dry ingredients first (cement, fine aggregates, and coarse aggregates) when these materials are thoroughly blended water can then be introduced to the dry mix until the concrete is homogeneous in appearance and has the desired consistency. This recommendation of mixing priority, i.e, cement and water then sand (CWS) or cement and sand then water (CSW) may not significantly affect the compressive strength for a normal concrete mix. However, when oil contaminated sand is used; the mixing procedure may play an important role and affect the compressive strength of the prepared mortar or concrete due to the presence of crude oil which reduce or inhibit the hydration processes. Hence, two different mixing methods were considered to determine its effect on the compressive strength of the mortar mix. In practice, CWS mixing procedure was compared with that of CSW.

On the other hand, the ratio of water and cement is an important factor in concrete production because it affects the fresh and hardened properties of concrete. The wc ratio is directly related to the spacing between the particles of cement in the cement paste, such that the smaller the spacing the faster cement hydrates fill the gaps between the particles and the links between hydrated particles grow stronger and form a stronger concrete [16]. In this regard, the effect of the wc ratio on the compressive strength of mortar containing light crude oil is also investigated. Three different water cement ratios, 0.4, 0.5, and 0.6 under different contents of crude oil content (0, 2 and 10%) are prepared and tested. It is anticipated that the results of this study will give a better understanding on the effect of mixing methods and wc ratios for properties of mortar using oil contaminated sand, in order to evaluate its suitability as an alternative concrete materials for building and construction.

## **2. Experimental program**

### **2.1 Preparation of oil contaminated sand**

Air dried fine sand; with particle size less than 2.36 mm was used due to its similarity to sand in the Libyan Desert where the first author came from. On the other hand, mineral Fork w2.5 motor cycle oil was used because its density and viscosity are similar to light crude oil [17, 18]. The samples were prepared by mixing dry sand with two different percentages of light crude oil (2 and 10 %) by the weight of dry sand. In addition, uncontaminated (0%) sand was prepared as a control sample. These percentages were selected based on the previous results of this ongoing project on the mechanical properties of sand contaminated with oil [19]. The oil was mixed manually with the dry sand and then the samples were placed inside a plastic container for 72 hours to allow the mixture to attain a homogenous condition. A lid was placed on the plastic container to prevent the crude oil from evaporating during this period of incubation.

### **2.2 Preparing, casting and curing**

All laboratory work was conducted at a room temperature around 22°C. The specimens were de-molded after 24 hrs and were cured in in a fog room up to 28 days at a temperature of 25°C and 85% humidity. Figure 1 shows the protocol of sample preparation based on the AS 2350.12 [2006].

The composition of the mortar was based on AS 2350.12-2006 [13] with mix proportions of 1 part cement and three parts sand (by mass).

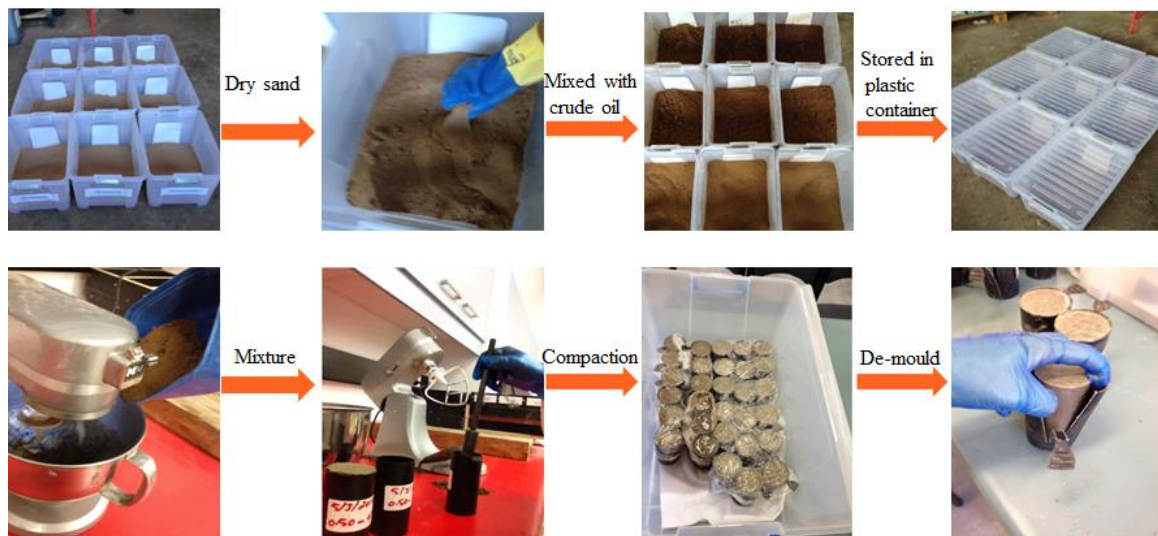

Figure 1: Sample preparation protocol.

### 2.3 Compressive Strength Test

Compressive strength tests were carried out for all the specimens after 28 days of curing. The specimens were tested to failure using a loading rate of 1.5 kN/min using 2 Channel Automatic Cube and Cylinder Compression Machine CT340-CT440 as shown in Figure 2(ab). The compressive strength of the samples was calculated by dividing the failure load by the actual cross sectional area. Both ends of the cylindrical specimens were ground before being placed in the testing machine mainly to smooth their cross sectional surface areas also the rubber capping was used to apply the load uniformly to the specimens as shown in Figure 2(c).

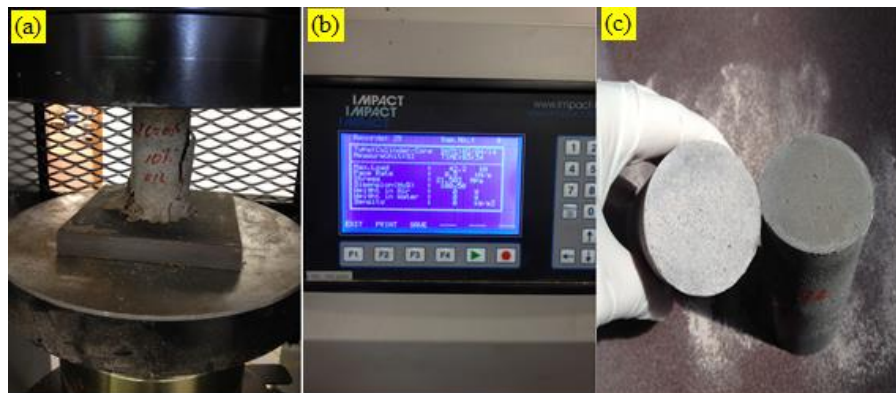

Figure 2: Compressive strength machine

## 3. Results and discussions

### 3.1 Effect of light crude oil on the flow

The flow table test was conducted based on the (ASTM C1437-07) as shown in Figure 3. The flow test results of the 0, 2 and 10% of crude oil contamination were 140mm, 147mm and 160mm respectively. Increasing the crude oil content increases the workability which indicates that the crude oil works as a plasticizer agent. This agreed with a previous study [20], which concluded that the oil acted like a chemical plasticizer and improved the fluidity and doubled the slump of the concrete mix, while maintaining its compressive strength. Furthermore, the increase in flow for mixes containing light crude oil is a similar outcome of the other studies by Hamad, Rteil and El-Fadel [7] and Nuruddin, Shafiq and Beddu [21]. In addition, Al-Mutairi [22] indicated a good effect with regard to slump of concrete made from oil contaminated sand.

Figure 3: Flow values for mixes containing deferent percentage of light crude oil

### 3.2 Effect of mixing method on compressive strength

The compressive strength of mortar mixes after 28 days are shown in Figure 4, where two different mixing methods and three different percentages of oil contaminated sand were investigated. In general, results indicate that the compressive strength of cylinders is higher when CWS mixing method was used compared to CSW mixing method. Nevertheless, it can be seen that there was an insignificant variation between the two mixing methods with the uncontaminated sample. The compressive strength between the two mixing methods was only 0.1 MPa, but when the content of crude oil was increased to 2%. A higher compressive strength by 5.4 MPa was obtained using CWS mixing method. Similar results were obtained by increasing the content of crude oil to 10%, and the compressive strength increased by 5 MPa when cement was first mixed with water and then contaminated sand was introduced CWS; this indicated that the mixing method has a significant effect on the compressive strength of concrete when contaminated sand is used. Mixing cement with contaminated sand first may affect or inhibit hydration due to the presence of crude oil.

Figure 4: Compressive strength as a function of crude oil content.

Hydration is the process by which cement and water react together [23]. Mortar sets when solid particles in the mix, mainly ettringite and calcium silicate hydrates, become weakly connected by the hydration reactions. Contaminate sand with a high percentage of oil may have affected hydration. Figure 5 shows the contaminated sand with cement just before mixing it with water following the CSW. By increasing the content of crude oil it can be seen that the oil has merged into the cement, which may decrease the reaction between the cement and water and reduce the compressive strength, unlike the CWS mixing method which decrees that cement should be first mixed with water, and then sand.

Figure 5: Oil contaminated sand mixed with cement

### 3.3 Effect of w/c ratio on the compressive strength

Figure 6 shows the effect of the water cement ratio on the compressive strength of mortar containing two different crude oil contaminations 2 and 10% and the uncontaminated sand (0%). Three different water cement ratios were investigated 0.4, 0.5, and 0.6. Disregarding the uncontaminated sample it can be seen that increasing the crude oil content from 2 to 10% decreases the compressive strength under the three different w/c ratios used. The reduction in the compressive strength of mortar when the crude oil content increased from 2 up to 10% agreed with the results of previous studies [24, 25]. Nevertheless the compressive strength of mortar under different w/c ratios with sand contaminated by 2% oil was higher than that for the mortar with uncontaminated sand. This result attributed to the degree of wettability caused by adding crude oil to dry sand because increasing its wettability by adding light crude oil decreased the amount of water the sand could absorb. Elsewhere it has been founded by Abousnina et al [19] that uncontaminated fine sand had the highest percentage of water absorption at 2.79%, but this percentage decreased as the amount of crude oil increased. However, water absorption was zero for sand with 2% of contamination and higher; this was due to the sand changing from dry to wet and met the saturated surface dry condition. Thus, all or most of the water added to the mix contacted the cement particles and helped complete the hydration process.

Figure 6: the effect of wc ratios on the compressive strength of mortar containing crude oil

Based on the literature, the effect of the wc ratio on the compressive strength has been studied widely and is very well known [26-28]. The compressive strength decreases with a higher water cement ratio. Of the three wc ratios used in this study, the compressive strength of the mortar mixes was highest with a 0.5 water cement ratio, whereas a water cement ratio of 0.6 caused a significant reduction in the compressive strength of mortar. These results agreed with previous studies [29-31] where it has concluded that increasing the w/c ratio decreased the compressive strength. The compressive strength of the uncontaminated sample of mortar decreased by 6% when a w/c 0.6 compared to the compressive strength obtained when w/c of 0.5 was used. The reduction of compressive strength by adding crude oil content with 2% and 10% was 15.7 and 33.6% respectively. The reduction in the compressive strength that occurred with wc ratio 0.6 compared to a w/c ratio of 0.5 may be due to an increase in porosity because by increasing the water cement ratio, the paste fraction of the mortar becomes increasingly porous and the mortar becomes weaker due to the increased porosity and more permeable because the pores are interconnected [32] which actually agreed with our visual observation showed in Figure 7. In addition to that, based on the visual observation as well as the microscope observation it can be seen that increasing the crude oil content from 2 to 10% increases the pore size and as a consequences the compressive strength decreased accordingly. Furthermore, X. H. Vu et al [33] claimed that the water/cement ratio, upon entering the concrete composition, is a major parameter affecting the porosity and strength of the cement matrix of hardened concrete.

Figure 7: Air voids on the surface of specimens

One of the interesting findings in this study is that the lowest compressive strength was observed at a wc ratio of 0.4. The reduction of the compressive strength compared to w/c ratio of 0.5 under the three percentages of crude oil contamination used 0, 2 and 10% vary with 26.2, 31.0 and 35.7% respectively.

This may rely to the other factors that influence the compressive strength because the relationship between the w/c ratio and the strength of concrete is only approximate because it can be affected by other factors. Neville [34] stated that the influence of the wc ratio on the strength does not truly constitute a law because the wc ratio rule does not include the qualifications needed for its validity. Indeed the strength of concrete at any wc ratio depends on factors such as the degree of hydration of the cement and its chemical and physical properties, the temperature at which hydration takes place, the air content of the concrete, the change in the effective wc ratio, and the formation of cracks due to bleeding. Furthermore, Gilkey [35] stated that for a given cement and acceptable aggregates, the strength that may be developed by a workable, properly placed mixture of cement, aggregate, and water is influenced by wc ratio, and the ratio of cement to aggregate, grading, surface texture etc. This indicates that other parameters can also affect the strength of concrete with different wc ratios.

The wc ratio determines the porosity of the hardened cement paste at any stage of hydration, because it will directly affect the volume of voids in concrete. The wc ratio also influences the porosity of the cement matrix within the hardened concrete [36, 37], which itself heavily influences the durability of concrete. In fact there is a minimum w/c ratio for hydration products to form because there is insufficient space at low wc ratios. For complete hydration the wc ratio should not be below 0.42 by weigh [34]. When w/c 0.4 was used the actual water used was less than this amount due to the use of dry sand. This indicated that the hydration processes was not completed with a w/c ratio of 0.4, which may increase total porosity due to the lack of water in order to complete the hydration process. Furthermore, when a w/c ratio of 0.4 was used the workability was less than with w/c ratios of 0.5 and 0.6, which indicates that removing the air voids is much harder than with more workable mortar. Winter, N [23] stated that workability is an important factor in mortar/concrete because it indicates how easy concrete can be compacted; in other words, how easy all the air voids in the concrete can be removed to achieve maximum density. Obtaining the maximum possible density of a wet mix is important to maximize the strength of the hardened concrete and its resistance to deterioration. This the main reason for the reduction in compressive strength for a WC ratio of 0.4 compared with the w/c ratios of 0.5 and 0.6. As a consequence, reducing the water cement ratio decreases the workability, and hence, higher porosity is expected because all the air voids cannot be removed during compaction and hence, the total porosity will be higher.

#### **4. Evaluation of the suitability of mortar with oil contaminated sand for construction**

The results of the preliminary studies conducted by the authors point towards the sustainable use of fine sand contaminated with light crude oil for construction. Mixing method plays a great role in terms of the compressive strength obtained. The compressive strength of specimens mixed under CWS was higher compared to CSW especially for higher level of oil contamination. For this reason, it is suggested that CWS mixing method should be followed when preparing mortar or cement using sand with oil contamination, i.e. water and cement should be thoroughly mixed first before adding the oil contamination sand. Furthermore, the compressive strength of mortar mixed with contaminated sand 2% of oil contamination is found higher than the uncontaminated samples. However, when the amount of crude oil was increased from 2 to 10%, the compressive strength decreased significantly which may due to oil in the mix hindered the cement from being hydrated. These result indicated that the compressive strength of contaminated sand can be increased more than the uncontaminated sand by adding a certain amount of oil. This indicates that this material is suitable for building and construction. Similarly, the results indicated that even the mortar using fine sand with 10% oil contamination with wc ratio of 0.5 and mixed under CWS can be used because its compressive strength is around 21.5 MPa, which is only 20% lower of uncontaminated sample. In fact, the British standard for precast concrete masonry units (BSI, 1981) requires only a compressive strength of 2.8 and 7 MPa for blocks and bricks, respectively and a minimum compressive strength of 15 MPa is required by the Department of Transport in UK for sub-base and base materials. These results clearly showed the high potential of using oil contaminated sand for construction. Moreover, this remediation method will solve one of the major issues of sand contamination in oil producing but developing countries because the cost of this method is cheaper compared to the existing remediation methods.

#### **5. Conclusion**

This study investigated how mixing methods and water cement ratio affected the compressive strength of mortar containing light crude oil. Based on the results, the following conclusions were drawn:

- The mortar produced by mixing cement and water first before mixing contaminated sand (CWS) produced higher compressive strength compared to CSW mixing method. CWS mixing method gives a high probability that the hydration process would be completed, which is not the case when cement was first mixed with contaminated sand before the addition of water as in the CSW mixing method.
- By increasing crude oil from 2 to 10%, the compressive strength decreased in both the mixing methods as well as the three different w/c ratios used. This result was due to a decrease or reduction in hydration because the cement was coated with oil.
- The optimum water cement ratio occurred with a water cement ratio of 0.5, whereas a w/c ratio of 0.6 increased the porosity while a wc ratio of 0.4 resulted in the lack of water to promote the hydration process and hence, resulted in a lower compressive strength.
- The mechanical properties of mortar with oil contaminated were found suitable for use in building and construction. In fact, the compressive strength of mortar with 10% oil contaminated sand is only 20% lower than that of uncontaminated sample.

**Abstract:** Styrene Butadiene Rubber (SBR), sourced from truck and passenger car tyres retain much of their physical, structural and chemical properties at the end of their life. This has encouraged researchers to consider recycling them in civil engineering applications and to assist with decreasing the detrimental effects of their growing disposal.

This paper reports on the fundamental findings of utilizing SBR granules as a potential source for replacing fine and coarse aggregates in fabricating reinforced concrete components. Elastomeric modified concrete (EMC) beams incorporating 6% and 10% of SBR granules are assessed for their dynamic and mechanical properties compared to control beams devoid of SBR granule additions. The load-deflection and stress-strain relationships are evaluated during the four-point bending test and cyclic test, hysteresis loops are also analyzed for the beams. Dynamic (impact) test was carried out parallel to the four-point bending test. An increase in the energy absorption and damping properties of the EMC beams was observed; while the ductility factor of the control beams remains the highest showing that EMC beams are more resilient than ductile. Addition of SBR granules also prevented the sudden brittle failure of the EMC beams. Such results confirm the feasibility of incorporating SBR granules in concrete structures.

**Keywords:** Styrene Butadiene Rubber, cyclic test, hysteresis loops, ductility and damping.

## 1. Introduction

With an increased awareness of environmental pollution and a reduction in naturally existing resources, sustainable development practices could find a high stage among constructors and governmental decision makers. Civil structures, especially buildings, are among the largest consumers of natural resources such as aggregates, water, and metal. Moreover, the mentioned structures are responsible for a significant portion of greenhouse emissions, especially if they are constructed with the most commonly used construction material: concrete, Chen, Okudan et al. (1). Accumulation of solid waste without any secure market to absorb it, on the other hand, has raised the question of what is the best solution to reduce the significant amount of waste with the minimum usage of other energy resources.

One approach in solving the above issue is to identify wastes suitable for use in the construction industry. This approach is not only a solution to decrease the amount of waste in the natural environment, but it can also be an appropriate and economical option to utilise waste to build more sustainable civil infrastructure.

A number of detected recycling materials, such as waste tyre granules, have shown significant useful properties other than being environmental friendly, which distinguishes them from other construction materials. Therefore, styrene butadiene rubber (SBR) granules sourced from waste tyre has been introduced as a new approach to solve environmental challenges.

Several works have been devoted to the use of rubber particles recovered from waste tyres to replace natural aggregates in concrete mix. Khaloo, Dehestani et al. (2) have exclusively studied the mechanical and physical properties of concrete containing fine, coarse, and combined rubber as a substitute of aggregates. Toutanji (3) studied the effect of the replacement of coarse aggregates with different volume contents of rubber tyre chips (25, 50, 75 and 100%) on the mechanical properties of the EMCs. There are several studies that worked on the concept of the ductility and damping of the members incorporating fibres; for instance in a study by Son, Hajirasouliha et al. (4), the improvement of the deformability of rubber-filled reinforced concrete (RC) columns by making concrete mixes with different strengths and waste tyre particle size and content was examined. Toutanji and Eldin (5) also reported that traditional concrete incorporating rubber particles showed more deformability and ductility in members. Ilker, Bekir et al. (6) in a paper entitled “The properties of rubberised concrete” examined the ductility properties of concrete. In a study by Yan, Jenkins et al. (7), the damping properties of fiber-reinforced concrete were assessed.

Due to the fact that most of the studies were focused on the mechanical and physical properties of EMCs, there is a need for further investigation, such as examining the energy absorption of EMC under dynamic loading. In this study, EMC reinforced beams were made in order to fulfil this need, and also to study the effect of SBR granules on real members.

## 2. Research Program

### 2.1 Styrene Butadiene Rubber (SBR)

The SBR granules used in this study are a general purpose synthetic elastomer, manufactured from a copolymer of styrene and butadiene. These elastomeric granules were sourced from waste passenger and four-wheel drive tyres with the size varying from 1 to 4 mm and 12 to 15 mm. The relative wet density of the SBR granules was determined to be 920 kg/m<sup>3</sup>. Illustrations of the typical small and large SBR granules used in this study are shown in Figure 1 and Figure 2. The 1 to 4 mm SBR granules were used to partially replace blended fine and coarse manufactured sand at proportion of 10%, and the 12 to 15 mm SBR granules were employed to partially replace 10mm and 20mm manufactured coarse aggregates at proportion of 6%.

Figure 1 SBR granules 1-4 millimetres

Figure 2 SBR granules 12-15 millimetres

### 2.2 Mix Materials

The raw materials used in batching of the concrete mixes included shrinkage limited Portland cement (PC), manufactured blended 50/50 fine and coarse sand (BS) as the fine aggregate component, and 10 mm and 20 mm gravel as the coarse aggregate (CA) fraction. In addition, fly ash (FA) sourced from Eraring power station was used as a supplementary cementitious material (SCM) addition to partially replace Portland cement (PC) at 30%. Drinkable grade water conditioned to 23 ± 2 °C was used for all mixes. The physical properties of all aggregates are summarised in Table 1. A high range water-reducing admixture (HWR) was also used to obtain the desired slump of 80 ± 20 mm. For all mixes, a fixed water-to-cementitious-material ratio (w/cm) of 0.35 was employed.

Table 1 Physical Properties of Aggregates

Aggregate Type	Particle Bulk Density (kg/m <sup>3</sup> )	Water Absorption (%)
10 mm CA	2700	1.8
20 mm CA	2710	1.6
Blended Sand	2650	1.2

### 2.3 Specimen Preparation and Testing

The proportioning of aggregates is shown in Tables 2 and 3, respectively. SBR granules were replaced by total mass of aggregates. SBR granules were premixed with other aggregates for 3 min prior to the adding of PC, FA and water. The raw materials were mixed based on the listed test method criteria of AS 1012.2-1994.

**Table 2 Experimental Program**

Mix	SBR Granules (%)		Fly Ash (%)	Blended 50/50 Sand (%)	10mm Coarse Aggregate (%)	20mm Coarse Aggregate (%)	SB Latex (%)
	(1-4 mm)	(12-15mm)					
C1	0	0	0	100	100	100	0
C2F	0	0	30	100	100	100	0
R4SBR6	0	6	30	100	97	97	0
R3SBR10	10	0	30	90	100	100	0

**Table 3 Concrete Mix Proportions**

Mix	Portland Cement (kg/m <sup>3</sup> )	Fly Ash (kg/m <sup>3</sup> )	Blended Sand (kg/m <sup>3</sup> )	10 mm Coarse Aggregate (kg/m <sup>3</sup> )	20 mm Coarse Aggregate (kg/m <sup>3</sup> )	Water (kg/m <sup>3</sup> )	Styrene Butadiene Rubber Granules (kg/m <sup>3</sup> )
C1	430.0	0.0	635.0	390.0	700.0	150.5	0.0
C2F	301.0	129.0	635.0	390.0	700.0	150.5	0.0
R4SBR6	301.0	129.0	633.0	378.0	674.0	151.0	33.0
R3SBR10	301.0	129.0	569.0	390.0	695.0	151.0	63.0

Beams were designed based on the specifications of Ultimate Strength Design Method and the final dimensions were as follows:

- Height 150 mm
- Width 200 mm
- Length 1,900 mm
- Length between supports 1,800 mm

#### 2.3.1 Four-point Bending Test Set up

In order to undertake the four-point bending test, ten channels were employed to capture the data via different tools as follows:

- Two channels for load cells
- Three channels for Linear Variable Differential Transformers (LVDTs)
- Three channels for strain gauges on the body of the beam
- Two channels for strain gauges on the reinforcing bar

Schematic of the four-point bending test set up is shown in the Figure 3 below.

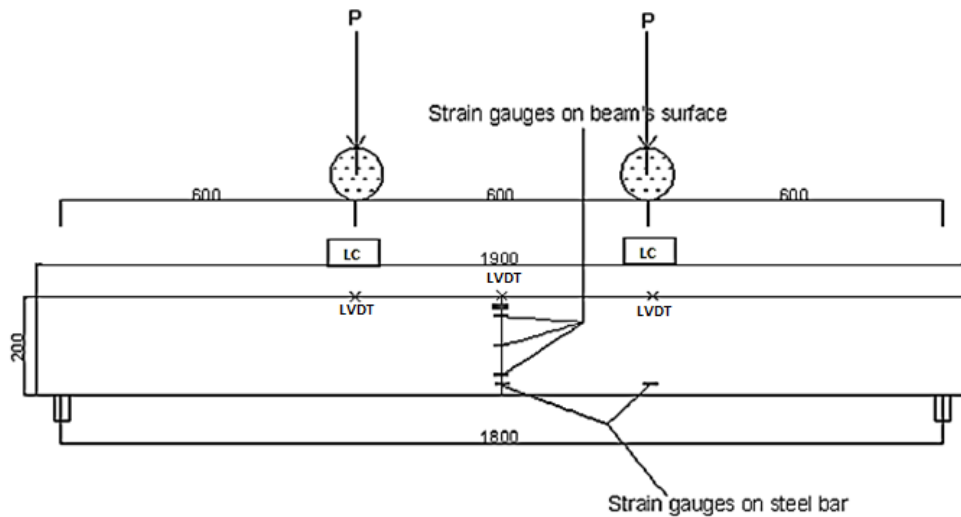

Figure 3 Schematic of the Four-point Bending Test Set up

### 2.3.2 Three-point Bending Test Set up

In order to carry out the three-point bending (cyclic) test, there were six channels as below:

- One channel for load cell under the applied load
- Three channels for LVDTs at half and one-thirds of the beam
- Two strain gauges at half span and one-third of the reinforcing bar

Figure 4 Schematic of the Three-point Bending Test Set up

### 2.3.3 Dynamic Test Set up

The hammer test is carried out parallel to the four-point bending test in order to study the transverse vibration (natural frequency and damping). The concrete beam is struck in two different places (close to two different accelerometers) three times prior to applying the load, and also after the failure. The schematic of dynamic tests on beams is shown in the Figure 5 below:

Figure 5 Schematic of Dynamic Tests on Beams

### 3. Results

#### 3.1 Four Point Bending Test

##### 3.1.1 Parameters Calculated in Four-point Bending Test

Using the data of the four-point bending test, the following parameters were calculated for each beam:

- The load and the corresponding deflection at the first crack; the location of first crack is assumed as the point where the curvature first increases sharply and the slope of the curve shows a definite change;
- The load and the corresponding deflection at proportional limit. Proportional limit is defined as a location on the curve where the elasticity region finishes and beyond which the slope changes. This limit is prior to the yield point;
- The maximum load and corresponding deflection: the deflection at the maximum load that the beam can take before failure; and
- Ductility Factor: defined as the ratio of maximum post-yield deformation to yield deformation which usually comes from steel yielding.

The Load – Deflection graph of the beams is shown in Figure 6 below:

Figure 6 (Load – Deflection) Curve of the Beams

The following graphs (Figures 7 to 9) show the results of the four point bending test.

**Figure 7 Load at Different Points of Four-point Bending Test**

**Figure 8 Deflection at Different Points of Four-point Bending Test**

**Figure 9 Ductility Factor of Beams**

With the calculated values described in Section 3.1.1, the area under the graphs were calculated roughly and shown in the Table 4 below:

**Table 4 Area under Load - Deflection Curve**

Area under the Curve (kN.mm)			
	Up to First crack	Up to Proportional Limit	Up to Maximum Load
C1	5.6	469.0	2542.0
C2F	2.3	458.0	1801.0
R3SBR10	3.0	399.0	555.0
R4SBR6	4.6	497.0	873.0

The area under the graph up to the proportional limit can be assumed as the Modulus of Resilience with a small change in its definition. The modulus of resilience is defined in the literature as the area under the curve up to the yield point (where the material remains unaffected by the applied load and will return to its initial shape when unloaded), however, in this paper, due to the fact that finding the yield point was not possible, the area up to the proportional limit is calculated as the Modulus of Resilience. Based on the test results, the resilience of R4SBR6 was the highest; this could be because of the presence of the larger size SBR in the mix and the mechanical properties of the SBR granule itself.

### 3.2 Three Point Bending Test (cyclic test)

The goal of this test was to investigate the energy absorption for each concrete reinforced beam; this was done by numerically calculating the area enclosed by the load-deflection curves for each hysteresis loop.

#### 3.2.1 Results

Total area and area up to 30 kN of three-point bending load-deflection curves are provided in Table 5 below:

**Table 5 Total Area and Area up to 30kN of Three-point Bending Load-Deflection Curve**

Specimen Name	Total Area	Area Up to 30kN
C1	531	28.3
C2F	268	9.1
R3SBR10	284	34.0
R4SBR6	519	56.1

All beams suffered a tension failure, and all exhibited almost the same general flexural behaviour. The total area under hysteresis loops is the highest in the control concrete followed by the beam incorporating 6% (12 – 15 mm) SBR granules. Concrete beams incorporating SBR granules have a higher resilience and the area under the curve at lower amounts of load is more significant, whereas at higher loads, the areas under the curves in beams without SBR granules are higher.

### 3.3 Dynamic Properties

#### 3.3.1 Results

The values for first frequency retrieved from relevant plots are shown in Table 6 below:

**Table 6 First Frequency of the Beams (from graph)**

Beam Identification	Before the Load Application (Hz)
C1	82.40
C2F	76.80
R3SBR10	76.70
R4SBR6	78.81

As can be seen in the table above, the first frequency of the reference beam with 100% PC is the highest before applying the load followed by the Beam with 6% SBR (12-15mm). By using the results of the hammer test and plotting the Acceleration–Time history graphs, damping ratio in very low damping is approximated as the following equation, Samali (8):

$$\xi = \frac{u_n - u_{n+m'}}{2m'\pi u_{n+m'}} \quad (1)$$

where:

$u_n$  = displacement on the curve at  $n^{\text{th}}$  cycle

$u_{n+m'}$  = displacement on the curve at  $(n+m')^{\text{th}}$  cycle

$m'$  = number of cycles

**Table 7 - Damping Ratio of Beams Before and After Failure**

Beam Identification	Damping Ratio (%)	
	Before failure	After failure
C1	3.71	3.89
C2F	3.27	2.67
R3SBR10	4.09	5.96
R4SBR6	4.96	6.12

In accordance to Table 7 above, the addition of rubber particles improves the damping properties of the concrete mix. This statement is supported by a study by Zheng, Huo et al. (9), which finds that with the increase of rubber content, the damping ratio will be improved, up to an optimum point of 30% rubber content.

An example of the Acceleration–Time history graph under free vibration is shown in Figure 10 below:

**Figure 10 Acceleration- Time History of C2F at Failure**

### **3.4 Modes of Failure**

In the current research, the failure of the control concrete is observed to be explosive, whereas by the addition of rubber the failure became more gradual and less explosive. Moreover, specimens containing SBR granules remained intact even after the failure. This could be due to the bridging of the rubber across the cracks which can decrease the crack propagation within the specimen. It is predicted that the gradual failure of the hardened concrete containing SBR granules could help with ductility and the ability to bear loads even after ultimate failure load. This property is also vital to prevent concrete shattering due to likely explosions and the safety it offers to potential victims. The statement above is supported in a study by Eldin and Senouci (10), which showed that the rubberised concrete did not show the typical brittle failure, but instead was observed to have a ductile, plastic mode of failure.

## **4. Conclusions**

This study highlights the feasibility of using SBR granules in concrete specimens. The main conclusions of this paper and the performed tests are as follows:

- The general observation indicates a lower stiffness and lower maximum load for beams incorporating SBR granules. This could be due to the weaker bond between rubber particles and cement matrix.
- The deflection of the beams did not vary much up to the proportional limit before the yield point, though, this value decreased between the yield point and the maximum load for EMC beams.
- The presence of SBR granules increased the resilience of the beams, however, the ductility factor decreased in EMC beams.
- The total area under hysteresis loops is the highest in the control concrete followed by the beam incorporating 6% (12 – 15 mm) SBR granules. Concrete beams incorporating SBR granules have a higher resilience and the area under the curve at lower amounts of load is more significant, whereas at higher loads, the areas under the curves in beams without SBR granules are higher.
- The value of frequency prior to Four-point bending test did not vary much among different beams.
- The addition of SBR granules improves the damping properties of the concrete beams.

# Twisted Steel Micro-Reinforcement: Proactive Micro-Composite Concrete Reinforcement

Luke Pinkerton<sup>1</sup>, Kevin Fuller<sup>2</sup>, Jeff Novak<sup>3</sup>

<sup>1</sup>Chief Technology Officer, Helix Steel

<sup>2</sup>Chief Executive, Helix Steel Australasia

<sup>3</sup>Vice President of Engineering, Helix Steel

**Abstract:** Reinforced concrete is a two-part system that at best can be described as a “macroscopic” composite made of reinforcement bar and a concrete matrix. The bar is designed to carry load only after the concrete fails – reactive reinforcement. Adding Twisted Steel Micro-Reinforcement (TSMR) at a specified dose to an ordinary concrete matrix creates a “microscopic” composite. The unique design of the TSMR allows for efficient load re-distribution prior to failure of the concrete. The result is a significant increase in the concrete’s strain capacity. TSMR provides proactive reinforcement as, unlike conventional reinforcement and other forms of reinforcement, it engages the material before it actually fails. Similar to conventional methods of reinforcement, TSMR also provides reactive reinforcement as it continues to provide stable tensile resistance after the concrete’s strain capacity is exceeded. With existing design methods, structural engineers are not able to calculate the required dosage of TSMR. The authors present a simple design method to determine the necessary TSMR dosage to resist the tensile forces in an area of concrete equal to or greater than the conventional reinforcement. The TSMR design models specifically for TSMR reinforcement have been developed and have been validated through third party testing at an IAS/NATA certified laboratory, full scale field-testing, calibration, and peer review by structural engineers in multiple countries.

**Keywords:** concrete, elastic, fibre, testing, design

## 1. Introduction

Reinforced concrete, by definition, gives the concrete its required tensile strength after the formation of a dominant crack in the concrete. While there are many interesting academic pursuits in Ultra High Performance Concrete that promise true composite behavior under high loads and deflections, the cost is prohibitive due to the quantity of fibre required and the need for expensive component materials. On the other hand, the fibre industry has promoted use of deflection controlled bending tests of deflection softening mixtures to derive tensile resistance of fibre concrete. In these tests, the machine is programmed to very carefully remove load from the specimen (so it does not fail suddenly) as deflection increases (1). Over the last several years the deflection limit at which the performance is measured using such tests has continued to increase. There are testing standards that actually compute strength based on crack widths near 20 mm, which are 50 times the code limit and twice the limit for a structure to be deemed stable for occupational health and safety (2). The industry has missed the fact that in practice a load would certainly not be so carefully applied and therefore security/safety that is being promoted with such standards is misleading. Also, there is no direct relationship between flexural strength and tensile strength once a crack has formed in the concrete and therefore several assumptions must be made to estimate the tensile strength (3). Finally, while testing has shown an alarming degree of creep in certain types of low modulus, non-metallic reinforcements, the industry has largely ignored the issue (4).

Twisted Steel Micro-Reinforcement (TSMR) offers a solution to these problems both in the product’s performance and in its design methodology. TSMR increases the flexural tensile strength of the concrete (Modulus of Rupture, MOR) and decreases the coefficient of variation of the MOR. TSMR increases the ductility of concrete in tension prior to the formation of a crack (more deflection at the point of crack). While it does exhibit strain-softening behavior at certain dosages after a crack forms, TSMR provides stable tensile resistance in the range of maximum allowable code crack widths. Its design method (Uniform Evaluation Service (UES), Evaluation Report (ER) # 279) fully recognizes its limits and gives the designer a safe, reliable, peer-reviewed design and field QA guidance. TSMR is made of high tensile, high modulus steel, which has been shown to perform well over time (5). Testing measures the real pre-crack properties (MOR, Splitting Tensile) of the TSMR concrete using methods that apply a constantly increasing load to failure just as would occur in real life (i.e. when an overloaded fork truck drives on a floor). Post crack design of TSMR is permitted when restrictions aimed at controlling maximum crack width to sizes consistent with codes are in place.

## 2. Testing and Design Approaches

### 2.1 Test Methods

Unlike traditional reinforcement, the performance characterization and design of steel fibre concrete is not uniform throughout the industry. There are many competing test standards (Table 1) and design procedures (Table 2). While direct tensile resistance is the performance measurement needed for design, most test standards involve flexural tests. Tensile resistance is derived by assuming a relationship between flexural stress (which only exists in linear elastic materials and is invalid after a crack forms) and direct tensile stress (6). A multiplier of 0.37 is typically used to relate the flexural stress in beams with large cracks (3.5 mm) to direct tensile strength (3). Beam testing is also plagued with so called “size effect,” the non-scalability of results to larger or smaller sections and/or cross correlation of crack size, fibre length and specimen size on results (7).

**Table 1. Common Test Methods.**

Test Standard	Type	Control	Measurement	Single Operator COV
ASTM C78 AS 1012.11-2000	Flexural Beam	Load	Peak only Post crack*	5.7%
ASTM C1609	Flexural Beam	Deflection	Peak Post crack	Peak: 8.2% Post: 17%
ASTM C1399	Flexural Beam	Load	Post Peak only	13%
ASTM C1550 RDP	Flexural Round Panel	Deflection	Peak Post crack	Peak 6.2% Post 10%
EFNARC	Flexural Square Panel	Deflection	Peak Post crack	Not Reported
EN 14651	Flexural Notched Beam	Crack Width	Post crack only	Not Reported
EN 12390-5	Flexural Beam	Load	Peak only Post crack*	Not Reported
RILEM TC 162-TDF	Flexural Notched Beam	Deflection	Post crack only	Not Reported

<b>UES EC 015</b>	<b>Direct Tension</b>	<b>Deflection</b>	<b>Peak crack Post crack</b>	<b>Peak 6.3% Post 11%</b>

### 2.2 Design Methods

While the fib Model Code 2010 (8) aims to become the general standard for fibre design in Europe, recently a new fibre design method was approved in Australia that is similar to the Model Code approach but contemplates an option to use direct tension design (9). There are still several competing design approaches and methods (Table 2). The design crack widths are different for different design methods. Some of the more robust approaches, like RILEM TC 162 TF (3), include some statistical considerations for variations in test results. UES EC 015 (10), is the only method evaluated that employs the Load and Resistance Factor Design (LRFD) method for deriving resistance factors employed by the world’s major design codes (11,12,13).

The Papworth 2002 method of design for shotcrete is the only empirical approach evaluated. It uses the relationship between energy (too large deflection) in the round or square panel testing to rock type presented in a prescriptive table instead of a physics-based tensile strength approach. This method favors fibres that behave well at large deflections in the round panel tests.

**Table 2. Fibre Design Methods.**

Design Approach	Application and Criteria	Design Assumption	Test	Test vs design Stress Model
ACI-360	Slabs only cracked stress	4 mm crack Yield Line	ASTM C1609	Linear, Re3
RILEM TC 162-TDF (3)	General, cracked stress & strain	1.5 mm 3.5 mm crack	EN 14651	Bi-Linear $f_{R,1} \times 0.45; f_{R,4} \times 0.37$

The properties of TSMR reinforced concrete with higher tensile strength could provide benefit to designs using provisions for elastic design (Table 3) and plain concrete design. Unlike with conventional non-linear reinforced concrete design, these approaches consider concrete tensile strength. Testing of MOR of TSMR reinforced concrete may be used along with the “deemed to comply” provisions of these codes to allow the use of the enhanced MOR.

**Table 3. Elastic Design Provisions**

Design Approach	Application and Criteria	Design Assumption	Test	Test vs design Stress Model
EN 1992	General Section 5.4	Elastic Design	EN 12390-6	Elastic
AS 3600	General Section 3.1.1.3	Elastic Design	AS 1012.11- 2000	Elastic

CSA 23.3	General Section 22.6.5	Elastic Design	ASTM C78 ASTM C496	Elastic

### 3. Twisted Steel Micro Reinforcement (TSMR)

TSMR is made from high carbon, cold-drawn, deformed steel wire complying with ASTM A 820, Type I. The steel wire has a tensile strength of 1850 MPa. TSMR comes in two sizes: TSMR 5-25 (0.5 mm x 25 mm length) and TSMR 8-50 (0.8 mm x 50 mm length). TSMR 5-25 has been proven to enhance MOR, splitting tensile and provides stable post crack performance. It has been employed successfully to replace conventional reinforcement and wire mesh for over a decade. TSMR 5-25 design and code approval is provided with an ISO Guide 65 Accredited Evaluation Report (10). TSMR 8-50 uses the same TSMR technology and advantages as 5-25, but its performance is optimized for standard post crack beam test performance (EN 14651) while still offering enhanced MOR and splitting tensile strength.

### 3.1 Functional Mechanism

Twisted Steel Micro-Reinforcement (TSMR) is produced with a unique twisted profile (Figure 1) that allows each piece to bond to the matrix over its full length. In addition, the reinforcement must untwist as it pulls out of the concrete. This makes the product significantly different from traditional steel fibres because pullout is governed by untwisting resistance rather than friction. TSMR is active in both the “Proactive Phase” (pre-crack), increasing peak tensile strength, and during the “Reactive Phase” (post-crack) providing ductility and stable tensile resistance to large crack widths.

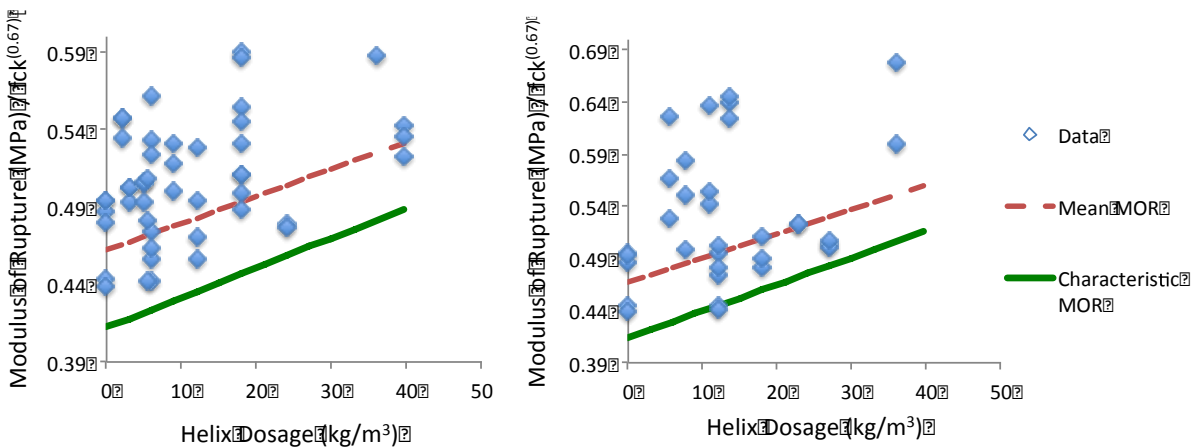

Figure 1: Twisted Steel Micro Reinforcement

## 4. TSMR Advantages

### 4.1 Flexural Tensile Strength (Modulus of Rupture)

Testing at independent laboratories has established a statically significant increase in the modulus of rupture (MOR) of concrete reinforced with TSMR. This is a unique feature of TSMR (as shown in Figure 2) as most codes and design guidance documents state that fibres do not increase the modulus of rupture (MOR) of concrete. The values are computed in accordance with RILEM TC 162 TDF Equations 5 and 6 (3). These equations take into account the mean and coefficient of variation of each of the source data sets. A mean and characteristic value is computed at each dosage tested. Linear regression is used to fit these points to establish the mean and characteristic curves.

(a) TSMR 5-25 (16)

(b) TSMR 8-50 (17)

Figure 2. Flexural Tensile Strength

### 4.2 Splitting Tensile Strength

Testing at multiple independent laboratories has shown significant increase versus the control (plain concrete) in splitting tensile with TSMR reinforced concrete as the dosage increases and as the age increases. The tests show that TSMR does not suffer from the age embrittlement (shift of failure

mechanism from pullout to fibre fracture over time) that traditional steel fibres have exhibited in testing (18). Instead, the testing shows the strength of TSMR reinforced concrete increases as age increases. The increase in splitting tensile strength has particular advantages in tunnel construction where a tunnel boring machine's ram forces are high during segment installation. As a result, larger concrete segment designs may be viable with TSMR than previously thought possible.

(a) TSMR 5-25 Splitting Tensile Vs Dosage (19)

(b) TSMR 8-50 Splitting Tensile Vs Curing Time (20)

**Figure 3. Splitting Tensile Strength**

## 4.3 Modulus of Elasticity

### 4.3.1 Modulus of Elasticity of TSMR Vs Plain Concrete

The stiffness of TSMR is equal to that of structural steel (200 GPa), 8 times stiffer than 25 MPa concrete (25 GPa) and 24 times stiffer than polymer fibres (8 GPa). Given polymer fibres have stiffness significantly less than concrete, it is physically impossible for them to carry any load until the concrete has cracked and become effectively softer than the polymer from which they are made. This helps explain why some testing and design methods that currently exist are based on large crack widths and do not conform with current concrete standards for allowable crack widths. While it is tempting to claim that a polymer fibres can provide the same structural integrity as steel, it's impossible to do so without allowing large cracks to form allowing the fibres to stretch enough to carry load (as Hooke's law requires).

### 4.3.2 Modulus of Elasticity of TSMR vs Reinforced Concrete

TSMR significantly increase the compressive modulus of elasticity (initial tangent modulus) of concrete. Tests have shown an increase of up to 38% (at 25kg/m<sup>3</sup> dosages). The strain at failure in compression, however, increases to 40% over the control as the dosage increases to 25 kg/m<sup>3</sup> (21). This is a clear indication of increased plasticity prior to failure and increased ductility (Figure 4a).

TSMR also increases the strain at failure in tension (Figure 4b). Testing of TSMR confirmed the increase in strain at first crack with TSMR versus the control with 99% and 98% confidence respectively. TSMR technology is the only fibre type studied – steel or polymer – that exhibits this behavior (22). The strain at which force is transferred through shear into TSMR is very low due to the efficient bond the twist provides. TSMR can carry load almost immediately after strain is applied due to the high stiffness of the material. This condition provides alternative load paths that allow micro-cracking to initiate and higher strains than plain concrete at the development of the first visible crack. While this affect can appear as an increase in deflection at peak measurement in flexural testing, this value is typically ignored in favour of looking at the residual load after the formation of a crack up to 20 mm wide, well after the concrete would have catastrophically failed.

(a) Compressive Stress Vs Strain (21)

(b) Tensile Load Vs Displacement (22)

**Figure 4. Modulus of Elasticity**

#### 4.4 Post Crack Behavior

Direct tension testing of TSMR (Figure 5a) shows stable load carrying capacity at code maximum crack widths (EN 1992 states that the maximum crack width in a low environmental exposure area is 0.4 mm).

Flexural testing of notched beams (for the EN 14651) indicates TSMR 8-50 performed 40% better than hook ended steel fibre at 3.5 mm crack width with more consistent results (Figure 5b). Post crack performance of 8-50, as measured in ASTM C1609, exceeds levels required in recent underground construction specifications at dosages lower than ever possible before with traditional steel fibres (23).

(a) TSMR 5-25 Direct Tension Vs Polymer (24)

(b) TSMR 8-50 Vs Steel Fibre EN 14651 (25)

**Figure 5. Post Crack Testing**

Round Determinate Panels (RDP) Testing of TSMR confirms the deflection at peak post-crack stability in the design crack width range exceeds hook ended steel fibres (Figure 6). TSMR holds a constant 15 kN load up to nearly 5 mm central panel deflection. While at very large cracks (40 mm central panel deflection) the product provides similar performance to hook fibres and polymer fibres, the behavior at these deflections is irrelevant due to the instability of the structure with cracks this large as determined by NIOSH, one of the worlds largest occupational health and safety organizations (2). In contrast, it should be noted that polymer fibres exhibit a sharp drop off in load carrying capacity to levels well below TSMR immediately after the crack. But, due the elasticity of the material, the polymer fibres provide a constant or increasing resistance as the crack is allowed to grow beyond the NIOSH limit of stability by the careful loading of the test machine (2).

## ASTM C1550

Figure 6. Post Crack Testing (26)

### 4.5 Fire and Blast Resistance

TSMR reinforcement does not adversely affect the fire resistance ratings when compared to conventionally reinforced concrete designs (5). Testing of steel fibres in general has shown enhancement of properties in precast tunnel segments (27). Blast resistance testing of TSMR shows efficacy of its use in conjunction with a reduced amount of conventional reinforcement to enhance the resistance of concrete to breach when exposed to explosives at close range, similar to a wearable improvised explosive device.

Figure 7 shows two 150 mm thick panels of equal cost after being exposed to 10 lb C4 at 380 mm standoff. Figure 7(a) is a concrete panel with two layers of 10 mm diameter bars at 100 mm spacing each way and Figure 7(b) is a concrete panel with 33% less conventional reinforcement than Panel 1 (two layers 10 mm bar at 150 mm) and 18 kg/m<sup>3</sup> TSMR.

(a) Control 2 Layers of 10 mm Bar at 100 mm

(b) TSMR 5-25 at 18 kg/m<sup>3</sup> with 10 mm Bar at 150 mm

Figure 7. TSMR Blast Testing (28)

## 5. Design of TSMR Reinforced Concrete

Extensive research and testing has been carried out to develop a suitable design methodology and provide practical and safe applications of TSMR. TSMR design methodology has been independently evaluated (ISO Guide 65 Evaluation Report 279). TSMR 5-25 reinforced concrete using this method of

design has been used successfully in Australia in hundreds of projects. Based on this approach to design, Elastic Design of TSMR 5-25 has also been used successfully in slabs-on-grade in hundreds of projects globally for 10 years. Furthermore, TSMR 8-50 provides the benefits of TSMR technology (increased MOR, Splitting Tensile, Pre-crack Ductility) along with improved post crack strengths at large crack widths. This improved large crack width performance allows TSMR 8-50 to conform to existing design methods listed in Table 2.

## 5.2 Evaluation Report 279 of TSMR 5-25

A unique method of design based on rigorous peer reviewed direct tension testing is available for TSMR 5-25. The ISO Guide 65 Evaluation Report (UES ER 297) described in other works (5, 10, 29), has been validated against hundreds of laboratory and field tests over a period of 10 years in nearly 30 countries. Furthermore, the ISO report is recognized in nearly 100 countries via mutual recognition treaties. The report includes a design guideline structured in a way that is familiar to engineers who are used to designing with conventional bar reinforcement. The report provides the required restrictions on its use and field QA procedures. This report is available for download at [www.iapmoes.org/Documents/ER\\_0279.pdf](http://www.iapmoes.org/Documents/ER_0279.pdf). This document provides a building official with a third party review of all the performance testing required to meet the performance based “deemed to comply” provisions in the BCA for alternative building materials.

Testing conducted at the University of New South Wales illustrates the accuracy of of ER 279 design when using a combination of TSMR and conventional reinforcement as well as the ductility TSMR provides in both static and cyclic loading. Four 200 mm diameter by 1.5 meter span circular beam with one N16 in the center and 25 kg/m<sup>3</sup> Helix were tested, three statically and one cyclically. Two different shear spans, (minimum distance between support and load point) were evaluated, 0.5 and 0.2 m). A maximum bending moment of 11.5 kN-m was computed. The tests results ranged from 12-13 kN-m (4 beams). All of them, even the specimen tested under cyclic loading, exceeded the ER 279 prediction. The beams exhibited ductility that exceeded what was expected with ordinary plain concrete producing a stable response even when 15 mm cracks were present (30). A similar test confirmed that shear was also accurately predicted by ER 279.

(b) Load - Deflection Results  $a=0.5, 0.2$

**Figure 8. UNSW TSMR Hybrid Beam Testing (30)**

## 5.2 Elastic Design

Until now, the usefulness of the elastic (plain concrete) provisions of the building codes (Table 3) was limited due to the requirement for very thick and/or high strength concrete needed to develop the same resistance of thinner reinforced concrete sections. Both TSMR 5-25 and 8-50 exhibit increased modulus of rupture with low coefficient of variation with increasing dosage as reported in section 4.1. The curves in Figure 2 may be used in place of the standard values used to compute flexural tensile strength in the code. Many codes require a resistance factor or factor of safety be applied to this value. When the dosage is low, below 15 kg/m<sup>3</sup>, the standard plain concrete resistance factor should be used. At higher

dosages, an increased resistance factor of 0.9 is recommended for both the mean and characteristic curves (16, 17) The factor is computed in accordance with the Load and Resistance Factor Design (LRFD) method assuming reliability levels ( $\beta=4$ ) appropriate for plain concrete design (31).

In the case of AS 3600 section 3.1.1.3, one would use the Characteristic MOR value in Figure 2 to compute the flexural tensile strength,  $f_{ctf}$  and use 0.9 in place of the standard value of  $\phi$  for plain concrete as stated in table 2.2.2. When designing structural concrete, the standard plain concrete resistance factor should be used when the TSMR dosage is below 15 kg/m<sup>3</sup> because testing indicated that while there is an increase in MOR, there is still high variation at low dosage (Table 4). The mean value rather than the characteristic value is allowed for slab design in many slab design approaches (ACI 360). All other restrictions of the code for structural plain concrete/elastic design or slab design must be followed when using the enhanced design with TSMR. Since this method relies on enhanced modulus of rupture versus code values, engineers need to obtain approval through the “deemed to comply” provision of the code BCA. The reference documents (16,17) provided the test data needed to satisfy these provisions.

## 6. Conclusions

After 10 years of successful implementation worldwide, the success of TSMR reinforced concrete is undeniable. This very fact, in addition to the significant increases in modulus of rupture and splitting tensile strength TSMR provides, calls into question common fibre testing and design guidelines that assume the concrete has failed prior to any contribution. A fundamental question must be addressed, is it really OK to design fibre concrete assuming large cracks have formed? And why do we give up on the concrete so easily?

- TSMR has successfully achieved what the fibre industry has been in search of for decades – a fibre reinforcement that engages the concrete before it fails, i.e. TSMR increases the modulus of rupture of concrete. This increase starts at very low dosage and increases further as dosage increases. The variability (COV) is also lower on average, than the control. All existing design procedures examined in this report completely ignore the pre-crack phase.
- The existing design procedures in table 2, examined in this report use post crack performance measurements for design, ignoring the pre-crack phase.
- Current test and design methods fail to provide adequate tools to the engineering community to design safe, reliable, structural concrete with fibres as they place too much emphasis on capacity at large crack width (after the structure would have far exceeded its ultimate limit state in real life).
- Steel and Polymer fibres are designed for optimum performance in these tests but most do not perform well until cracks larger than code limits (about 0.4 mm) have formed.
- TSMR increases splitting tensile strength of concrete. The increase becomes even larger as the concrete ages and as dosage increases. This addresses concern with age embrittlement of TSMR concrete and may allow design of larger tunnel segments than ever before possible with other fibres.
- The modulus of elasticity of TSMR is 24 times that of polymer fibres and 8 times that of plain concrete. The high modulus of elasticity, in addition to the efficient bond provided by the twist provides enhanced ductility in both tension and compression.
- Both TSMR 8-50 and 5-25 exhibit deflection softening but stable post crack behavior at typical dosages (below 30 kg/m<sup>3</sup>) beyond code allowable crack widths (0.4-1 mm) in standard beam and panel tests. TSMR 8-50 outperforms leading hook ended fibres even at large crack widths (R4 value at 3.5 mm crack width).
- The enhanced ductility of TSMR is dramatically demonstrated in blast testing where spalling was almost completely eliminated by partially substituting traditional reinforcement with TSMR.
- Design of TSMR 5-25 may be accomplished using an ISO Guide 65 Evaluation report that demonstrates compliance with the “deemed to comply” provisions of various building codes including the BCA.
- Design may alternatively be accomplished using the elastic design provisions of the code along with the enhanced MOR values provided by TSMR reinforcement at respective dosages.

# Design of UHPFRC Mixtures to be used in Structures Subjected to Impact Loads

Michael F. Petrou<sup>1</sup>, Konstantinos G. Trezos<sup>2</sup> and Anna L. Mina<sup>3</sup>

<sup>1</sup>Professor of Civil and Environmental Engineering, University of Cyprus

<sup>2</sup>Associate Professor of Civil engineering, National Technical University of Athens

<sup>3</sup>Phd Candidate of Civil Engineering, National Technical University of Athens/ University of Cyprus

**Abstract:** This research presents the findings of an experimental study aiming to determine the mechanical properties of Ultra High Performance Fibre Reinforced Concrete (UHPFRC) specifically designed for sustaining impact loads. UHPFRC is a cement – based material that is composed of portland cement produced in Cyprus, sand from a local quarry grading 125 – 250micron and 250 – 500micron, microsilica, super plasticizer and a combination of steel fibers. The combination of steel fibers comprises of two different kinds of fibers: 6mm long with 0.16mm diameter and 13mm long with 0.16mm diameter. Three different mixtures were tested, each containing a different percentage by volume of steel fibers 6%, 2% and 0%. The specimens were submitted to hot curing at 90°C for 11 days. The effect of the steel fibers' volume on the compressive strength, direct tensile strength, the modulus of elasticity and the Poisson's ratio were measured at different ages. Finally, a complete stress – strain curve in compression was obtained for all UHPFRC mixtures. The mechanical properties were utilized in order to select the best UHPFRC design for concrete structures subjected to impact loading conditions.

**Keywords:** UHPFRC, Stress – Strain Curve in Compression, Modulus of Elasticity, Poisson Ratio, Impact Loads.

## 1. Introduction

During the last few decades, concrete industry was forced to develop and enhance concrete compositions following higher standards due to societies' higher demands (1). Thereby, today we are able to speak about Ultra High Performance Fibre Reinforced Concrete (UHPFRC) with great confidence. UHPFRC is a special type of concrete with advanced mechanical properties while many of its advantages result from the presence of steel fibres, silica fume, water reducing agent and lack of coarse aggregates. Much experimentation has been conducted on UHPFRC in order to improve its composition and utmost efficacy (2, 3, 4 and 5). In Cyprus, a series of experiments, recently completed, ended up into a mix design of an UHPFRC with the use of materials available in Cyprus (2). This design has been also tested for impact loads with very satisfying results (6 and 7). This mix design opened the field for further investigation regarding the full stress strain curve in compression, modulus of elasticity, Poisson ratio, and tensile strength. Thereby, the aim of this experimental study is to further investigate the original mix design and to measure the above mechanical properties for different mixtures. Three different mixtures were tested at the following steel fibers volumes, UHPFRC - 6%, UHPFRC - 2% and UHPC - 0% with the objective to show the effect of steel fibres on their mechanical properties and toughness which are equally important for reinforced concrete structures subjected to impact loadings.

## 2. Experimental Procedure

### 2.1. Mix Design – specimens

The details of the mix proportions used in the present study are illustrated in Table 1. This mix design was the first UHPFRC mixture in Cyprus and it was developed after an extensive experimental investigation by Nicolaidis et al. (2) based on a previous study by Benson and Karihaloo (2 and 3). Specifically, Nicolaidis et al. experimented with the different potential variations of the design composition in order to enhance its workability and mechanical properties. The variables considered were: water/cement ratio, the time of curing under different temperatures, the optimum percentage of silica fume, and the volume of steel fibres. In this study we used two types of steel fibres, one 6mm long with a diameter of 0.16mm and another one, 13mm long with a diameter of 0.16mm. In every mixture the quantity of the 6mm long fibres was five times the quantity of the 13mm long fibres.

**Table 1: Mix design (w/b=0.16)**

Constituents (Kg/m <sup>3</sup> )	UHPC - 0%	UHPFRC - 2%	UHPFRC - 6%
Cement	880	880	880
Microsilica (20%)	220	220	220
Silica sand 125-250µm	475	475	475
Silica sand 250-500µm	358	358	358
Water	176	176	176
Superplasticizer	67	67	67
Fibres 6mm	0	134	401
Fibres 13mm	0	27	80
Water / cement	0.20	0.20	0.20
Water / binder	0.16	0.16	0.16

We implemented the following mixing procedure, based on the studies by Benson and Karihaloo (3). First, the silica sand, the silica fume and the cement were mixed together for 6 minutes. Afterwards, steel fibres were added, while passing through a vibrating sieve, in 3 different dosages with 2 minutes of mixing in each one. Then, two – thirds of the superplasticizer were added in the water. The created liquid mixture was divided in three parts of one half, one quarter and one quarter. These proportions were continuously added in the dry mixture with 2 minutes stirring for each dosage. Finally, the remaining one – third of the superplasticizer was added in the mixture until the mix reached its required workability. All the specimens were cast into moulds and they were compacted on a vibrating table. All the specimens were created based on the CYS EN 12390 – 1:2009 standard (8). Specimens were composed of cubes 100x100x100mm, cylinders with a 100mm diameter and 200mm height and beams of 100mm height, 50mm width and 500mm length. The specimens were left for 24 hours in the moulds, covered with damp hessian sheets. Afterwards, they were removed from the moulds and placed in a hot curing tank of 90°C, where they remained for eleven days. Specimens from the three mixtures were tested as follows:

- Cubes at 14, 28, 56 days underwent uniaxial compression test in order to measure their ultimate compressive strength.
- Cylinders were evaluated at 14 and 28 days in order to determine their behavior in compression and capture the full stress – strain curve.
- Beams were tested under direct uniaxial tension in order to get the maximum tensile strength.
- Modulus of elasticity and Poisson ratio were measured in both compression and tension.

It is necessary to mention that all specimens for each mix design were cast from the same batch and the three different mixtures were made using the same equipment in order to eliminate any deviations in the results.

## **2.2. Tension Test**

Our aim was to use a technique for measuring the direct uniaxial tension strength without using dog – bone specimens which require preclusive moulds with casting difficulties. Subsequently, we followed a technique based on Stelios Koliass and R. I. T. Williams prototype (9). The technique – composed of a double scissor

friction grid system and plain geometrical specimens like beams – had the same efficacy as the dog – bone procedure. Since the distribution of the fibers depends on the shape and size of the specimens (10), the width of the beams for tensile tests was more than two times the length of the longer fiber. One longitudinal and one transverse strain gauge were placed on the beam’s surface to measure the modulus of elasticity and the Poisson ratio. Additionally, three linear variable displacement transducers (LVDTs) were placed on the specimen, at three different locations.

### 2.3. Compression Test

Cylinders were capped according to the ASTM C 617-98 (2003) standard (11). Loading was applied under displacement control for the compression tests. Two circular rings were mounted around the cylindrical specimen and were tightly fastened with four screws at 90° in order to maintain the rings’ stability. The rings should be horizontal with 70cm space between them symmetrically to the specimen’s center. On the top of the rings, three LVDTs were placed at 120° angle between them, in order to measure the occurring displacements. Two more LVDTs were placed on the machine’s plates in order to measure the plate’s displacement. This experimental setup was adopted from Hassan et al. study as a backup system (12). Additionally, for the investigation of the Poisson ratio and the modulus of elasticity one longitudinal and one transverse strain gauge were placed close to each other. The longitudinal strain gauge was placed at the mid-height of the specimen. The rate for the compression tests of the cylinders was 0.015mm/min. The cubes performance under compression was evaluated at a rate of 0.5MPa/s according to CYS EN 12390 – 3:2009 (13).

## 3. Results

### 3.1. Discussion

The results in Table 2 clearly show that the modulus of elasticity between the UHPC – 0% and UHPFRC – 2% remained constant while for UHPFRC – 6% was significantly increased. We also observe that Poisson ratio was slightly fluctuated. The above findings, however, need further investigation due to the fact that UHPFRC – 2% specimens provided slightly lower values for the tension tests than the rest of the specimens.

**Tables 2. Modulus of elasticity and Poisson ratio for three mixtures.**

		<b>UHPC - 0%</b>	<b>UHPFRC - 2%</b>	<b>UHPFRC - 6%</b>
<b>tension test</b>	<b>E (GPa)</b>	34,40	38,28	49,88
	<b>v</b>	0,25	0,17	0,24
<b>compression test</b>	<b>E (GPa)</b>	34,31	34,22	42,48
	<b>v</b>	0,22	0,24	0,20

Figures 1, 2 and 3 show the cubes’ compressive strength at three different ages, 14, 28, 56 days. It seems that after hot curing, and the passing of 14 days, compressive strength remains almost constant. The only mixture which presents a minor decrease with age is UHPC but this difference is due to fact that one of the tested cubes exhibited very low compressive strength. Additionally, these figures show that the compressive strength had an increase due to the increase of the fibers which is disproportionally less than the increase of the fibres. Subsequently, the UHPFRC – 6% is not recommended for cases requiring high compressive strength, due to its higher cost and low workability. The higher cost is due, not only to the increase in steel fibers, but also to the lower workability which necessitates extra amount of superplasticizer.

Figure 1. Compressive strength for UHPC – 0%.

Figure 2. Compressive strength for UHPFRC – 2%.

Figure 3. Compressive strength for UHPFRC – 6%.

UHPFRC – 2% during the compression test under maximum stresses was unable to sustain the imposed load and failed in a brittle way. This is confirmed by the results presented in Figure 4, where it is illustrated that out of the five cylinder specimens of UHPFRC – 2% that were examined under compression, only one was able to enter the strain softening phase.

**Figure 4. Full stress strain curve for UHPFRC – 2% cylinders.**

In comparison to the UHPFRC – 2% (Figure 4), all four cylinder specimens of UHPFRC – 6% exhibited strain softening behavior as shown in Figure 5. It is interesting to note that, Hassan et al. achieved strain softening behavior with UHPFC 2% steel fibres. Such a behavior may be observed depending on the properties of the fibers (length and diameter) and the mix design. The above findings, however, need further investigation.

Figure 5. Full stress strain curve for UHPFRC – 6%.

What has been proven from the above stress strain curves is also confirmed by observation of the materials photos after failure. Figure 6 shows the specimen's typical failure of UHPFRC – 6% and UHPFRC – 2% respectively.

Figure 6. Typical failure of UHPFRC – 6% (left) and UHPFRC – 2% (right).

On the other hand, during the tension tests in all the three mixtures, beam specimens behaved elastically until peak strength was reached and then a sharp fall was observed. This proves that after, the first cracking, the resistance of the fibres in pull out is lower than the imposed load. The tensile strength of the three mixtures increases as the percent of the fibers increases (Table 3). Alike with the compression test results, Hassan et al. had also managed to obtain a full stress strain curve in tension with a softening phase. That could similarly be associated with the geometrical characteristics of steel fibres and the mix design.

**Table 3. Tensile strength for three mixtures**

UHPC - 0%		UHPFRC - 2%		UHPFRC - 6%	
beams specimens	tensile strength (MPa)	beams specimens	tensile strength (MPa)	beams specimens	tensile strength (MPa)
1	4,97	1	3,97	1	6,39
2	5,15	2	4,75	2	1,98
3	3,50	3	4,13	3	6,41
4	3,29	4	5,02	4	5,61
average	4,23	average	4,47	average	5,10

The illustrations below show cubes and beams of the UHPC – 0% taken after failure and reveal visible zones of matrix that are unhydrated. Those weak zones of the matrix and fibre distribution are probably the reasons for the high deviations of tensile strength observed among the specimens in Table 3.

**Figure 7. Weak Zones of Unhydrated Matrix**

For the impact resistance of structures, the concrete needs to have high compressive strength so that penetration is avoided. According to Zhang M. H. et al., a compressive strength beyond 150MPa does not affect significantly the penetration resistance on the concrete targets (14). Adequate compressive strength was achieved with both UHPFRC – 2% and UHPFRC – 6% mixes. The second substantial factor that has also been taken into consideration was to ensure the materials toughness against spalling. From the UHPFRC – 6% full stress strain curve it emerged that such a design is best suitable to achieve high levels of spalling resistance. As far as the UHPFRC – 2% is concerned further investigation is needed in order to increase its toughness by utilizing longer fibers and improving fiber distribution and hydration of the matrix.

### 3.2. Conclusions

The following conclusions can be drawn based on the results and the discussion presented above:

- The maximum compressive strength remains almost constant after 14 days of hot curing and exhibited a small increase with the addition of steel fibres.
- The modulus of elasticity improved by increasing the percentage of steel fibres and the Poisson ratio remained constant.
- Strain softening behavior – toughness of the UHPFRC in tension and compression, does not depend only on the percentage of steel fibres, but also on the geometrical characteristics of steel fibres and on the mix design. Further investigation is needed, in order to determine the parameters that control the toughness of these materials.
- For the impact resistance more suitable seems to be UHPFRC with high percentage of steel fibres because it achieved high compressive and tensile strength which are expected to increase its resistance to penetration. Furthermore, it has sufficient toughness to resist spalling.

<sup>1</sup>Professor of Civil Engineering, School of Planning, Architecture and Civil Engineering, Queen's University Belfast, UK

**Abstract:** The disposal of waste tyres is becoming a major waste management problem in the UK. It is estimate that more than 40 million car and truck tyres are being discarded annually. Landfill has been one the most convenient ways of disposing of waste tyres. However, landfill is no longer a viable option and solution due to the implementation of European Union Legislation, which currently bans the disposal of whole tyres and shredded tyres in landfill sites. Therefore, there is an urgent need to identify alternative solutions in line with the UK Government's waste management hierarchy. One of the potential recycling routes is in construction, but currently only about 5% of tyres are recycled in civil engineering applications. The aim of this paper is to investigate the effect that replacing the virgin aggregate with recycled rubber tyre aggregates has on the mechanical properties of the concrete. The increase of the % of rubberized aggregate as replacement of virgin aggregates led to a reduction of density, compressive strength, modulus of elasticity, flexural strength, splitting tensile strength and improved impact resistance and energy absorption.

**Keywords:** Performance, impact resistance, splitting tensile, tyres, tensile strength, Young's Modulus, waste.

## 1. Introduction

In the past number of years, environmental issues have come into focus within the construction industry. These issues regard the materials currently used by the construction industry, many of which are a finite resource, with recycling of construction wastes becoming a major topic of concern. For example consider virgin aggregate, which makes up approximately 50% of construction material in the United Kingdom by weight. To encourage the recycling and the use of recycled aggregates, an aggregate levy of £1.60 per tonne on virgin aggregates was introduced in 2002. The introduction of this levy and similar environmental levies and taxes worldwide has shifted the focus on the use of recycled aggregates and other substitutes for virgin aggregates in the concrete mix. Some of these substitutes consist of glass, demolition concrete, recycled asphalt pavements and recycled tyres.

To coincide with the building boom experienced in the western world, is the growth in the automobile industry. This growth has prompted the significantly increased use of automobile tyres. In the UK alone, 450,000 tonnes of used tyres are discarded annually, with an estimated 100,000 tyres being removed from vehicles in the UK daily. The numbers of used tyres discarded in the US has reached 290 million, according to statistics from the Rubber Manufacturers Association (RMA). This large number of worn tyres has lead to accruals of large number of tyres in illegal and unsafe stockpiles throughout the country, with RMA suggesting that stockpiles around the country storing as many as 190 million tyres (1).

The disposal of these used tyres is a major environmental problem. It was generally believed that the easiest and cheapest method of disposal was to burn the tyres. This practise is prohibited by law in many countries due to the significant amount of harmful chemicals and gases emitted by this method of disposal, along with the chemicals being released from the melting tyres contaminating the soil and subsequently the groundwater below (2). In Europe, landfill disposal was the most widely used form of discarding worn tyres. However, as of July 2006, the introduction of the EU Landfill Directive meant that the disposal of whole or shredded scrap tyres to landfill was prohibited throughout Europe. In order to dispose of these used tyres in a safe and environmentally friendly manner, innovative techniques will have to be adopted. Several uses for waste rubber have been identified, such as being used as a fuel for power stations and cement kilns, as feedstock for the production of carbon black, and as artificial coral reefs in marine environments (3). Other options include the incineration of tyres for the production of steam and the reuse of ground tyre rubber in a number of plastic and rubber products, but, due to the high

capital investment involved, using tyres as fuel is technically feasible but economically not very attractive (4).

It is however, the use of recycled automobile tyre rubber as partial replacement for the virgin mineral aggregate in the concrete mix, which will be discussed in this dissertation. It is hoped that the use of rubber aggregate in concrete will offer a possibility to reduce the use of virgin aggregate resources, while disposing of used automobile tyre rubber in an environmentally friendly manner.

Although the use of rubber in concrete has notable positive environmental effects, along with positive effects on some characteristics of the resulting concrete, it must be realised that rubbers inclusion in the concrete mix does have drawbacks in that compressive, tensile and flexural strengths and stiffness of the concrete are reduced (1, 5; 6). In the early stages of investigations into the suitability of scrap rubber as a replacement for the virgin aggregates in concrete, many researchers were deterred by the resulting concretes reduction in compressive and tensile strengths (7). Due to this perceived flaw, many researchers' attention switched to the use of crumbed rubber in asphalt highways and extensive studies were carried out (8). In 1995, 5% of federally funded highway construction projects were required to use recycled rubber tyres in asphalt, this was increased in 1998 to 20%. However, due to the high cost of producing crumbed rubbers and the time consuming and expensive process of producing the modified asphalt using the "wet process", whereby the rubber is blended with asphalt cement before the binder is added to the aggregate (9), use of rubber in this manner was halted in the USA. Therefore, due to the problems associated with the production of modified asphalt and the greater understanding and appreciation of rubberised concretes positive properties, more attention was paid to its use. Unlike rubber modified asphalt, rubberised concrete utilizes the low cost "dry process", with a portion of the mineral aggregates replaced with recycled rubber tyre chips (9).

The objective of this paper is to investigate the effect of replacement of virgin aggregates by rubberised aggregates on fresh properties, density, mechanical performance and the impact resistance. The percentages of replacements of aggregates by rubberised tyres were 10, 15, 20, 30, and 40%.

## **2. Materials, test methods and mix proportions**

### **2.1 Materials**

The concrete mixes investigated in this study were prepared with Portland cement CEM 42.5 which conformed to Standard BS EN 197-1 CEM1. Continuously graded crushed gravel aggregate with a nominal particle size of 20 mm and 10 mm were used and well-graded quartzite sand with a fineness modulus of 2.60 was employed. The relative density values of the coarse aggregate and sand were 2.63, 2.63 and 2.65, and their water absorption rates were 1.2%, 1.2% and 1.6% respectively. 20-mm rubberised aggregates and having water absorption value obtained of 5.6% and density of 1.16 were used. SP based on chains of modified polycarboxylic ether was used and had 40% solid content and specific gravity of 1.08.

### **2.2 Test methods**

After measuring the slump and the fresh density, 15 cubes 100 mm, 2 prisms 100 x 400 mm, and 2 cylinders 100 x 200 were taken in order to determine the mechanical performance. The compressive strength test was performed at 3, 7 and 28 days. Tensile Splitting Strength test was carried out in accordance with BS EN 12390-6: 2009 at 28 days. The flexural strength of the beam is determined at 28 days by using the four-point test was conducted according to BS EN 12390-5: 2009. The static modulus was carried on cylinders 100 x 200 mm. The impact the BRE screed tester apparatus was used on the concrete cube specimens to simulate the impact experienced by concrete safety barriers.

The test consists of a 100mm cube specimen and BRE tester apparatus. The BRE screed testing apparatus consists of an anvil located at the bottom of the apparatus that is placed onto the concrete cube and 4 kg weight located at the top that is trigger released. The apparatus is held vertical using a small level, and the weight is dropped from a height of 1 m onto the anvil 4 times. After the 4th drop, the cube is inspected for damage and cracks etc., the measuring device is then place on top and an indentation reading taken in mm.

### 2.3 Mix proportions

The mix compositions of 6 mixes is summarised in Table 1. The dosage of cement, water/cement ratio and dosage of superplasticiser were kept constant at 420 kg/m<sup>3</sup>, 0.45 and 0.7 L/m<sup>3</sup>. The dosage of replacement by mass of virgin aggregates was from 10 to 40% (48.5 to 197 kg/m<sup>3</sup>).

**Table 1. Mix proportions of all mixes.**

	Mix proportion (kg/m <sup>3</sup> )					
	0%	10%	15%	20%	30%	40%
CEM I	420	420	420	420	420	420
Water	190	190	190	190	190	190
Coarse Sand	630	630	630	630	630	630
10mm Coarse Aggregate	355	320	320	320	290	240
20mm Coarse Aggregate	745	670.5	625	570	490	430
Rubber Aggregate	0	48.5	73	98	147.5	197
Superplasticiser	0.7	0.7	0.7	0.7	0.7	0.7
Water / Cement Ratio	0.45	0.45	0.45	0.45	0.45	0.45

### 3. Results and discussion

The effects of a variation of percentage of rubberised aggregates on the slump and fresh density are shown in Figure 1. The results shown in Fig. 1 indicate that the slump and fresh density decrease with increasing percentage of rubberised aggregates. The most noteworthy is that when the percentage of rubberised aggregates in the mix exceeds 10%. It has been suggested that the rubberised concrete behaves in this manner as the rubber chips form an interlocking structure the rubber's rough surface texture that resists the normal flow of concrete under its own weight, and hence shows less fluidity than mixes containing lower quantities of rubber (7). This reduction can also be attributed to the reduction of the fresh density of concrete, which would affect the collapse of concrete under its own weight. The reduction of fresh density was also very important when more than 10% of rubberised aggregates were used.

**Figure 1. Variation of slump and fresh density vs. % of rubberised aggregates.**

The effect of rubberised aggregates on the compressive strength at 3d, 7d and 28 days are shown in Fig. 2. From the results given in Fig. 2, it can be observed that the compressive strength at 3 ages rapidly decreases with the increase in the percentage of rubberised aggregates. Using rubberised aggregates to replace the virgin aggregates resulted in a reduction in the 3 days compressive strength by 27%, 29%, 38%, 53% and 60% for replacement levels of 10, 15, 20, 30, and 40%, respectively. Similarly at 7 days, the reduction in the compressive strength by 30%, 34%, 43%, 58% and 66%, for replacement levels of 10, 15, 20, 30, and 40%, respectively. In case of 28 days, the reduction was 26%, 35%, 43%, 52%, and 66%.

The reduction in strength had solely been due to a reduction in load carrying material in the concrete specimens. Therefore the loss of compressive strength can also be attributed to poor development of the interfacial transition zone (ITZ) and disparity between the rubber and hardened cement paste composite

(7). The significant disparity between the young's modulus of the rubber aggregate and hardened cement paste has been highlighted as a contributor to reduced compressive strength. When an external load is applied, the rubber acts as a stress concentrator within the concrete and deform elastically, debonding the rubber from the cement paste and causing micro-cracking around the ITZ, with the cracks spreading rapidly throughout the concrete matrix leading to the inevitable loss of compressive strength (1, 9; 10). Due to the hydrophobic properties of rubbers, the inclusion into the concrete mix may be disrupting the flow of water at ITZ of the rubber and cement paste, thus preventing the full hydration of the cement regionally within the concrete, contributing to failure of the concrete specimen (11). Finally, the reduction is due to the possible reduction of the concrete matrix density, which depends greatly on the density, size, and hardness of the aggregate. While the current investigation examined the use of virgin rubberised aggregates i.e., without any surface treatments, other researchers showed such surface treatments to enhance bond strength (12, 13, 14).

**Figure 2. Variation of compressive strengths vs. % of rubberised aggregates.**

The effects of the rubberised aggregates on splitting tensile and flexural strength are shown in Fig. 3. It can be seen that the introduction of rubber aggregate to the concrete mix led to a decrease in split tensile strength, with the decrease increasing as the rubber content is increased. Similar decrease in split tensile strength has been reported by Kew & Kenny (2008), Guneyisi et al (2004) and Eldin & Senouci (1994). It can be seen that the reduction in split tensile strength was up to 62% for 40% rubber content.

It was observed that the rubberised cylindrical specimens did not split into two halves like the plain concrete, except for one 10% rubberised specimen which was extremely difficult to open by hand. Similar observations were made by (15). This was due to the specimens exhibiting less virgin aggregate shear than the plain concrete, with the rubber aggregate holding the specimens together. From observing figure 56, it could be seen that when the two rubberised specimen halves were separated, there was evidence that the soft rubber aggregate debonded from the hardened cement paste, leaving a void, thus reinforcing the notion that poor development of the ITZ bonding has led to the accelerated and systematic reduction in split tensile strength.

The results of the flexural strength in Fig. 3, it can be seen that the introduction of rubber aggregate to the concrete mix also leads to a decrease in flexural strength, with the decrease increasing as the rubber content is increased. These results are similar to the findings by (1, 2, 16, 17).

The control plain concrete flexural strength specimen demonstrated a characteristic brittle failure in that the control specimen broke into two separate pieces under flexural loading. The coarse aggregate was sheared as expected, however in case of the rubberised specimens demonstrated a notably less brittle mode of failure, with the modified concrete demonstrating a more ductile mode of failure under flexural loading. This behaviour of the modified concrete was expected as reported by (18), the brittleness index

decreased after 15% rubber content. It was also visible that the specimens after failure did not separate into two pieces due to the rubber chips holding the sample together, demonstrating increased toughness and flexibility.

It can be noted that when the rubberised concrete specimens were opened by hand, the rubber aggregate had debonded from the hardened cement paste. Further examination of the specimens show that as the rubber content was increased there was a noticeable decrease in aggregate shear, with a visible failure of hardened cement paste present. This poor interfacial bonding is a major factor in the reduction of flexural strength of the rubberised concrete specimens as compared to the plain control concrete, as good bonding is the key to high flexural strength (1).

**Figure 3. Variation of splitting tensile strength and flexural strength vs. % of rubberised aggregates.**

**Figure 4. Variation of static modulus vs. % of rubberised aggregates.**

Fig. 5 shows the effect of using different replacement levels of rubberised aggregates on the impact test. It can be observed that increasing the replacement level of rubberised aggregates significantly improved the impact strength of the concrete up to a replacement level of 20%. Further increase in the rubberised aggregates contents beyond this level resulted in a similar impact strength of the rubber concrete. This pattern of energy absorption in relation to the rubberised aggregates content might be explained by viewing the energy absorption of the concrete matrix as a trade-off between the composite matrix flexibility and strength. At low to medium replacement levels, the low stiffness of the rubberised aggregates allowed the rubber-cement composite to have a relatively high flexibility and thus absorb a considerable amount of energy higher than that absorbed by normal concrete. As the rubberised aggregates replacement level increases the rubber-cement composite gets weak as high strains are generated under loading which limits the material's ability to absorb energy. However, it is worth noting that even with this

relatively high replacement level, the impact resistance is still higher than that of concretes without rubberised aggregates. The ability of the rubberised aggregates to enhance the ductility and strain capacity as indicators of energy was reported by other researchers (18).

It is important to note that the low Young's modulus of the rubber aggregate compared with the cement paste will result in dissimilar deformation in the rubber aggregate phase compared to the cement paste phase (Fig. 4). This in its turn will result in cracking in the less deformable phase here the cement paste. While this mechanism represents an obvious limitation for developing high strengths in rubber concrete, it represents a favourable mechanism as it enables rubber concrete to have high deformability, toughness, and energy absorption characteristics. It is essential to realise that such micro-cracking would be relatively extensive and will occur at stress levels considerably lower than those observed in normal strength concrete.

**Figure 5. Variation of impact value vs. % of rubberised aggregates.**

#### **4. Conclusions**

The use of rubberised aggregates as aggregate in concrete showed promising results in producing a new type of concrete that has relatively enhanced energy absorption and fracture criteria compared with normal concrete. Incorporating rubberised aggregates in the concrete matrix as replacement of coarse resulted in a decrease in the fresh concrete slump and fresh density. While the compressive strength, the splitting tensile strength and flexural strength and static modulus of the rubberised concrete were significantly reduced as the rubberised aggregates replacement level increases, significant enhancements in the impact resistance of concrete were observed.

The major reduction of strength might be attributed to the behaviour of the rubberised aggregates as a soft aggregate rather than to the reduction of bond between the rubberised aggregates and the cement paste. It also becomes evident that the rubberised aggregates provide other energy consumption toughening mechanisms in the concrete such as particle pullout and rubber internal cracking that do not exist in normal concrete. It is obvious that the choice of the optimal replacement ratio of the rubberised aggregates should be governed by achieving a compromise between strength and the impact and fracture toughness based on field of application. Potential use of this material includes concretes with limited strength requirements and high fracture toughness/energy demand such as those used in bridge barriers and new-jersey barriers.

# The Effectiveness of Mineral Admixtures and Low Water to Cement Ratio in Concrete for Immobilizing Cesium, Sodium and Iodide from Radioactive Waste Material

Irfan Prasetya<sup>1</sup> and Kazuyuki Torii<sup>2</sup>

<sup>1</sup>Dept. of Civil Engineering, Lambung Mangkurat University, Indonesia

<sup>2</sup>Prof. Dep. of Env. Design, College of Science & Eng., Kanazawa University, Japan

**Abstract:** Nuclear accident at Fukushima Daiichi Nuclear Power Plant has caused a huge leakage of radioactive materials such as cesium, iodine, and strontium. Therefore, in Japan, efforts and research works to overcome this problem are needed. This paper investigated the ion diffusivity of cesium and sodium iodide through cement pastes. The purpose is to find out the influence of mineral admixtures along with low water to cement ratio (W/C) on the immobilization of cesium (Cs<sup>+</sup>), sodium (Na<sup>+</sup>) and iodide (I<sup>-</sup>) ions. Blast furnace slag (BFS) and fly ash (FA) are used as the mineral admixtures with W/C set at 30%. The experiments are conducted through diffusion cell tests and followed by a range of post-analysis such as DSC, XRD and SEM. The results show that Cs<sup>+</sup>, Na<sup>+</sup> and I<sup>-</sup> ions are better absorbed in cement paste using 40% replacement ratio of BFS. These findings confirmed that the calcium aluminosilicate hydrate, which is formed from the hydration product in hardened BFS samples, absorb the ions from the solution. Experimental results also show that lower W/C significantly decreases the ion diffusivity. Finally, the experiment results and post-analysis indicate the effectiveness of mineral admixtures, especially BFS40%, and low W/C for immobilizing radioactive wastes materials.

**Keywords:** mineral admixture, diffusion, cesium, SEM.

## 1. Introduction

The 2011 Tohoku earthquake in Japan has caused extensive and severe structural damage in north-eastern Japan. This earthquake, followed by tsunami, has made three reactors in the Fukushima Daiichi complex suffered meltdowns. Due to this accident, huge leakage of radioactive materials such as cesium (Cs), iodine (I), and strontium (Sr) are occurred in Japan. Many efforts have been made to overcome this problem. One of which is an attempt to monitor the levels of radioactive material that leached to the environment. In addition, efforts to control, decontaminate and dispose the released radioactive waste material also have been started.

In terms of radioactive waste treatment facility, portland cement is commonly used to immobilize low level until intermediate-level radioactive waste (1). However, some researched found out that portland cement has low ability in immobilization of Cs ions (2; 3). As stated by McCulloch et al. (4) and Bagosi et al. (5), portland cement has low retention degree on Cs ions, which leads to relatively high leaching rates of cesium through portland cement. Moreover, hardened cement paste has intrinsically interconnected microspores, through which diffusion could readily occur, and will make the nuclides can easily leach out from the waste form (6).

One way to cover the shortage of portland cement for immobilizing Cs ions is by lowering the water to cement ratio (W/C). Reduction of W/C is at present one of the main possibilities to improve the properties of cement based materials (7). It is well known that a low W/C ratio leads to low porosity which, in turn, leads to greater strength and dimensional stability (8). In addition, lower W/C will also increase the biding capacity of the hydration products and increase the homogeneity of the pore structure (9).

In addition, another way to effectively confining radioactive waste materials is by using blended cement. Mineral admixtures, also called as Supplementary cementitious materials (SCMs), are known for its advantage in improving the final properties of the concrete. SCMs, such as blast furnace slag (BFS) and fly ash (FA), when used as replacement of portland cement, not only increase the final strength but also chemical resistance of concrete, and reduce the porosity of concrete. Thus, a durable concrete will be achieved. In terms of environment point of view, blended cement is also known as a green concrete which can reduce energy consumption and CO<sub>2</sub> emissions.

Recently, mineral admixtures also actively investigated to reveal its potential on absorbing the radioactive ions. Goni et al. (1) and Xuequan et al. (6) have confirmed the effectiveness of fly ash belite cement and alkali-activated slag cement for immobilizing radioactive waste material. Moreover, Hong et al. (10) and Glasser (11) have studied the potential of pozzolanic additives to improve the immobilization of highly soluble ion such as Cs.

Furthermore, as reported by Malhotra et al. (12), the Calcium Silicate Hydrates (C-S-H) gel produced from the pozzolanic reaction between amorphous silica from the SCMs and Calcium Hydroxide (CH), which is a product of cement hydration, showing a lower Ca/Si ratio compared with C-S-H gel from the hydration of cement. The lower Ca/Si ratio in the paste has advantage in showing higher binding capacity and bond strength of Cs ions to the cementitious pastes (10; 11).

In order to confirm the effectiveness of mineral admixtures and low water to cement ratio in concrete for immobilizing cesium (Cs<sup>+</sup>), sodium (Na<sup>+</sup>) and iodide (I<sup>-</sup>) ions from radioactive waste material, this study investigates the ion diffusivity of cesium and sodium iodide solutions through cement pastes according to self-diffusion cell tests. For this purpose, BFS and FA cement paste were prepared with W/C ratio set at 30%. As a control sample, ordinary portland cement (OPC) samples were also prepared. In addition, post-analysis such as DSC, XRD and SEM are also carried out to the cement paste samples after the completion of the diffusion cell tests.

## 2. Experiments

### 2.1 Materials and mix proportions

In this study, ordinary portland cement (OPC), from T Co, Ltd., (density: 3.16 g/cm<sup>3</sup>, blaine: 3300 cm<sup>2</sup>/g) was used. As for the mineral admixtures, fly ash (FA) from Nanao coal thermal power plant product (I-type fly ash classified by JIS A6201, density: 2.44g/cm<sup>3</sup>, blaine: 4780cm<sup>2</sup>/g, lg.loss: 2.0%), and blast furnace slag (BFS) manufactured by S Co. Ltd (density: 2.91g/cm<sup>3</sup>, blaine: 6030cm<sup>2</sup>/g, lg.loss 1.0%) were used. The chemical compositions of OPC, FA and BFS are shown in Table 1. Five types of cement pastes were prepared, which are OPC, 40% and 60% replacement ratio of BFS (BFS40% and BFS60%), and 15% and 30% replacement ratio of FA (FA15% and FA30%). In order to assess the effect of low water to cement ratio, the water to cement ratio (W/C) was set at 30% for all types of cement paste. Cesium iodide (CsI) and sodium iodide (NaI) solutions were selected as the electrolytes sources. The concentration was set at 1 mol/L.

### 2.2 Test method

After mixing, cement pastes were cast into PVC acrylic rings, with 5mm thickness and 30mm internal diameter, placed on glass plates, manually compacted and covered for one day to prevent early dryness and water loss. Then, the cement pastes were cured in Calcium Hydroxide (Ca(OH)<sub>2</sub>) saturated water solution for 28 and 91 days curing time under room temperature of 20°C and 60% R.H.

The diffusion cells were setup by adding 100ml of electrolyte sources of Cesium and Sodium Iodide solutions in the tracer cell (cell on the right side) and 100ml of de-ionized water in the measurement cell (cell on the left side) with the cement paste forming the partition between the two sides. After 24 hours, first sampling was performed by extracting 2ml of de-ionized water in the measurement cell and replaced again with the same volume of de-ionized water to keep a constant volume on the measurement cell. This procedure was repeated every 2 days afterwards. The ionic concentration was measured by a PIA-1000 ion analyzer. After the completion of the diffusion test, post analysis such as DSC, XRD and SEM were also conducted.

## 3. Results and Discussions

### 3.1 Diffusion starting time (DST)

The diffusion starting time (DST) of cesium (Cs<sup>+</sup>) and iodide (I<sup>-</sup>) ions from CsI solution, and sodium (Na<sup>+</sup>) and iodide (I<sup>-</sup>) ions from NaI solution at 28 days and 91 days curing time are shown in Figs. 1 and 2, respectively. The DST results were proportional to curing time. The figures show that there is

**Table 1. Chemical composition of OPC, FA and BFS (%).**

Mat.	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	TiO <sub>2</sub>	MnO	SO <sub>3</sub>	Na <sub>2</sub> O	K <sub>2</sub> O	Total
OPC	21.2	4.9	3.4	66.4	1.3	0.0	0.0	1.9	0.3	0.5	99.9
FA	53.6	28.9	6.7	3.2	0.8	1.4	0.1	0.2	0.3	0.7	96.2
BFS	33.0	13.6	0.1	42.6	5.8	0.6	0.2	3.1	0.2	0.2	99.3

a significant delay of DST from samples at 91 days curing time compared to samples at 28 days curing time. These results are more pronounced for BFS samples. Compared to portland cement, blended cement has a slower pozzolanic reaction, between 28 days until 6 months. However, within time, the blended cement will improve the engineering properties of the hardened concrete.

Overall, the occurrence of Cs<sup>+</sup> and I<sup>-</sup> ions were slower compared to Na<sup>+</sup> ions. Especially for the I<sup>-</sup> ion, there is a significant delay on the DST of I<sup>-</sup> ion from all samples including OPC sample. This might be the evidence that the low W/C ratio could decrease the porosity of cement paste, thus make the penetration of ions through cement paste becomes difficult. Table 2 shows the comparison of porosity of cement paste samples with W/C ratio set at 30% (W/C=0.3) and 50% (W/C=0.5) for OPC, FA15%, and BFS40% samples at 28 days curing time. It shows that by decreasing the W/C ratio, the porosity of the sample is significantly decreasing, especially for 0.3 OPC. In addition, the higher porosity that the blended cement paste samples have might be due to the fact that the pozzolanic reaction of blended cement is slower at 28 days. However, the difference in porosity for W/C ratio set at 30% is not significant.

Figure 2. DST of Na+ and I- ions from NaI solution.

Table 2. Porosity of OPC, FA15%, and BFS40% samples at 28 days curing time.

Sample	Total Intrusion Volume (ml / g)	Total Pore Area (m <sup>2</sup> / g)	Median Pore Diameter (Volume) (µm)	Average Pore Diameter (4V/A) (µm)	Bulk Density at 0.50 psia (g / ml)	Apparent (skeletal) Density (g / ml)	Porosity (%)
28d OPC W/C=0.3	0.0523	26.025	0.011	0.008	2.0939	2.3513	10.9438
28d OPC W/C=0.5	0.1649	69.923	0.0165	0.0094	1.6399	2.2476	27.0402
28d FA15% W/C=0.3	0.0648	32.245	0.0103	0.008	1.9952	2.2912	12.9202
28d FA15% W/C=0.5	0.2054	79.267	0.0203	0.0104	1.5336	2.2387	31.4955
28d BFS40% W/C=0.3	0.0591	34.104	0.0093	0.0069	1.9781	2.24	11.6921
28d BFS40% W/C=0.5	0.1814	103.651	0.0075	0.007	1.5739	2.2031	28.5577

As for the BFS samples, the I<sup>-</sup> ion does not occur in both solutions and curing time. This finding suggests that I<sup>-</sup> ion was completely absorbed into the pozzolanic reaction of BFS cement. In addition, it is also important to note that the determination of DST for Na<sup>+</sup> ion from NaI solutions in the latter is fairly a difficult task. It is due to Na<sup>+</sup> ion is immediately released from the pore solution of cement pastes.

### 3.2 Diffusion coefficient (De)

The effective diffusion coefficient (De) of Cs<sup>+</sup> and I<sup>-</sup> ions from CsI solution, and Na<sup>+</sup> and I<sup>-</sup> ions from NaI solution, calculated by Fick's Law, are shown in Figs. 3 and 4, respectively. In addition, Table 3 shows the Effective Diffusion Coefficient (De) of all ions. The results show that the curing time also has a great influence in decreasing the De of all ions, especially for I<sup>-</sup> ions. The effect of lower W/C is also significant in decreasing the diffusivity of Cs<sup>+</sup>, Na<sup>+</sup> and I<sup>-</sup> ions. As could be seen on the OPC sample, the De for all ions are very low which the highest is only around 0.3e-12 for Na<sup>+</sup> ions. Moreover, the influence of lower W/C on OPC sample is significant for Cs<sup>+</sup> and I<sup>-</sup> ions, especially at latter curing time.

As for the blended cement pastes (BFS and FA samples), the combination between using mineral admixtures and low W/C ratio are showing more remarkable effect on confining Cs<sup>+</sup>, Na<sup>+</sup> and I<sup>-</sup> ions. Especially for 91 days curing time samples, the diffusion of Cs<sup>+</sup>, Na<sup>+</sup> and I<sup>-</sup> ions from the blended cement pastes are lower compared to OPC sample. However, higher replacement ratio of BFS and FA tends to have higher diffusivity of Cs<sup>+</sup> compared to OPC. Overall, BFS40% sample shows superiority in immobilizing Cs<sup>+</sup>, Na<sup>+</sup> and I<sup>-</sup> ions since the early curing time, while FA15% sample show almost the same effect as BFS40% at the latter time.

The ion immobilizing effect of the blended cement, especially BFS, can be explained due to the pozzolanic reaction of mineral admixtures with calcium hydroxide (CH) from cement hydration which produce calcium silicate hydrates (C-S-H) and calcium aluminosilicate hydrates (C-A-S-H) that have a 'pore-blocking' effect. This effect improves the binding and adsorptive capability of blended cement and gives higher strength and lower permeability (13). In addition, the CSH and CH formed in OPC paste may charge more negatively compared with FA or BFS samples, which will influence the immobilization of cation and anion ions. Moreover, in terms of Ca/Si ratios, previous experiment using the same OPC, FA and BFS show that the Ca/Si ratios for OPC paste, FA15% paste and BFS42% paste were around 1.7, 0.9 and 1.5, respectively, as been reported by Hasimoto, et al. (14). Lower Ca/Si ratios of FA and BFS will give higher ions binding capacity compared to OPC.

Moreover, blended cement increase the workability of concrete thus will reduce the water demand. Lower water demand will lead to smaller pore size in concrete due to the same mix water that hydrates the cement also occupies space between the cement particles, thereby the concrete strength continues to increase and permeability continues to decrease at lower values of W/C ratio (15). Thus, based on this facts, the combination of blended cement and low W/C ratio will give a significant influence for immobilizing radioactive waste material.

	BFS 40%	0.052e-12	0	0.0822e-12	0
	BFS 60%	0.149e-12	0	0.153e-12	0
	FA 15%	0.0785e-12	0	0.0861e-12	0
	FA 30%	0.121e-12	0	0.097e-12	0

### 3.3 Differential scanning calorimetry analyses (DSC)

DSC analyses was carried out upon diffusion test completion. DSC curves of samples subjected to Csl and NaI diffusion tested at 28 days are shown in Figs. 5 and 6, respectively. The formation of ettringite (Ett) was confirmed by a peak between  $100^\circ\text{C}$  and  $130^\circ\text{C}$  in all samples. Calcium silicate hydrates (C-S-H) peaks were observed in all samples around  $160^\circ\text{C}$  to  $170^\circ\text{C}$ . Peaks similar to Friedel's salt ( $\text{FS}_t$ ) were observed in all samples around  $320^\circ\text{C}$  to  $350^\circ\text{C}$ . Residual calcium hydroxide was confirmed by sharp peaks in the vicinity of  $480^\circ\text{C}$ . Between  $680^\circ\text{C}$  and  $740^\circ\text{C}$ , flat exothermic peaks were observed in all samples. These peaks are a result of decarbonation of  $\text{CaCO}_3$  (CC), which is formed due to material exposure to air and probable contamination of CH with  $\text{CO}_2$  during the analysis.

In terms of residual CH, the formation of CH peaks on BFS samples are lower compare to the other samples. In addition, although FA samples have high residual CH at the early curing time, but within longer curing time the formation of CH peaks on FA samples are decreasing, especially samples tested with NaI solution. Smaller residual CH amount occurred on the DSC analysis is due to the pozzolanic reaction of BFS and FA consume CH to form C-S-H gel, thus it could reduce the amount of CH in the pore system. Moreover, the fact that the amount of residual CH of FA sample is higher compare to the BFS samples at 28 days curing time could be the evidence that the pozzolanic reaction of FA sample is slower and not yet stable compared to BFS sample at early curing time. Thus, lead to a larger diffusivity of  $\text{Cs}^+$ ,  $\text{Na}^+$  and  $\text{I}^-$  ions in FA samples at 28 days curing time.

Furthermore, in terms of BFS samples, although the BFS60% sample also shows a small amount of residual CH, the amount of C-S-H gel is smaller compared with other blended cement pastes, in both solutions and curing time. The small amount of C-S-H gel that produced might be the reason of larger diffusivity of  $\text{Cs}^+$  and  $\text{Na}^+$  ions in BFS60% sample. This result is in line with the experiment of Shariq, et al. (16) on the effect of fine aggregates on compressive strength development of cement mortar with GGBFS replacement. Shariq, et al. (16) found out that 40% replacement ratio of BFS is highly significant to increase the compressive strength of concrete compared to 60% replacement ratio. The reason is due to the presence of excessive fines on the 60% replacement ratio of BFS which will cause greater mobility of the unhydrated BFS particle. The failure takes place due to early crushing of paste and hence strength is found lower than 40% replacement of BFS.

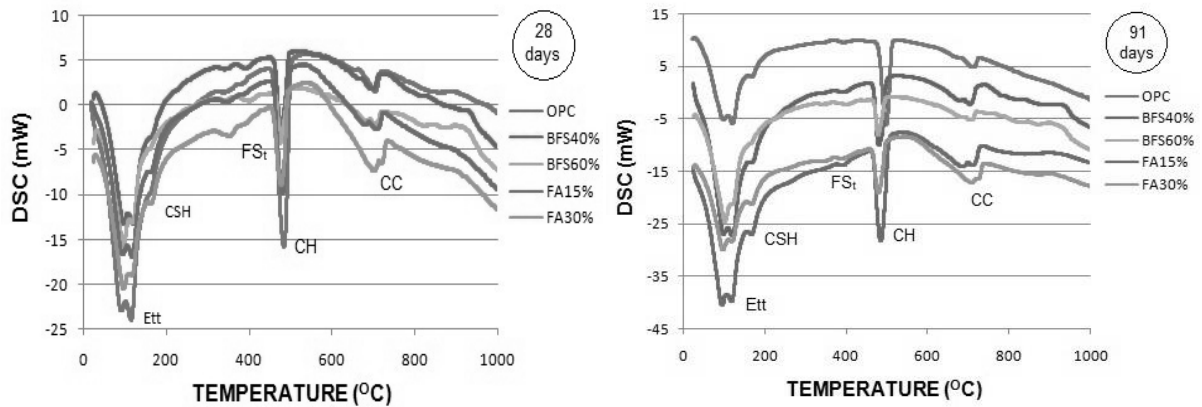

Figure 5. DSC of Cs<sup>+</sup> and I<sup>-</sup> ions from CsI solution.

Figure 6. DSC of Na<sup>+</sup> and I<sup>-</sup> ions from NaI solution.

### 3.4 X-ray diffraction analyses (XRD)

XRD patterns subjected to CsI and NaI diffusion tested at 28 days are shown in Figs. 7 and 8, respectively. Ettringite peaks (Ett) were observed at 8.8°, 15.6° and 23° in all samples. At 11.2°, peak which resembles Friedel's salt (FS<sub>t</sub>) was observed in all samples. Residual calcium hydroxide (CH) peaks were confirmed by sharp peaks at 18° and 34°. Consistent calcium silicate hydrates (C-S-H) peak was observed in all samples at 29.4°. Small calcium carbonate (CC) peak was observed around 38°, as result of sample exposure to CO<sub>2</sub> during the analysis. Overall, the XRD analysis backed up the finding from DSC analysis.

As could be observed on the DSC results, peaks which resemble Friedel's salt (FS<sub>t</sub>) were also observed on XRD results in all samples. These peaks might be the evidence of iodine binding into the cementitious paste. As a result, as could be seen on the De results, the De of I<sup>-</sup> ions for all samples are very low. The Friedel's salt might be formed due to the chemical reaction between the anion (i.e. chloride or iodide) and tri-calcium aluminate (C3A) in the cement paste. Luo, et al. (17) and Cheewaket et al. (18) reported that the higher C3A content in the paste will lead to more anion will be bound.

Mineral admixtures such as BFS and FA are rich in aluminium oxide (Al<sub>2</sub>O<sub>3</sub>) compared to portland cement. Thus, it is expected that the iodide binding capacity of blended cement paste will be more pronounced compared to the OPC cement paste. However, slower pozzolanic reaction of fly ash will make the iodine binding effect of Friedel's salt in FA samples might be delayed compared to the BFS samples.

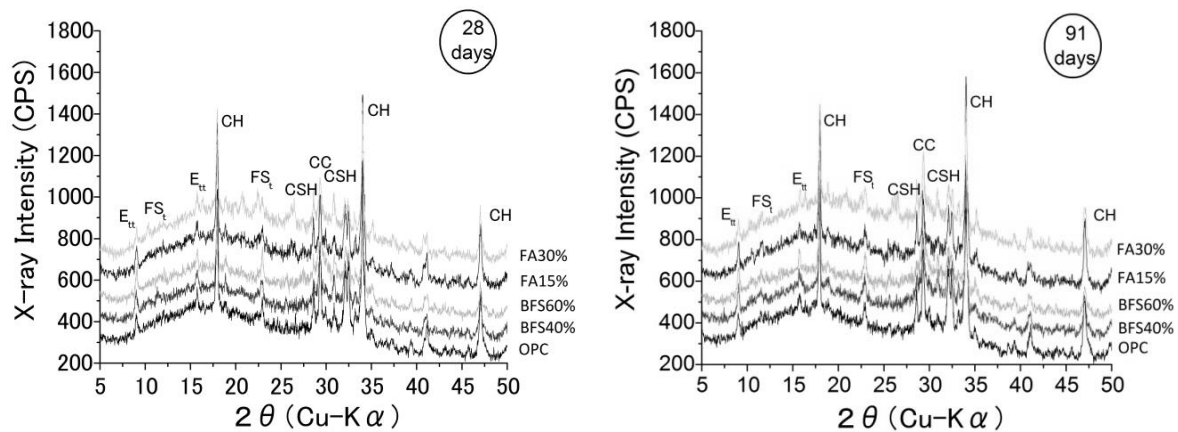

Figure 7. XRD of Cs<sup>+</sup> and I<sup>-</sup> ions from CsI solution.

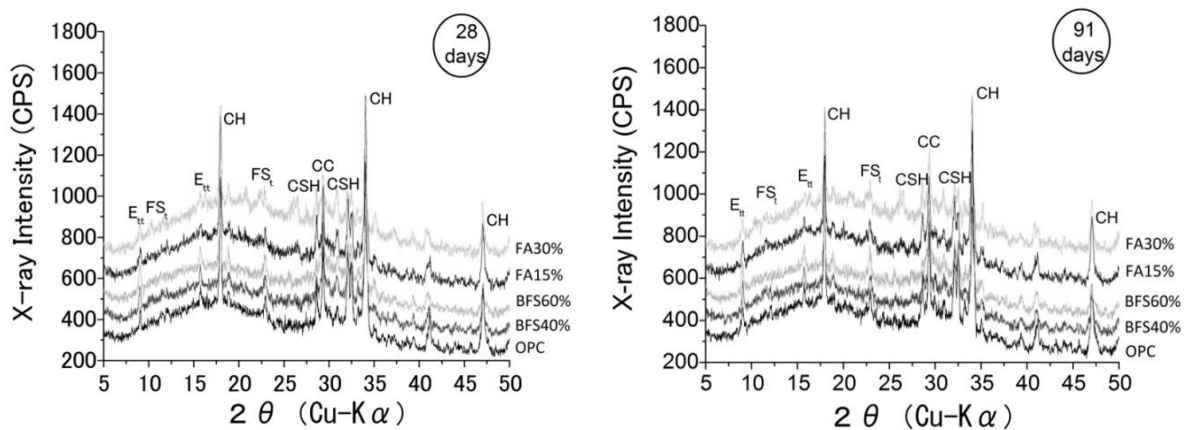

Figure 8. XRD of Na<sup>+</sup> and I<sup>-</sup> ions from NaI solution.

### 3.5 Scanning electron microscopy analyses (SEM)

Scanning Electron Microscopy analyses (SEM) were conducted to the samples at 28 days curing time tested with CsI solution. As shown in Fig. 9(a) the microstructure of BFS40% sample shows a denser structure. In this figure, it also could be observed that the larger slag is only partially reacted, but small slag is fully reacted. In addition, fibrous C-S-H gel could be easily detected in the microstructure of BFS40%. Moreover, as shown in Fig. 9(b), due to BFS is rich with Al<sub>2</sub>O<sub>3</sub>, the formation of Friedel's salt could easily be observed.

As for BFS60% sample, the microstructure for this sample is less dense compared to BFS40%. Ettringite (Fig. 10 (a)) and hydroxide crystal accompanied by hexagonal monosulfate plate (Fig. 10 (b)) are could be easily detected. The fibrous C-S-H gels of BFS60% are also much less compared to BFS40%. This finding is in the agreement with the DSC and XRD results. These results could be the reason of the high diffusivity of Cs<sup>+</sup> and Na<sup>+</sup> ions through the BFS60% sample. Furthermore, the formation of Friedel's salt (Fig. 10 (c)) could also be easily observed as well as BF40% sample.

As for the FA samples, both samples show a lot of unreacted fly ash as could be seen in Fig 11(a) and 11(b). However, it could be observed that the microstructures of both FA samples are dense. This is might be contributed due to the low water to cement ratio. Even though the pozzolanic reaction of fly ash is slow, but the hydration of cement is starting earlier. The low water to cement ratio reduces the porosity of the cement paste, thus make the microstructure become denser. In addition, in both FA samples C-S-H gel could also be observed. Moreover, it can be noted that slag or FA with bigger particle size tends to hardly reacted compared with the smaller particle size.

Figure 10. SEM images of BFS 60% at 28 days curing time tested with CsI solution.

Figure 11. SEM images of (a) FA15%; (b) FA30% at 28 days curing time tested with CsI solution.

#### 4. Conclusions

The ionic diffusivity of cesium iodide (CsI) and sodium iodide (NaI) through cement pastes using mineral admixtures were measured according to self-diffusion test. These experiments, accompanied by post analysis such as DCS, XRD and SEM, are conducted to find out the influence of mineral admixtures along with low water to cement ratio (W/C) on the immobilization of cesium ( $\text{Cs}^+$ ), sodium ( $\text{Na}^+$ ) and iodide ( $\text{I}^-$ ) ions. The experiment results are confirming some concluding remarks.

From all the samples tested, BFS40% is showing smaller diffusivity compared to the other samples. Thus it is recommended to use BFS with this level of replacement ratio for immobilizing radioactive

wastes material. Although FA samples also show a good immobilizing effect of radioactive wastes material, the pozzolanic reaction of FA cement is slower and not yet stable at 28 days compared to BFS sample.

The ion immobilizing effect of the blended cement paste is due to the pozzolanic reaction of mineral admixtures with calcium hydroxide (CH) from cement hydration which produce calcium silicate hydrates (C-S-H) and calcium aluminosilicate hydrates (C-A-S-H). In addition, due to the pozzolanic reaction of blended cement pastes produce C-S-H gel with lower Ca/Si ratio, the binding and adsorptive capability of Cs<sup>+</sup>, Na<sup>+</sup> and I<sup>-</sup> ions were greatly improved compared to OPC sample. Moreover, it also could be noted that the formation of Friedel's salts also give influence in chemically bind the I<sup>-</sup> ions, especially for BFS samples, as could be confirmed by post analysis such as DSC, XRD and SEM analysis. Furthermore, ion diameter of Cs<sup>+</sup> is larger than that of Na<sup>+</sup> or K<sup>+</sup>. It is expected that the denser concrete with fine pores will give a significant immobilization effect of the Cs<sup>+</sup> ion.

In addition, decreasing W/C ratio is also significantly reducing the diffusivity of ions, especially for the I<sup>-</sup> ion, due to lower W/C ratio could reduce the porosity of cement paste. The lower W/C ratio not only significantly reduces the diffusivity of ions through OPC paste but also for the blended cement pastes. Especially for the FA samples, lower W/C ratio could replace the deficient of FA samples which have slower pozzolanic reaction.

# Challenges contemporizing Australian Standards: Supplementary Cementitious Materials

**Craig Heidrich<sup>1</sup>**

<sup>1</sup>Ash Development Association of Australia, Suite 2 – Lvl 1 –336 Keira Street  
Wollongong, NSW Australia

**KEYWORDS:** Australian Standards, internationalization, fly ash, slag, amorphous silica

## ABSTRACT

The review of Australian Standards AS 3582, Part 1 – 1998 (Fly ash), Part 2 – 1991 (Slag – Ground granulated iron blast-furnace) and AS/NZS 3582, Part 3 – 2002 (Amorphous Silica) commenced in 2011 aimed at contemporising these material Standards of which selected standards have not been reviewed for more than 20 years.

In planning and undertaking this review process, a major function was to consult with, and seek the views of, major stakeholders prior to the commencement of the formal Standards review, through Standards committee BD-031. A collaborative pathway with Standards Australia was funded to achieve the review.

The review process included various producers, manufacturers and suppliers of these materials being consulted through the key industry association stakeholders. Considerable energy was spent on reviewing the existing national standards, elaborating proposed changes, collating supporting information for those changes and consulting across the appropriate membership groups to ensure alignment across the supply chain (generators, process and consumers). A review of international standards was undertaken to compare and contrast standards and test methods to ensure Australian standards are aligned, where appropriate.

The purpose of this paper is to inform of the work of Standards Committee BD031 which commenced in July 2014 on changes to Australian Standards AS 3582, Part 1 – 1998 (Fly ash), Part 2 – 1991 (Slag – Ground granulated iron blast-furnace) and AS/NZS 3582, Part 3 – 2002 (Amorphous Silica), rationale and supply uncertainty issues.

## INTRODUCTION

Large-scale use of coal in power generation gives rise to significant quantities of coal combustion products from which important ‘hard won’ end use markets have been established after many years, i.e. cement and concrete. The earliest recorded use of fly ash to enhance the properties of concrete occurred in the 1930s by the Cleveland Electric Illuminating Company based in the USA (Abdun-Nur 1961).

Existing and proposed end use markets for coal combustion products (CCPs) are not only of critical importance to the economics of power generation, but also to the established supply chain participants which have invested, researched, developed and promoted CCPs use into various applications, for example the construction sector use large quantities of CCPs. (Heidrich et al, 2013) reported globally, the continued growth in utilization of CCPs is dependent on many factors beyond the quality and characteristics, e.g. security of supply.

Appropriate legislation and regulation coupled with the development of international classification systems, standards and codes of practice are only a few of the important enablers for easing the way towards increasing utilization and securing the 'legal certainty' for continued investment. Maintaining contemporary standards are essential to functional supply chains (Heidrich et al, 2014).

## CONTEMPORIZING AUSTRALIAN STANDARDS

Focusing on Standards within Australia, a review of Australian Standards AS 3582, Part 1 – 1998 (Fly ash), Part 2 – 1991 (Slag – Ground granulated iron blast-furnace) and AS/NZS 3582, Part 3 – 2002 (Amorphous Silica) commenced in 2011 aimed at contemporising these material Standards of which selected standards have not been reviewed for more than 20 years. These supplementary cementitious materials (SCM's) account for more than 30 percent of all cementitious materials used in the Australia (ASA, 2013, ADAA, 2013, ASiAA, 2013).

In planning and undertaking this review process, Standards Australia strongly encouraged the stakeholder Association's to consult with, and seek the views of, major sectors prior to the commencement of the formal Standards review, through nominated representatives to Standards committee BD-031. The stakeholder Association's funded a collaborative pathway.

The review process, prior to submitting the 'Project Proposal' was conducted over two (2) years, during which time the various, generator, processor and suppliers of these materials were consulted through the respective industry associations of Ash Development Association of Australia (ADAA), Australasian (iron & steel) Slag Association (ASA), Amorphous Silica Association of Australia (ASiAA) and Cement Concrete Aggregates Australia (CCAA).

During this period considerable effort was committed to reviewing the existing documents, elaborating proposed changes, collating any supporting information for those changes and consulting across the appropriate membership groups to ensure alignment within the supply chain. In particular, changes in use and availability of materials meeting the requirements of AS 3582, was undertaken to understand the changing supply chain practices and emerging capacity constraints.

## EMERGING CAPACITY CONSTRAINTS

Over the last decade, a number of changes have occurred in the coal-fired power generation sector that has impacted on CCPs production volumes (supply), physical and chemical characteristics (quality), and environmental legislation. These changes include: modifications to coal-fired power generation plants to reduce emissions (in-

boiler and post combustion); the development of more fuel-efficient and more operationally flexible boiler plants; fundamental changes to the basic combustion process to prepare for carbon-capture technologies (for example oxyfuel combustion); changed legislative operating environment, e.g. impost of carbon tax, renewable energy targets, alone or together impacting of base load demand as reported by (Heidrich, 2013) and more recently the continued privatization of the public power generation.

Being by-products of coal fired power generation, CCPs in particular fly ash as defined in AS3582.1, has come under increased scrutiny for intermittent supply and quality issues in selected regions by major consumers. These regional shortages have raised concerns about changing economic impacts and practices of 'rationing' fly ash, from what is generally considered an abundant resource (ADAA, 2013). This supply uncertainty has resulted in major consumers conducting adhoc reviews of key specifications where, SCM's have secured hard won inclusions.

## SUPPLY UNCERTAINTY

Increasingly major consumers of CCPs report concerns regarding ongoing supply and availability issues across Australia. Examples of statements by major users such as *"...these supply shortages are unacceptable and costly....there clearly will be no [fly] ash available in 5 years as all power stations are shut down".... "we [major user] need to consider alternative materials for projects if these shortages continue"* and *".... we [major concrete pavement construction company] are aware of supply constraints on fine grade fly ash and are concerned about specifying fly ash in upcoming projects"*. These are just some examples of conversations with major consumers.

On investigation of these supply shortages claims during interviews with selected generator(s) advised they had undertaken various unplanned capital works (maintenance programs) with power stations units being placed into shut down, accordingly impacting on regional supply of graded fly ash. Given the planned nature and limited supply chain inventory associated with fly ash shortages had occurred. In isolation (one site) these activities would have limited impact, however in combination (multiple sites) these events seem to have resulted in what has been termed by major consumers that supply (cement and concrete) companies are 'rationing' fine grade fly ash, from what is an abundant resource.

Questions arising from this preprimary investigation identified the following questions

- Q. Is fly ash rationing occurring?
- Q. What are the facts about continued coal fired generation and accordingly coal combustion products supply?
- Q. Has coal fired generation capacity reduced i.e. Stations closed, resulting in shortages?
- Q. Are there capacity constraints and if so what capacity for other various grades exist and what is the role for the Standards review?

The first question.. *Is fly ash rationing occurring?..* is fraught with difficulties in determining, moreover uncovering the facts. The role of collection, processing and

distribution of fly ash is primarily controlled by companies owned or operated by cement companies, with a few exceptions. Requests for details are treated as commercial in confidence. Accordingly, no reliable analysis can be conducted on this question by the author. The remaining questions can be addressed using available primary and secondary data of the Associations to determine the facts about production and capacity to produced fine grade fly ash, moreover possible corrective measures and amendments to Standards.

## PRODUCTION AND CAPACITY ANALYSIS

Fortuitously a 'Production and Capacity Analysis', albeit limited in scope was undertaken, as part of the Cement Industry Action Agenda (DTIR, 2006), with the primary objective being to understand current coal fired generation capacity, fuel burned, coal combustion product generated and total stored which could be exploited by the cement industry. The analysis has been expanded and completed again in 2011 and 2013 providing some historical comparison and insights into changes for fly ash production; furnace bottom ash production; production capability for - Graded (fine), Ungraded (coarse & medium) and furnace bottom ash.

The production and processing capability stated in Table 1 is based on installed site design infrastructure capability at 100% utilisation. For example 'Generation Capacity' is the total MW installed for a given operating site at a given point in time, where as 'CCP Generated' is a function demand for energy i.e. 'Coal (fuel) Burned' x apparent ash content of coal. 'Fly Ash Graded Capability' means where processing capacity exists onsite to collect, capture and load vehicles with fine grade fly ash (AS3582.1). 'Fly Ash Ungraded Capability' means where processing capacity exists onsite to collect, capture and load vehicles with ungraded fly ash (1 to 300um). See Table 1 – Capacity Analysis 2006 to 2013.

State	Generation Capacity	Coal (Fuel) Burned	CCP Generated	Fly Ash	Furnace Bottom Ash	Fly Ash Graded Capability	Fly Ash Ungraded Capability	Furnace Bottom Ash Capability	CCP Diverted Storage	Total CCPs Stored
	MW	tonnes	tonnes	tonnes	tonnes	tonnes	tonnes	tonnes	tonnes	tonnes

Effective use			40.9%	17.8%	20.5%	60.9%	13.2%	37.5%		

Table 1 – Capacity Analysis 2006 to 2013

## OBSERVATIONS FROM THE ANALYSIS

Since 2006 total coal fired power generation capacity installed mega watts (MW) has decreased by 441MW or -1.5%. Plant maintenance upgrades to capacity at various

sites across Australia, less closure of older plant having been retired during the period. Retired sites were not identified as significant supply sites for fine grade ash. To summarise no significant change to installed power generation capacity has occurred.

The overall reduction in coal (fuel) used on the base line (2006) equates to 20 million tonnes or 15.5% reduction. Reduced fuel used means less total energy (MWh) being generated by coal fired power generation. In other words there is less demand for energy from coal with demand gaps being primarily filled by other renewable sources, driven mainly by government incentives and regulation, e.g. Renewable Energy Targets.

Interestingly, while there has been a reduction in total fuel used, coal combustion products generated have increased slightly by 0.540 million tonnes or 4%. This is consistent with trends identified in annual membership surveys that coal fired generators are using more marginal thermal coal sources with higher ashing contents - a trend that continues here and overseas. So in real terms, whilst energy from coal has reduced by some 15%, fly ash production has remained mostly unchanged over 10 years.

Focusing on graded<sup>1</sup> materials, capacity is reported at 2.5 million tonnes concentrated within NSW and QLD within two (2) power station sites. Whilst no data was captured in 2006, no significant change has been observed over the period. CCP used in cement and concrete applications for the 2013 was 1.6 million tonnes or 61% and in 2011 some 2.1 million tonnes or 81% of capacity utilised. Some possible factors attributed to a supply constraints;

- High concentration (> 60%) of fine grade (Graded) processing capacity centralized into limited coal fired power stations. Any unplanned interruptions in fly ash production will quickly translate to shortages
- No significant additional processing capacity for graded (fine) fly ash has been added in over 10 years
- Limited to no evidence of supply chain demand planning to compensate for low inventory capacity. Contributing factors to reduced volumes
- Renewables and lower emissions fuels being used in preference to coal
- Current Standards limit capability to use ungraded fly ash, where performance could be demonstrated

Installed coal fired power generation capacity and accordingly coal combustion products have not changed significantly in over ten (10) years, however capacity constraints for processing of fine grade ash have featured over the period through selective unit shut downs with sites where more 60% of processing capacity exists. Capacity for 3.7 million tonnes of ungraded materials has been installed over the past 10 years, but this material is poorly exploited by the current Standards. The question arises what is the role for the Standards review?

## ENABLING FUTURE CHANGE

<sup>1</sup> Fine Grade Fly ash -- Australian Standards AS 3582, Part 1 – 1998 (Fly ash)

The first change is in the title, and this change is proposed for all of the parts of AS 3582. The previous AS 3582 documents are entitled “Supplementary cementitious materials for use with Portland and blended cements”. The current proposal is to limit the title to “Supplementary cementitious materials”. There has been an attempt, for some time, to have the fly ash Standard in particular cover all aspects of fly ash use – not only for concrete, but for renders, mortars, grouts, stabilisation and various other potential uses such as geopolymers. The only real exception is when used as a mineral filler for asphalt residing in another Standard. By keeping the title to Supplementary Cementitious Materials (SCM) it is less specific about the options, but does at least confine them to cementitious uses.

The major areas of change in the draft are related to:

- alignment with AS3972 (2010) – Cement
- change in classification of the Grades of fly ash
- change in specified properties for Grades of fly ash
- adopt strength index (similar to ASTM)
- include measures of consistency for fineness and LOI values
- removal of available alkali test requirement given long term data
- review of testing frequency and reporting requirements
- alternate test method validation process
- alignment with AS3582.2 and AS3582.3

Standards are referenced in AS3600, AS1379 and AS3972. Where appropriate consequential amendments and alignment required to AS3600, AS1379 and AS3972 were considered along with consequential amendments and alignment with various Federal and State agencies infrastructure, building and construction related sector specifications. Alignment with international best practice adopted in similar standards globally will be considered as part of the review.

In summary the review consisted of updates of the standard requirements and inclusion of; scope of standard to include non-concrete related uses; new classes of materials; review appropriateness and confirm test methods and general updating of references to ensure the validity of the content. Test methods to be reviewed include

- 3583.1 Method 1: Determination of fineness by the 45 µm sieve
- 3583.2 Method 2: Determination of moisture content
- 3583.3 Method 3: Determination of loss on ignition
- 3583.5 Method 5: Determination of relative density
- 3583.6 Method 6: Determination of relative water requirement and relative strength
- 3583.8 Method 8: Determination of sulfuric anhydride content
- 3583.12 Method 12: Determination of available alkali
- 3583.13 Method 13: Determination of chloride ion content

Once finalized revisions to the Standard(s) will be reviewed by inviting public comment. The working committee currently expects to publish revised AS 3582 Series by the end of 2015.

## ABUNDANT AND POTENTIALLY EXPLOITABLE RESOURCE

The various utilisation pathways for CCPs reliant on the legislative, regulation and economics that drive the different participants (coal suppliers, generators, ash marketers and ash users) can have polarised interests in regards to the overarching utilisation goals. For example coal suppliers and generators prefer 'demand to be greater than supply' whereas ash marketers and ash users prefer 'supply to be greater than demand' with the corresponding value (Heidrich et al, 2014).

In microeconomics terms, supply and demand has important implications for price determination in any market. As an economic model used in competitive markets, the unit price for goods will vary until it settles at a point where the quantity demanded by consumers (at current price) will equal the quantity supplied by producers (at current price), resulting in an economic equilibrium for price and quantity.

The market for utilisation of CCPs however can be very broad, with an enormous range of potential applications. These applications range from cementitious uses through to bulk fills and emerging agricultural opportunities (Aiken et al, 2015). In addition a wide range of niche uses contribute small increases in total tonnages sold.

The beneficial use of coal combustion products (CCPs) consolidated during 2013 with 5.7 million tonnes or 52% effectively utilised resulting in the conservation of energy, finite natural resources, the reduction of greenhouse gas emissions and recovery of mineral by-product resources that would otherwise be placed into long term storage or emplacement.

The survey results for CCP production and categorised end uses for the period January to December 2013 can be found at ([www.adaa.asn.au](http://www.adaa.asn.au)) In summary from the 12.3 million tonnes of all CCPs produced some 52% of were effectively utilised within various civil and construction applications throughout Australasia (Australia and New Zealand). This compares well, given the uncertainty over with the introduction and subsequent withdrawal of Carbon Tax Legislation and wide ranging environmental reforms over the past 3 years. For previous periods of 2001, 2011, 2010, 2009 and 2008 resulted in effective utilisation of 42%, 48%, 41%, 34% and 31% respectively.

## SUMMARY

The review of the AS/NZS 3582 series was a planned process aimed at contemporizing these material Standards having not been reviewed for more than 13 years. In planning and undertaking this project a staged approach was considered in consultation with Standards Australia. That is, the project proponents consulted with, and sought the views of, major stakeholders prior to the commencement of the formal Standards review, through Joint Standards Australia/Standards New Zealand Committee BD-031.

The initial project review encompassed the various manufacturers, suppliers, users and academics with interest in these materials. Stakeholders were consulted through respective industry associations with a series of consultative meetings conducted to determined the review needed to address contemporary performance based

approach, widening the Standards application and methods of demonstrating compliance.

The major contributing supply chain factors were identified during the review were related to; closure/retirement of older coal fired power stations, the short-term closure of units to undertake earlier than planned maintenance; unplanned maintenance/repairs and ongoing privatization of coal fired power stations are contributing to uncertainty factors for supply. The net result during 2013 was a continuation of short-term interruptions within the supply chain for fly ash consumers, which highlight the limited and highly centralised processing and distribution capacity for fine grade fly ash across selected coal fired power station sites.

Accordingly, the Standards review introduces new classes of materials, definitions for proven and unproven sources and corresponding testing frequencies, incorporating product conformity requirements in the normative section which was previously in the 'informative' section.

The review considered and recommended, where appropriate, adopting international and national standards; existing referenced standards documents were reviewed, changes proposed and elaborated upon, and supporting information collated, with consultation across appropriate membership groups to ensure alignment across the supply chain.

In closing, the recovery and reuse of CCPs has been proven to provide positive and significant environmental impacts, including resource conservation and in this case, the reduction of greenhouse gas emissions from the processing of virgin resources, resulting in the reduction of carbon emissions. However, processors and major consumers singular focus on sourcing exclusively using fine grade fly ash, where other ungraded materials maybe suitable is unsustainable without significant investment into additional fine grade capacity.

Given uncertainty factors for with operation of coal fired power stations, more consideration should be given to exploitation or recovery of conditioned coal combustion products placed into ash dams.

# Effects of Chemical Admixtures and Aggregate Particles on Spatial Distribution of Cement Particles and Capillary Pores in Mortars

Takuma Nakagawa<sup>1</sup> and Shin-ichi Igarashi<sup>2</sup>

<sup>1</sup>Engineer, Aichi Prefecture Government Office, Japan

<sup>2</sup>Professor, Department of Civil and Environmental Engineering, Kanazawa University

**Abstract:** The point process statistics was applied to results of image analysis for backscattered electron images of cement pastes and mortars. Effects of chemical admixtures and sand particles on spatial distribution of unhydrated cement and capillary pores were investigated. Their distributions in actual mortars were compared to point patterns simulated by a thinning operation for the corresponding cement pastes. In cement paste specimens, cement particles dispersed randomly. However, spatial distribution of capillary pores exhibited clustered patterns if a superplasticizer or a viscosity enhancement admixture was not used. When the chemical admixtures were used, distributions of the pores nearly followed the complete random pattern. In mortars with a workable cement paste matrix, distributions of cement particles and the pores were the same as the ones obtained by thinning points from basic processes. Distributions of cement particles and capillary pores were not disturbed by sand in the workable mixtures. Sand particles had a simple role to delete points of cement and pores randomly. However, in mortars without the admixtures, clustering of cement particles and capillary pores was clearly reduced compared to the thinned processes. This mitigation of clustering depended on water/cement ratios. The more room for the particles, the greater mitigation was seen in mortars.

**Keywords:** point process, thinning, clustering, summary statistics, chemical admixtures

## 1. Introduction

It is needless to say that the most fundamental and important parameter to determine properties of concrete is a water/cement ratio, which is defined as a mass ratio. However, taking account of the fact that the density of Portland cement is not changed frequently, it is also possible to say in other words that properties of concrete are determined by the initial volume ratio of water against cement in a space available for a cement paste matrix. Furthermore, cement is a powder of which particle sizes are properly controlled in its production process. Therefore, as far as concrete is appropriately processed, the initial spatial distribution of cement particles can be regarded as a crucial parameter to determine the subsequent properties of concrete. Of course, pore structure affects strength and durability of concrete. However, its evolution with time is influenced by the initial arrangement of cement particles since the initial space for water, i.e. potential room for capillary pores is considered as a complementary set of cement particles dispersed in fresh cement paste.

In order to examine spatial structure of constituent phases in cement paste, image analysis techniques have been used. Geometrical features in images are evaluated based on the concept of stereology. The first-order stereology concept has been used for evaluating the quantity of constituent phases such as unhydrated cement and pores. However, these days, the summary statistics of second-order properties have been obtained for microstructure in cement paste since it enables to evaluate not only the quantity of the phases but also characteristics of spatial distribution such as clustering or regularly dispersing [1]. Furthermore, it also gives specific distances which characterize the distribution [2,3].

In this study, the point process statistics was applied to cement particles and capillary pores in backscattered electron images. They were converted to points. Effects of water/cement ratios and the addition of chemical admixtures on spatial distribution of the points are discussed. Furthermore, their distributions in actual mortars are compared with simulated patterns, which are obtained by a thinning operation for basic distributions in cement pastes. Effects of aggregate particles on the point patterns are discussed also from the viewpoints of interruption of free distribution and deflocculation of the points.

## 2. Experimental Procedure

### 2.1 *Materials and mix proportion of cement pastes and mortars*

The cement used was an ordinary Portland cement with a Blaine fineness value of 331m<sup>2</sup>/kg. River sand was used as a fine aggregate. Cement paste and mortar specimens of 100mm in height and 50mm in

Table 1 Mix proportion of cement pastes and mortars

SP: Superplasticizer, VE: Viscosity enhancement admixture

diameter were produced in accordance with JIS R5201. The water/cement ratios were 0.30 and 0.60. The mass ratio of sand to cement in mortars was 2.0. A superplasticizer (SP) and a viscosity enhancement admixture (VE) were also used to improve workability of mixtures. Mix proportions of cement pastes and mortars are given in Table 1. They were demolded at 24h after casting. The specimens with a water/cement ratio of 0.6 were then cured in water at 20°C for 3d.

## 2.2 Image acquisition and its conversion to a point process

At the age of 1d for w/c of 0.30, or 3d for w/c of 0.60, slices about 10 mm in thickness were cut from the middle of the height of cylinder specimens. They were dried by ethanol replacement and a freeze-drying procedure with t-butyl alcohol. Then they were impregnated with a low viscosity epoxy resin. After the resin hardened at room temperature, the slices were finely polished with abrasive papers. The polished surfaces were then finished with diamond slurry for a short time.

The polished samples were examined using an SEM equipped with a quadruple backscatter detector. In order to observe a wide field, the backscattered electron (BSE) images were acquired at a magnification factor of 60x (Fig.1(a)). The size of one pixel is about 1.85µm. Binary segmentation was made for pixels of unhydrated cement particles and pores (Fig.1(b)). Using a function of the image analysis software, coordinates of the centroid of each particle in the binary images were obtained. Then all the particles were converted to the points in the observation field. Those points in a 2-D image were regarded as a point process  $X = \{x_i; i = 1, \dots, n\}$  (Fig.1(c)).

## 2.3 Evaluation of cement paste matrix as a random field in mortar

A cement paste matrix in a mortar is considered as a complementary set of aggregate particles. If it is assumed that aggregate particles are distributed randomly throughout a mortar section, the cement paste matrix surrounding the aggregate particles is considered to occupy a region as a random field between the particles. In order to characterize geometrical features of the random field of the cement paste matrix, covariance function for the field was calculated. When a cement paste matrix is considered as a spatial set  $\mathcal{E}$ , its covariance function  $C(r)$  is given by Eq.(1).

$$C(r) = \Pr(x_1 \in \mathcal{E}, x_2 \in \mathcal{E}) \quad (1)$$

Where  $x_i$  ( $i=1, 2$ ) is a position vector of  $\|x_2 - x_1\| = r$ . To calculate the covariance function, a template with eight radial directions was placed on a binary image, in which a region of cement paste matrix was segmented. Whether both the center and the endpoints of the template fell in the cement paste matrix phase or not, was determined. This operation was repeated at different positions to obtain 10,000

Fig.1 Example of conversion of unhydrated cement particles to a point process; (a) Backscattered electron image, (b) Binary segmentation of cement, (c) Point pattern

samples for a distance of  $r$ .

## 2.4 Point process statistics for cement particles and pores<sup>1)</sup>

### 2.4.1 K-function and the nearest neighbour distance function (G-function)

The point intensity  $\lambda$  of the point process  $X$  was determined from the images by the following equation.

$$\lambda = \frac{N(W)}{A(W)} \quad (2)$$

$N(W)$ : the total number of points in the observation window  $W=a \times b$

$A(W)$ : the area of  $W$

K-function ( $K(r)$ ) was calculated from the point pattern using Eq.(3).

$$K(r) = \frac{1}{\lambda^2} \sum_{i=1}^n \sum_{\substack{j=1 \\ (j \neq i)}}^n \frac{1_{[0,r]}(|x_j - x_i|)}{\bar{y}_W(|x_j - x_i|)} \quad (3)$$

Where  $1(\cdot)$  is the indicator function, i.e. equal to one if its argument is true and zero otherwise.  $r$  is distance, and  $\bar{y}_W(r)$  is the isotropized set covariance function of the window  $W$ . It is given as the mean area of the intersection of  $W$  with the  $W$  shifted by a random vector of length  $r$ .

The nearest neighbour distance function (G-function) was also calculated using Eq.(4).

$$\hat{G}(r) = \frac{\sum_{i=1}^{N(W)} \mathbf{1}(s_i \leq r) \cdot \mathbf{1}(s_i \leq b_i) \cdot w(s_i)}{\sum_{i=1}^{N(W)} \mathbf{1}(s_i \leq b_i) w(s_i)} \quad (4)$$

Where  $b_i$  is the shortest distance from each point  $x_i$  to edges of the window.  $s_i$  is the distance to the nearest other point in the point process.  $w(s_i)$  is a weighting factor, and given as the inverse of the window area eroded by a circle of radius  $s_i$  (Eq.(5)).

$$w(s_i) = \{(a - 2s_i)(b - 2s_i)\}^{-1} \quad (5)$$

From the K-function and the G-function, clustering tendency was simply judged for the point processes of unhydrated cement particles and capillary pores (Fig.2).

### 2.4.2 Thinning points from a basic process in a cement paste and K-function of the thinned process with a less point intensity

Spatial distribution of particles in cement paste specimens was used as a basic point process  $X_b = \{x_i | i = 1, 2, \dots, n\}$ . The K-function  $K_b$  for the basic pattern  $X_b$  was calculated following the same procedure as described in 2.4.1. Distribution of particles in actual mortar specimens was also considered as a point process  $X_p$ . If the point process  $X_p$  can be obtained by a thinning operation for  $X_b$ , then  $X_p = X_b \cap \Xi$ . Then the K- function of particles left in the thinned process,  $K_p$  can be calculated by Eq.(6) [1,4].

$$K_p(r) = \frac{1}{p^2} \int_0^r C(x) dK_b(x) \quad (6)$$

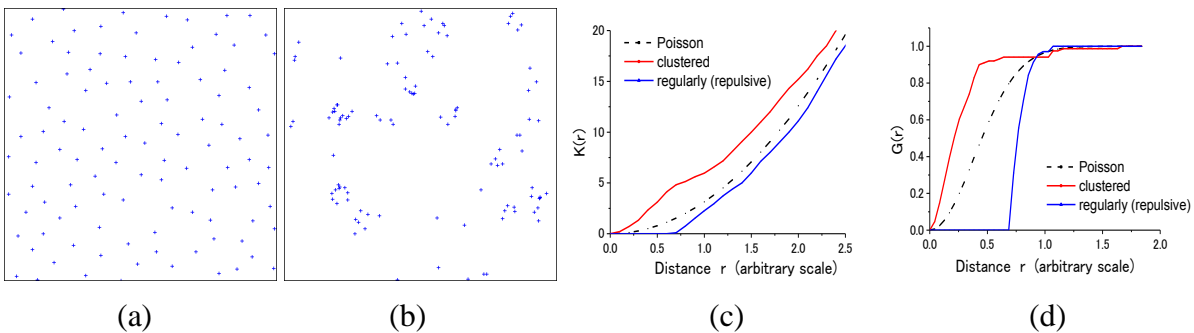

Fig.2 Examples of point patterns and their K- and G- functions (a) regular (repulsive) distribution (b) clustered distribution (c) K-function for the patterns (d) G-function for the patterns

### 3. Results

#### 3.1 Spatial structure of cement particles and pores in cement pastes

Fig.3 shows K- and G- functions of unhydrated cement in cement pastes with a water/cement ratio of 0.30. Broken lines in the figures are the functions of completely random distribution, i.e. the Poisson point process. Regardless of the addition of a superplasticizer, the K-function of unhydrated cement particles follows the Poisson process. However, in the range shorter than  $50\mu\text{m}$ , the G-function of cement particles is smaller than the Poisson process. Hard core distances of about  $10\mu\text{m}$  are seen in the both cement pastes with and without the superplasticizer. This suggests that they dispersed regularly or repulsively in the short ranges. This distribution is due to the fact that the residual cement particles still have their own particle sizes. In particular, some of them are still large since it is at an early age of 1d. Therefore, points of the centroids cannot be closer each other.

Fig.5 Distribution of unhydrated cement particles in cement pastes with a high w/c of 0.60; (a) K-function of unhydrated cement (b) G-function of unhydrated cement

Fig.6 Distribution of capillary pores in cement pastes with a high w/c of 0.60; (a) K-function of pores (b) G-function of pores

On the other hand, situation of capillary pores (Fig.4) is different from that of the cement particles. When a superplasticizer is used, the K-function of the pores is almost the same as the Poisson process (Fig.4(a)). However, the K-function of the pores in cement paste without the superplasticizer exhibited a clustered pattern. The G-function of the pores in cement paste with the admixture exhibited a regular pattern within the distance of  $20\mu\text{m}$ , then followed the Poisson process beyond  $20\mu\text{m}$ . As for the pores in cement paste without the admixture, their distribution pattern varies with distances. In the range less than  $20\mu\text{m}$ , they are distributed regularly as well as in the cement paste with the admixture. In the range from about 20 to  $40\mu\text{m}$ , a clustered pattern is observed. However, beyond about  $40\mu\text{m}$ , the pattern follows a regular pattern again. It seems that the pores in the cement paste without the admixture are distributed more inhomogeneously. This heterogeneity is also found from convergence distances of the G-function. The convergence distance without the admixture is appreciably greater than that with the superplasticizer. This suggests that it is necessary to observe larger areas for unbiased evaluation of pore patterns since the pores disperse heterogeneously.

Fig.5 shows K- and G- functions of unhydrated cement in cement pastes with a water/cement ratio of 0.60. In this case, effects of bleeding on spatial distribution are of interest. Therefore, comparison is made between the distributions with and without the VE admixture. Cement particles in the cement pastes follow the Poisson process as well as at the water/cement ratio of 0.30. In other words, those particles dispersed randomly regardless of the addition of the VE admixture. Actually, bleeding was observed in the

specimens without the admixture. In this study, samples were taken from the middle of the height of specimens. In spite of some segregation, cement particles could disperse randomly in the middle of specimens. Capillary pores (Fig.6) also exhibit the similar patterns to those at the water/cement ratio of 0.30 (Fig.3). When the VE admixture was not used, the pores exhibited a clustered pattern (Fig. 6(a)). In the range of short distances, capillary pores were clustered between 20 and 40 $\mu\text{m}$  (Fig.6(b)). Their distribution is heterogeneous like the distribution with the w/c of 0.30.

It is found from Figs. 3 to Fig.6 that the admixtures did not greatly affect spatial distribution of cement particles in cement pastes. However, distribution of capillary pores was influenced by the admixtures to some extent. When the admixtures were used, their distribution became closer to the Poisson process as a whole. In other words, as long as cement pastes are workable due to the addition of the admixtures, cement particles and capillary pores disperse more randomly. However, if they are not used, inhomogeneous distribution appears for capillary pores. Capillary pores are considered as a complementary set of cement particles. However, they showed clustered patterns whereas cement particles showed almost random ones. This suggests that the evolution of pore structure depends on not only the initial arrangement of cement but also subsequent local geometrical conditions, which are changed by deposition of hydration products.

### 3.2 Spatial structure of cement particles and pores in mortar

Fig.7 shows covariance functions of cement paste matrices in mortars. It is difficult to specify a characteristic distance at which the function converges on the square of a volume fraction of the matrix. However, at least, it seems that two points are independent each other when the distance between them is beyond a few hundreds  $\mu\text{m}$ . Theoretically, the covariance at zero distance is equal to the area fraction (i.e. the volume fraction) of cement paste matrix in each mortar. They are 0.43 for the mortars with a w/c of 0.30, and 0.54 for them with a w/c of 0.60. When the chemical admixtures were used to obtain workable mixtures, the y-intercepts were almost the same as those theoretical values. However, in the mortars without the admixtures, there were certain differences between the theoretical values and experimental evaluations. This reflects inhomogeneous internal structure in the mortars with less workability.

Fig.8 shows K-functions of cement particles and capillary pores in mortars with a w/c of 0.30. In actual mortars, they are not allowed to disperse freely since there are aggregate particles. Therefore, the particles must exhibit clustered patterns. Actually, as expected, they exhibited clustered patterns in mortars. If these K functions for actual mortars agree with those for thinned point processes, then the actual distribution of the particles could be simulated by a simple thinning operation for the corresponding cement pastes. In view of the results of the thinning operation for cement particles in Fig.6(a), as expected, the particles in the thinned process exhibited clustered patterns regardless of the use of superplasticizer. In particular, a greater clustering tendency was seen when the superplasticizer was not used. Such a clustered distribution resulted from the fact that locations of cement particles were confined

Fig.7 Covariance functions of cement paste matrices in mortars with and without admixtures

Fig.8 Comparison of K-functions of cement particles and pores between thinned processes and actual mortars with a w/c of 0.30; (a) cement particles (b) capillary pores

in the thinned point process also. The distribution of cement particles in actual mortars without the superplasticizer was similar to that in the thinned process in the range of a short distance up to 200 $\mu\text{m}$ . However, beyond this distance, the K function of cement in actual mortars showed less clustering than the simulation without the admixture. In other words, expected clustering of cement particles was mitigated. Contrary to this, there is little difference in the K-functions of cement particles and capillary pores between actual mortars and the thinned processes with the admixture. The agreement of the K-functions between the actual and the simulated point processes suggests that presence of aggregate particles simply reduces room for the particles. It does not affect spatial arrangement between the dispersed particles. This is quite different from the mortars without the admixture where clustering of the particles was appreciably mitigated by being mixed with aggregate.

Fig.9 also shows comparison of the K-functions at w/c of 0.60. As well as the distribution at w/c of 0.30 (Fig.8(a)), cement particles in the thinned processes were clustered (Fig.9(a)). When they were mixed with sand, their clustering was mitigated. Distributions of cement particles in the actual mortars were closer to the Poisson process. Mitigation of clustering was also clearly seen in distribution of capillary pores in mortars without the admixture. The K-functions for the actual mortars are appreciably smaller than those for the thinned processes. However, if the VE admixture was used, there were no differences in distribution of the pores between the thinned processes and the actual mortars. As long as the VE admixture was used as to obtain workable mixtures, in which no segregation occurred, spatial arrangement of capillary pores could be represented by the simulation. Deleting points in accordance with probability of being a matrix led to the actual distribution. Aggregate particles just played a role to reduce room for capillary pores.

#### 4. Discussion

It is found from Figs. 8 and 9 that aggregate mitigates clustering of the particles in mortars without chemical admixtures. As a result, distribution patterns become closer to the Poisson point process. On the other hand, when a superplasticizer or a viscosity enhancement admixture is used, effects of aggregate on spatial distributions of the particles are decreased so that characteristics of original distribution of cement and pores in workable cement pastes are substantially maintained in the mortars. Therefore, if the mixtures are workable, it is possible to simulate spatial distributions of constituent particles such as unhydrated cement and capillary pores by the thinning operation. The cement paste matrix in the workable mixture provides a random field in which the particles can survive. Each individual particle does not interfere with other particles.

In addition to workability, water/cement ratios also affect spatial distribution of the particles. When the superplasticizer was used, there was little difference in the K-functions of unhydrated cement particles between the thinned process and actual mortars at w/c of 0.30. On the other hand, when the viscosity enhancement admixture was used at w/c of 0.60, the K-function of unhydrated cement in actual mortars was smaller than in the thinned process. This means clustering of cement was mitigated at w/c of 0.60 whereas substantial mitigation was not seen at lower w/c of 0.30. This mitigation may result from a shear effect of aggregate particles, which breaks flocculation of cement particles during mixing of mortars. In order to break flocculation of cement, room for dispersion is necessary. At low w/c of 0.30, there is not enough margin for dispersing cement particles. As a result, similar distributions of cement are present in both of actual mortars and the thinned processes. However, at high w/c of 0.60, there is sufficient room for

Fig.9 Comparison of K-function of cement particles and pores between thinned processes and actual mortars with a w/c of 0.60; (a) cement particles (b) capillary pores 584

dispersion of cement particles. Therefore, more random distribution of cement is possible so that the K-function of unhydrated cement in actual mortars is closer to the Poisson process.

## 5. Conclusions

In order to quantitatively evaluate spatial distribution of constituent particles of cement and capillary pores at early ages, the point process statistics was applied to 2-D distribution of unhydrated cement particles and capillary pores, which were segmented from backscattered electron images of cement pastes and mortars. Effects of the addition of a superplasticizer and a viscosity enhancement admixture on distribution of those particles were discussed in terms of summary statistics of the K-function and the nearest neighbor distance function (G-function). Effects of aggregate particles on distribution of those particles were also investigated based on the comparison between the simulated point patterns and the actual distributions in mortars. In the simulation, a cement paste matrix in each mortar was considered as a random field to keep the particles. The point process statistics were successful in evaluating differences in spatial distributions for cement and capillary pores. Major outcomes of this study are as follows;

- (1) In cement paste specimens, effects of the addition of a superplasticizer and a viscosity enhancement admixture on distribution of cement particles were relatively small. They distributed almost randomly irrespective of the chemical admixtures.
- (2) Capillary pores in cement paste specimens exhibited clustered distribution when the specimens didn't have proper workability. However, when the admixtures were used to obtain proper workability, clustering of capillary pores was mitigated. Their distributions followed a completely random process.
- (3) In the cement pastes without the admixtures, spatial distribution of capillary pores was inhomogeneous in the range of short distances.
- (4) Clustering of cement particles and capillary pores were mitigated in mortars with an unworkable cement paste matrix. Their distributions were closer to the random pattern.
- (5) In mortars with a workable matrix, characteristics of random distribution in the corresponding cement paste were largely maintained in the mortar.
- (6) If mortars are workable, distribution of cement particles and capillary pores in the mortars could be represented by the thinning operation, in which a cement paste matrix was regarded as a random field.
- (7) Effect of aggregate particles on spatial distribution of cement particles depended on water/cement ratios of the mixtures. Clustering of cement particles was effectively mitigated at a high w/c. The aggregate made a distribution of cement particles closer to the random point arrangement.

**Abstract:** The development of alkali activated binders with equivalent or better engineering properties has emerged as an alternative to Portland cement concrete. It is possible to use alkali activated fly ash to prepare environmentally friendly geopolymer concrete, which contribute to sustainable development. This paper presents a summary of an experimental program that has been conducted to determine mechanical properties of geopolymer concrete prepared with five different fly ashes obtained from different power plants in Australia. The variation in optimum 28-day compressive strength for the five fly ash based geopolymers was observed to be between 21.3 and 40.6MPa. The applicability of current relationships between compressive strength and tensile and elastic properties of concrete in AS 3600 for the range of fly ash geopolymers was then examined. The analysis showed that the flexural strengths of all geopolymer concretes are higher than the prediction of AS 3600, however, splitting tensile results appeared to depend on the fly ash source. When compressive strengths of fly ash based geopolymer concrete are below 40 MPa the model employed by AS 3600 for Portland cement concrete overestimates the modulus of elasticity. The Poisson's ratio's lie in the range reported for Portland cement concrete and show a general increase with increasing of compressive strength.

## 1. Introduction

Concrete made with Portland cement (PC) is a major construction material used worldwide. However, the production of PC releases large amounts of CO<sub>2</sub> into the atmosphere, making a major contribution to the greenhouse effect and the global warming of the planet. The PC production involves very high temperatures (1400 to 1500 °C) and contributes between 5-7% of the anthropogenic CO<sub>2</sub> emissions worldwide [1, 2], with the production of 1 tonne of Portland cement producing from 0.6 up to 1 tonne of CO<sub>2</sub>, depending on the performance of cement kilns [3-7]. The 100% fly ash cements, widely known as geopolymer, is an emerging cementitious materials with greatest potential to provide a feasible alternative to PC in terms of CO<sub>2</sub> emissions. It is estimated that CO<sub>2</sub> emissions can be reduced by 26-45% with the replacement of PC concrete with geopolymer concrete [7, 8].

Fly ash (FA) production has increased up to 900 million tonnes per year by 2008 and it is anticipated to increase up to about 2000 million tonnes in 2020 [9]. While about 45% of this is being utilized for various purposes including cement and concrete production the balance is disposed of in landfills and storage lagoons at significant cost, posing a huge potential risk to local aquifers due to the possible leaching of heavy metals. Thus, producing geopolymer binders using FA is an added benefit is to convert a waste product into a useful by-product, conserving landfills and storage lagoons [10]. In the geopolymerization process, silica and alumina molecules contained in the FA react under highly alkaline conditions, typically provided by sodium based hydroxide and silicate solution. FA geopolymers need heat curing to increase the geopolymerization reaction while slag based geopolymers react at lower temperatures. However, couple with other environmental issues, FA based geopolymer production can contribute to precast concrete products such as structural elements, railway slippers and sewer pipes which can be highly resistant to the aggressive environments and fire expose.

In geopolymerization process, an amorphous three-dimensional network of silicon and aluminum atoms are linked by oxygen atoms in a four-fold coordination similar to the one exhibited by zeolites. While the formation mechanism of the geopolymer network is still debated, it was suggested that the reaction can be divided into three main stages, i.e. dissolution of silicate and aluminate species from the FA, transportation and coagulation/gelation, and condensation forming a three-dimensional network of alumino-silicates.

A number of studies have been conducted to investigate the material properties of FA geopolymer concretes and demonstrated the similarity of FA based geopolymer concrete to PC concrete in terms of the mechanical properties. However, most of the studies to date investigated the mechanical properties using a single type FA in each study using a mixing process unique to that study. The present study aims to investigate key mechanical properties of geopolymer concretes made with five Australian FAs with a range of chemical and physical properties, using the same mixing process. The mechanical properties investigated were compressive strength, tensile strength, modulus of elasticity and Poisson's ratio. The variation of test results in different FA geopolymers are explained in conjunction with the applicability of current relationships between compressive strength and the mechanical properties based on AS 3600 [11]. Finally, test results will be compared with previously reported research on mechanical properties of geopolymer concrete.

## 2. Experimental work

### 2.1. Materials

Class F fly ash conforming to Australian standard, AS 3582.1 were obtained from Gladstone(G), Port Augusta(PA), Collie(C), Mount Piper(MP) and Tarong(T) power stations in Australia. The chemical composition, particle size distribution and mineralogical composition of each FA, determined by X-ray fluorescence (XRF), Malvern particle size analyser instruments and X-ray diffraction (XRD), respectively are shown in Table 1, 2 and 3. Brunauer Emmett Teller (BET) method by N<sub>2</sub> absorption was used to determine the FA surface area. The alkaline liquid used in geopolymers consisted of a mixture of commercially available sodium silicate solution with a specific gravity of 1.53 and an alkaline modulus ratio (Ms) equal to 2 (where Ms= SiO<sub>2</sub>/Na<sub>2</sub>O, Na<sub>2</sub>O=14.7% and SiO<sub>2</sub>=29.4% by mass), and sodium hydroxide solution (15M). Both coarse and fine aggregate were prepared in accordance with AS 1141.5. The moisture condition of the aggregate was in a saturated surface dry condition. The fine aggregate was river sand in uncrushed form with a specific gravity of 2.5 and a fineness modulus of 3.0. The coarse aggregate was crushed basalt aggregate of two-grain sizes: 7 mm (2.58 specific gravity and 1.60% water absorption) and 10 mm (2.62% and 0.74%). Demineralized water was used throughout the experiment.

## 2.2. Mix designs

A similar mix design procedure, based on FA geopolymer mortar, reported in reference [12] is used to optimize the mix design for each FA geopolymer concrete. The blended sodium silicate and sodium hydroxide solutions are characterized by the activator modulus (AM), i.e. SiO<sub>2</sub> to Na<sub>2</sub>O ratio in the activator solution, was varied from 0.75 to 1.75 by 0.125 intervals, until the optimum compressive strength for each FA geopolymer concrete at 28 days. Table 4 shows the ingredients of each optimum mix design. In this study, the Na<sub>2</sub>O dosage is fixed at 15% while the total aggregate in the concrete was kept to 64% of the entire mixture by volume for all mixes. The ratio of ingredients (FA, chemical activator, aggregate, and water) was calculated based on the absolute volume method [13], as a result, the total weight of binder and water was varied to keep the volume of material and water/solid ratio (0.37) constant. The mass of water in the mix was taken as the sum of mass of water contained in the sodium silicate, sodium hydroxide and added water. The mass of solid is taken as the sum of FA, the solids in the sodium silicate solution and the sodium oxide pellets.

**Table 4. Optimum mix design details (kg/m<sup>3</sup>)**

## 2.3. Mixing, curing and testing

The mixing of geopolymer concrete was carried out using a 90 litre concrete mixer. The dry materials (FA, fine and coarse aggregates) were mixed first for 4 minutes. Then activator and water were added to the dry mix and mixed continuously for another 8 minutes until the mixture was glossy and well combined. The mixture was then poured into moulds and vibrated using a vibration table for 1 minute to remove air bubbles. After vibration the moulds were kept at room temperature for 1 day and then heat cured in an oven for 24 hours at 80°C temperature with 95% relative humidity. The inside surfaces of the moulds were coated with a high performance silicon grease to prevent the samples from sticking to the moulds surface during the heat curing process. Moulds were removed from the oven and left to cool to room temperature before demoulding, and then the samples were kept at room temperature.

Compressive strength test was performed by MTS machine with a loading rate of 20MPa/min according to AS 1012.9. The flexural tensile strength and splitting tensile strength tests were conducted to determine the tensile strength of fly ash based geopolymer concretes in accordance with AS 1012.11 and AS 1012.10, respectively. The flexural tensile strength test was carried out on a MTS machine with additional testing apparatus under a four point bending test with a loading rate of 1 MPa/min. The indirect tensile strength test was performed on MTS machine equipped with indirect tensile strength test equipment under a loading rate of 1.5 MPa/min. The static elastic modulus and poisson's ratio of geopolymer concretes was determined using TCM machine coupled with the compressometer/extensometer with a loading rate of 0.25 MPa/sec in accordance with AS 1012.17. The dry density of hardened geopolymer concrete was determined accordance with AS 1012.12.2. All tests were conducted at 28 days of casting. The reported test results in each specific test are an average of three samples.

## 3. Results and discussion

The 28-day strength properties related to different FA geopolymer concretes are presented in Table 5. Density of geopolymer concrete ranged from 2017 to 2167 kg/m<sup>3</sup> which agrees with the previously reported work [14, 15]. The density of FA geopolymer concrete is generally lower than PC concrete which is characteristically cited with a density of approximately 2400 kg/m<sup>3</sup> in accordance with Australian standard, AS 3600. This might be attributable to the specific gravity of the raw materials used to produce FA geopolymer concrete, i.e. experimentally measured specific gravity of the FA is 2.0–2.3 which is lower than that of PC with a specific gravity of 3.0–3.2. In contrast, all FA geopolymers except MPFA displayed a very high, collapsed slump, thus workability of this study is

represented by the average diameter of slump flow ranging from 365mm to 665mm. Demie et.al [16] also reported higher slump flow values attributed to low calcium FA which ranged between 625mm to 710mm. This is attributed to the spherical shape of fly ash particles combined with the lubricating effect of sodium silicate solution. However, MPFA leads to a very stiff mix and achieved a low workability with 40mm slump height.

**Table 5. Experimentally measured strength properties**

Geopolymer	Workability (Slump flow mm)	Dry density (kg/m <sup>3</sup> )	Strength property (MPa)		
			Compressive strength (fc)	Splitting tensile strength (fct.sp)	Flexural tensile strength (fct.f)
GFA	665	2142.1	40.6	3.67	5.07
PAFA	645	2017.9	33.5	2.87	4.40
TFA	560	2164.2	31.0	1.84	4.13
CFA	365	2115.8	22.8	2.78	4.56
*MPFA	-	2166.2	21.3	0.94	3.22

\*40mm of slump height is achieved.

### 3.1 Compressive Strength

In this study, the compressive strength ranged from 21.3 to 40.6 MPa while highest and lowest values were obtained by GFA and MPFA geopolymers, respectively. As specified in AS 3600, the 28 day compressive strength for standard site concrete under exposure classification B1 and B2 is  $40 \pm 10$  MPa. However, only GFA, PAFA and TFA geopolymers achieved this strength. The compressive strength achieved by other two geopolymer concretes only satisfied the exposure classification A1 compressive strength of 20 MPa. Hence, this significant variation of data clearly shows that properties of geopolymer concretes are strongly dependent on the characteristics of the source material, that is type of FA used in here. The GFA has highest surface area with higher level of finer particles passing at 10, 20 and 45 micron sieves. It further consists with higher percentage of reactive alumina-silica amorphous phase. Formation of aluminosilicate gel,  $[\text{Na}_z(\text{AlO}_2)_x(\text{SiO}_2)_y \cdot \text{NaOH} \cdot \text{H}_2\text{O}]$ , in the geopolymerization process primarily relies on the extent of dissolution of FA. The finer particles coupled with greater surface area increase the reactivity of FA, because a significant part of the reaction occurs at the particle-liquid interface [17]. On the other hand, the reactive amorphous alumina-silica species contained in FA precursor rapidly reacts with alkaline activator. Thus, aforementioned properties of GFA are attributed to the rapid gel formation, the dominant step in formation of an amorphous structure of FA geopolymers which determined the highest compressive strength for GFA.

The CFA and MPFA have lowest surface area coupled with higher percentage of coarser particles, Table 2, i.e. lower level of finer particles passing at 10, 20, 45 micron sieves. Hence, these FA characteristics lead both geopolymers to the lowest compressive strength while contained with high amount of reactive amorphous alumina-silica species than GFA. As well, both geopolymers show lower workability than GFA, which is also attributed to the higher content of coarser particles. Because, during the mixing of geopolymer, the activator solution demand rises as the fineness of the FA decreases due to the need to fill larger voids among coarser FA particles to achieve a workable material. And also high unburnt carbon in FA acts as an inert particulate and absorbs the activator solution [17], hence this further reduced the workability of MPFA, making a stiff, non-workable concrete mix.

While the PAFA and TFA contain higher percentage of finer particles (percentage passing at 10, 20, 45 micron sieves), both surface area and reactive amorphous content of these FAs are lower than GFA. This leads both geopolymers towards the moderate compressive strengths. Moreover, the PAFA has highest CaO percentage while TFA has the lowest. A high content of CaO in the FA allows the calcium silicate glass structure in the FA to react with the water and to form calcium silicate hydrate (C-S-H) compounds that improve the compressive strength of the resultant geopolymer. On the other hand, TFA contains higher unburnt carbon which attributes to its lower workability than PAFA. Hence, highest CaO coupled with lower unburnt carbon in PAFA leads to a slightly better compressive strength and workability though it has lower surface area than TFA.

### 3.2 Tensile Strength

Tensile strength of geopolymer concrete was measured using both splitting tensile and flexural tensile strength tests. The splitting tensile strength varied between 0.94 and 3.67MPa, whereas, the flexural tensile strength ranged from 3.22 to 5.07 MPa (Table 5). The flexural strength ranged between 12 and 20% of the compressive strength, compared to a range of 9 to 12% typically cited for PC concrete. Diaz-loya et al. [14] also reported a similar trend, that the flexural strength ranged between 7 and 26% of the compressive strength. The splitting tensile strength in this study ranged between 4 and 13% of the compressive strength which agreed with the Literature [18].

Similar to compressive strength, GFA gave the highest splitting and flexural tensile strength results while MPFA had the lowest. Fly ash is dissolved in sodium hydroxide while forming a gel layer on their surfaces. Then gel diffuses outward from the particle surface into larger interstitial spaces between the particles with precipitation of gel and concurrent dissolution of new fly ash grains. When the gel phase hardens, the separate fly ash particles are bound together by the gel which acts as a binder [19]. Tensile strength of FA geopolymer is highly dependent on the bond between this gel binder and aggregates. Due to high reactivity and concurrent gel formation of GFA geopolymer produce a strong bond between aggregates and gel binder which contributes to the highest tensile strength in concrete. In contrast, MPFA contains high unburnt carbon content which is hypothesised as weakening the bonding with aggregates, thus lower dissolution, reactivity and gel formation coupled with weak bonding characterise the lower tensile strength achieved in MPFA.

While TFA had a compressive strength in excess of 30 MPa, it had relatively low splitting tensile strength. Fernandez-Jimenez et.al [20] has reported that presence of  $\text{Si}^{+4}$  ions in the alkaline solution has a substantial negative effect on the very strong matrix/aggregate bond. TFA contains the higher amorphous  $\text{SiO}_2$  content, which may result in more  $\text{Si}^{+4}$  ions being leached into the alkaline solution and hypothesized as remaining as free ions, leads to lower tensile strengths. Though CFA geopolymer achieved very low compressive strength, it shows higher tensile strength which is almost similar to PAFA. This indicates that while CFA gel binder has less strength, it creates better bonding with aggregates. However, further study needs to verify this behaviour.

The uniaxial tensile strength of FA geopolymer concretes is calculated in accordance with AS 3600. The calculated uniaxial tensile strength based on measured flexural strength is higher than calculations based on splitting tensile strength in all geopolymers, except GFA which shows slightly higher value. However, both TFA and MPFA geopolymers showed significant variation in uniaxial tensile strength based on splitting and flexural strength data. Thus the choice of the test on which to base the uniaxial tensile strength is a critical factor. According to Neville [13], the splitting test is both simple to perform and gives more uniform results than flexural strength test. The splitting test gave the most conservative estimates for the uniaxial strength, which would provide more confidence in designing structures and as such would be recommended as the most appropriate test for geopolymer concretes.

**Table 6. Calculated uniaxial tensile strength,  $f_{ct}$  based on AS 3600**

Geopolymer	Based on Split tensile strength $f_{ct} = 0.9f_{ct.sp}$	Based on Flexural tensile strength $f_{ct} = 0.6f_{ct.f}$
GFA	3.28	3.14
PAFA	2.58	2.64
TFA	1.66	2.48
CFA	2.50	2.74
MPFA	0.85	1.93

### 3.3 Relationship between compressive and tensile strengths

For design calculations, it is usual to estimate the tensile strength from the compressive strength for PC concretes which is illustrated in AS 3600. In order to examine the applicability of this relationship for geopolymer concretes, splitting tensile and flexural strength data were plotted against measured compressive strengths of five concretes at Figure 1 and 2, respectively. Previously reported results and derivations based on FA geopolymers were reported in order to verify the spread of the present experimental data.

Figure 1. Splitting tensile strength vs. compressive strength

Figure 2. Flexural strength vs. compressive strength

Previously reported splitting strength data were based on the single type of FA and all of them exceeded the AS 3600 model whilst demonstrating spread of results (Figure 1). Three of five examined geopolymers, namely GFA, PAFA and CFA, achieved the splitting tensile

strengths above the AS 3600 prediction of PC concrete and Ryu et.al's [18] prediction of geopolymer concretes. However, TFA and MPFA geopolymer concretes had measured splitting tensile strength below those predicted by the AS 3600. This indicates that the correlation of splitting tensile strength with compressive strength depends on the type of FA used as source material and there is no direct relationship between the compressive and tensile strength of geopolymer concrete made with different FA materials. In contrast, both experimentally measured and previously reported flexural strengths of FA geopolymer concretes exceeded the prediction of AS 3600, Figure 2. That is unlike splitting tensile data, all five fly ash geopolymers showed the conservative approach at the design stage. In previously reported results, except Diaz-loya et.al. [14], all others worked with single type of FA. The present study results are slightly higher than the previously reported relationships by Diaz-Loya et al. [14] for geopolymer concrete. Hence, this analysis confirmed that while flexural strength is changed based on the type of FA, those variations may not affect the design standards.

### 3.4 Modulus of Elasticity and poisson's ratio

**Table 7. Experimentally measured elastic properties**

GP	Elastic property	
	Modulus of Elasticity Ec, (GPa)	Poisson's ratio
GFA	24.3	0.16
PAFA	14.8	0.18
TFA	8.3	0.13
CFA	16.2	0.10
MPFA	11.4	0.09

The modulus of elasticity is a property of concrete defined as the stress retained to induce a unit strain within the elastic limit. A higher modulus of elasticity indicates a better quality of concrete. Measured modulus of elasticity and poisson's ratio of five FA geopolymer concretes are presented in Table 7. Modulus of elasticity of five FA geopolymers ranged from 8.3 to 24.3 GPa. The elastic modulus of geopolymer concrete is affected by the curing temperature, i.e. if water is lost due to evaporation at higher temperature curing before the full strength is gained, modulus of elasticity reduces [21]. MPFA geopolymer initially produced very stiff, non-workable mix that is opposed to the GFA mix which has highest workability, thus this workability difference which reflects the content of water in the initial geopolymer mix, may be attributed to the significant variation of concrete stiffness among the two geopolymers. On the other hand, formation of micro-cracks at the geopolymerization process with a higher curing temperature may reduce the stiffness of geopolymers than PC concrete. Liu et.al. [22] also reported that the pore volume and elastic modulus have a liner relationship, as the increase in the density of the geopolymer concrete enhances the stiffness. However, the present study showed FA geopolymer concretes have lower density compared to typical PC concrete that is again a factor of overall reduction of elastic modulus of FA geopolymers than PC concrete. The formation of micro-cracks at the geopolymerization of TFA is hence hypothesized as the reason for lowest elastic modulus observed despite having high compressive strength. However detailed microstructural analysis is required to confirm this phenomenon. PAFA and CFA geopolymers achieved moderate elastic modulus, however, the stiffness achieved by CFA is suspicious with respect to its lowest compressive strength and need further studies to understand the reason behind that.

The previously reported modulus of elasticity data coupled with present experimental data are plotted in Figure 3 against respective compressive strengths. Two regression models based on AS 3600 and Diaz-loya et.al. [14] are also presented in the same graph in order to compare the test results. In this study, only the elastic modulus of GFA was observed to fall within the limits provided by the AS 3600. The CFA concrete just achieves the lower limit of the standard though it has very low compressive strength, but all the other geopolymer concrete mixes fall below the lower limit. Analysis of these results and other data would suggest that if the concrete achieves a compressive strength greater than 40MPa, then the material will have a modulus of elasticity above the lower bound as predicted in AS 3600. Dias-loya et.al.[14] as well worked with range of fly ashes and his results confirmed this finding. Thus, when compressive strengths of fly ash geopolymer concrete are below 40MPa, the model in AS 3600 for PC concrete overestimates the modulus of elasticity when applied to FA geopolymer concretes.

**Figure 3. Modulus of elasticity vs. compressive strength**

The experimentally measured poisson's ratio of five FA geopolymers ranged between 0.09 and 0.18. Poisson's ratio values of PC concrete can range from 0.11 to 0.21 but usually fall in the range from 0.15 to 0.20 [23]. Values obtained for the geopolymer concretes, tend to populate the lower end of this range. The Poisson's ratio data in this study showed an increase with an increase of compressive strength while GFA showed a slight reduction than PAFA. A similar trend has reported by Setunge et.al. [24], which refers to the Poisson's ratio of high strength concrete.

#### 4. Conclusion

Based on the results of the experimental study, the following conclusions can be made:

- The density of FA geopolymer concrete is lower than PC concrete which is attributed to the lower specific gravity of the FA used to produce geopolymer concrete.
- The compressive strength of five different FA based geopolymers ranged from 21.3 to 40.6MPa. This strength variation is attributed to the characteristics of specific FA, mainly three parameters identified, i.e. surface area of FA coupled with amount of finer particles passing at 10, 20 and 45 micron sieves, the reactive amorphous alumina-silica percentage and CaO content of FA.
- Tensile strength of FA geopolymer concretes is also affected by the specific FA type. The splitting tensile strength varied between 0.94 and 3.67MPa whereas, the flexural tensile strength ranged from 3.22 to 5.07 MPa. Tensile strength of FA geopolymer concrete is dependent on the bond between aggregates and gel binder; that strong bond formation will leads to a higher reactivity and concurrent gel formation of FA which is again governed by the fineness and surface area.
- The unburnt carbon in FA precursor is hypothesised as weakening the bonding between geopolymeric binder and aggregates which is confirmed by the MPFA with lowest tensile strength. TFA contains the higher amorphous SiO<sub>2</sub> content, which may result in more Si<sup>4+</sup> ions being leached into the alkaline solution and hypothesized to stay as free cations that reduce the formation of very strong matrix/aggregate bond hence the lower tensile strengths achieved.

- The correlation between splitting tensile and compressive strength relies on a specific FA type, thus applicability of AS 3600 prediction is dependent on the FA source. However, flexural strength values of FA geopolymer concretes are higher than the AS 3600 predictions, while flexural strength is varied with FA source. In contrast, splitting test gave the most conservative estimates for the uniaxial tensile strength, hence would be recommended as the most appropriate test for design of FA geopolymer concrete structures.
- Modulus of elasticity of five FA geopolymers ranged from 8.3 to 24.3 GPa. The workability difference which reflects the content of water in the initial geopolymer mix affects the stiffness of the heat cured FA geopolymer concrete. This may be the reason for lower and highest elastic modulus for MPFA and GFA, respectively. The formation of extra micro-cracks at the geopolymerization of TFA is believed to be the reason for its lowest stiffness.
- When compressive strength of FA geopolymer concrete below is 40MPa, the model in AS 3600 for PC concrete overestimates the modulus of elasticity of geopolymer concretes.

## 5. Acknowledgement

The authors wish to express their thanks to Cement Australia Pty Ltd. and Flyash Australia Pty Ltd for the supply of fly ash. PhD scholarship provided by the school of Civil, Environmental and Chemical Engineering of RMIT is gratefully acknowledged.

**Abstract:** This document provides a summary of results for the comprehensive test program to investigate the properties and performance of General Purpose (Type GP) cement prepared with up to 12% limestone content. An extensive literature review was carried out initially, and then an experimental research program designed. Cement, mortar, and concrete tests were conducted on a variety of mixes to evaluate the effect of introducing higher limestone mineral addition content to cement. The test results showed that there is no significant effect on most concrete properties due to increasing the limestone addition in cement. The result of this research supports the recommendation to increase the allowable limestone content of General Purpose (Type GP) cement to a maximum of 12%.

**Keywords:** General purpose (GP) cements; Limestone cement; Australian Standard AS 3972; Australian Standard AS 2350; Sulfate expansion; Rapid chloride penetration

## 1. Preface

The intent of the testing program was to study whether there is any detrimental effect on cement or concrete performance from the use of limestone mineral addition levels higher than the 7.5% allowed in AS 3972-2010 [1]. The upper limit chosen for this test program is 12%, based on the prevailing technical literature at the time the program was designed.

The program was designed and completed over 3 years (2011-2014) in two main stages under the supervision of Standard Australia BD-010 Working Group members. After the first stage of this research was completed, several members of the BD-010 Working Group sought to determine the effect of increasing limestone content in the cement used in a number of specific concrete systems. Therefore, an additional suite of tests was agreed among Committee members and carried out in 2014. The results of both research stages were documented and presented in two reports [2,3].

During the course of research program, combinations of different types of cementitious materials with plain Type GP cement were tested. Both plain cement and combinations of cement with supplementary cementitious materials (SCMs) were utilised to prepare cement paste, mortar, grout and different specific types of concrete samples. The research program included examining both laboratory and commercial mix designs. The suite of binder combinations included over two hundred different commercial concrete mixes, and involved standard laboratory mix designs, industrial grouts, normal and structural concrete grades, self-compacting, high-strength and durable concretes. The results of this research support the recommendation to increase the allowable limestone content of General Purpose (Type GP) cement to a maximum of 12%.

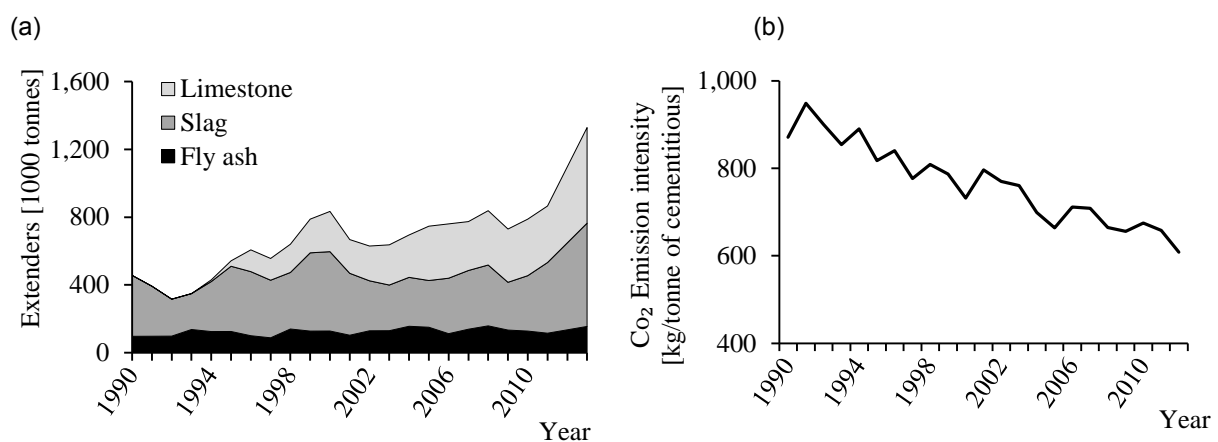

## 2. International Context for Cements with higher Limestone Contents

There is a strong international alignment for producing cement with higher limestone contents. For the past two decades European standards have permitted up to 20% and 35% limestone content for widely used CEM II types A/L and B/L, respectively. In a similar but later approach, Canada in 2008 and then in the USA in 2012 permitted higher limestone content in manufactured cement up to 15%.

The intent of this testing program is very clear. It is to determine whether there is any detrimental effect on cement or concrete performance from the use of limestone mineral addition levels higher than 7.5%, congruent with international practice.

### 3. Environmental Benefits of Cement manufactured with Higher Limestone Content

In the Australian context, the need to continue emissions reduction is clear. There is a long history of the use of supplementary cementitious materials in concrete in Australia. More recent data regarding the use of mineral additions in cement manufacturing are presented in Figure 1 (a). According to the Cement Industry Federation, gross emissions in 2010 were as shown in Figure 1 (b), at 660 kg per tonne of cementitious products, and further reductions have been seen in subsequent years [4]. A little over 25% reduction has been achieved since 1990. However, with community requirements influencing the use of alternative fuels, limited opportunity for thermal and electrical efficiency gains due to the relatively young age of cement manufacturing equipment, and little or no exploration of carbon capture & storage (CCS) strategies, clinker substitution remains the only viable alternative for emissions reduction. The most recent data, illustrated in Figure 1 (b), shows a continued downward trend in 2013/2014, co-incident with the increase in allowable mineral addition in cement. To continue this trend, an increase in mineral addition in the most commonly used cements is required.

**Figure 1: (a) Use of mineral components in Australian cement manufacture 1990-2012, (b) CO<sub>2</sub> emissions per tonne cementitious product produced, - Australia- 1990-2013 [4]**

Overall, from an environmental point of view, intergrinding of limestone and clinker reduces clinker content of cement, saves energy and produces cement with lower embodied CO<sub>2</sub> emissions. The use of mineral additions reduces the embodied emissions in cement roughly in proportion to the reduction in proportion of clinker in the cement. Increasing the mineral addition content of cement provides more sustainable Type GP cement, without compromising the existing structural and durability properties of concrete made with it.

### 4. Research Methodology

In practice, the achievable level of mineral addition and the material used as mineral addition will be determined by the cement manufacturer. Such decisions will be made with due reference to market requirements, cement manufacturing equipment capability and the availability of allowable materials. The cement Standard will prescribe the maximum level of allowable mineral addition in cements, but the actual level may vary from one cement manufacturer to another, as has always been the case.

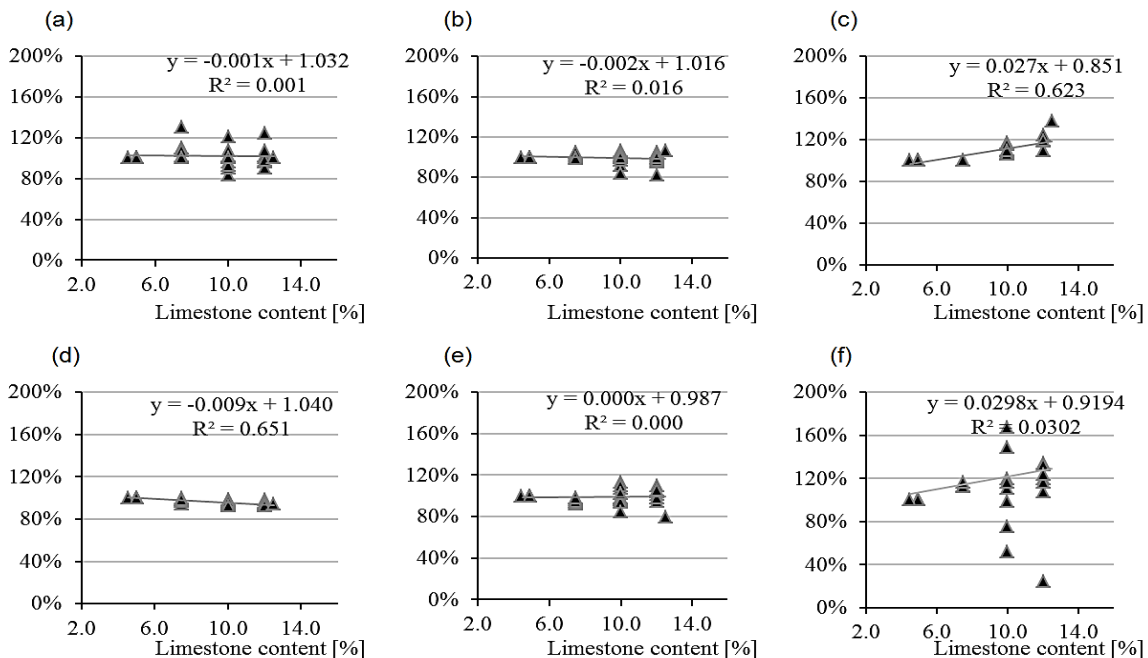

More than 200 high-quality international published research documents were reviewed. Accordingly a research methodology was selected which is congruent with the American research “Specifications and Protocols for Acceptance Tests on Processing Additions in Cement Manufacturing” conducted by NCHRP [5]. The statistical evaluation involved three stages. Firstly, investigating any correlation between laboratory test results and limestone content of cement; secondly, checking the compliance of the test results with Australian standards and industry specifications; and, finally, investigating if any significant change in properties of cement, mortar or concrete is due to the increase in limestone content of General Purpose (Type GP) cement by conducting experimental inferential analysis.

## 5. Results and Discussion

### 5.1. Cement, Cement Paste and Mortar Results

In total, 43 binder combinations from different Australian manufacturers were prepared, using Type GP cement and flyash or slag. Limestones used were sourced from the mines used by each of the cement suppliers providing product for the trials. Selected limestones contained not less than 75% by mass of  $\text{CaCO}_3$  as prescribed in the Australian Standard. Limestone with  $\text{CaCO}_3$  content equal to or greater than 75% and less than 80% was acceptable provided the clay content determined by the methylene blue test, as given in EN 933-9, did not exceed 1.20%, and the total organic carbon (TOC) content, as given in EN 13639, did not exceed 0.50% by mass. For limestone with  $\text{CaCO}_3$  content of 80% or greater, testing for clay content and TOC was not required. Cement samples with different limestone contents were prepared in plant trials carried out in the various cement plants providing product for the trials. This enabled an assessment of the performance of actual industrial product with increased limestone content.

Samples of cement were prepared with limestone mineral addition levels up to 12%. Thereafter, the effect of higher limestone on different properties of cement and cement paste, including chemical properties, setting time, hydration heat also compressive strength, drying shrinkage and sulfate expansion for mortar samples were examined.

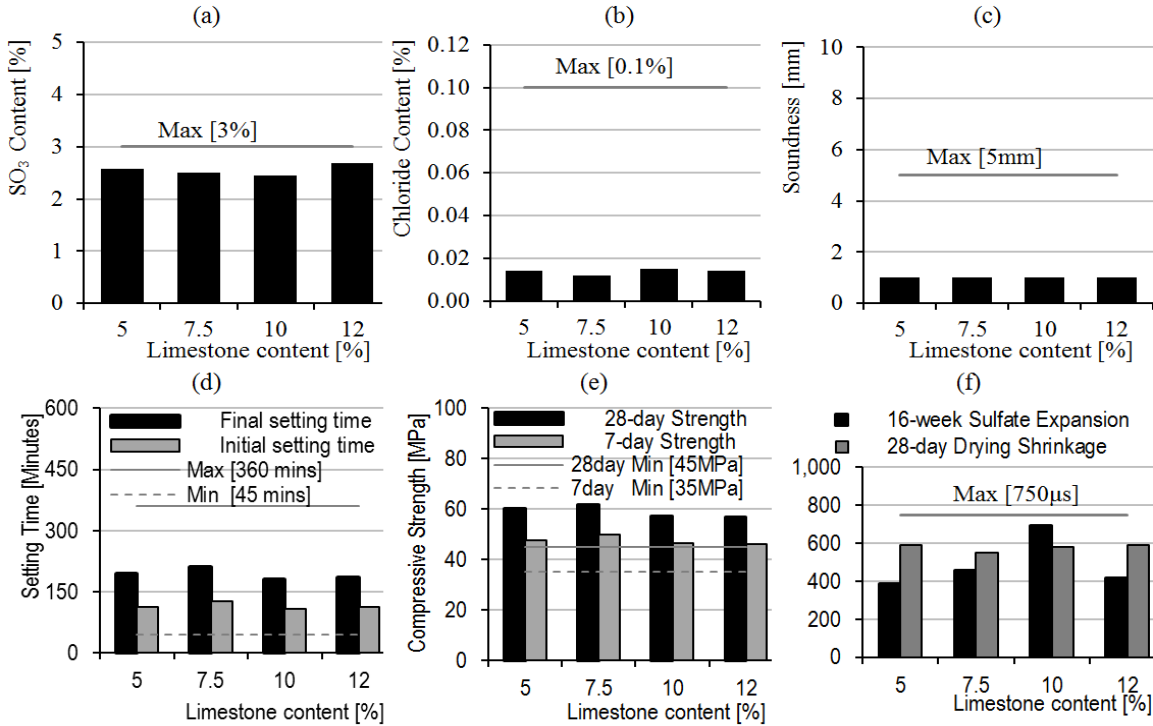

**Figure 2: Relative change of cement and mortar properties to control samples (a) Initial setting, (b) Final setting, (c) Fineness, (d) compressive strength, (e) Drying shrinkage, and (f) Sulfate expansion**

All tests were performed in accordance with the relevant Australian Standard testing procedure in different industrial laboratories. The correlational analysis of data showed there is no significant correlation between properties of cement or mortar with limestone content of cement up to 12%. An insignificant increase (<3%) in 16-week sulfate expansion of some samples was observed which was statistically scattered and had  $R^2$  of 3%. The only notable changes in characteristics were found for fineness. However, higher fineness and lower  $45\mu$  sieve residue were specifications set for the manufacturing process.

Results showed performance properties which were scattered within the usual statistical deviations arising from the number of test cements and binder combinations. Full cement and mortar correlational detail are available in the project reports. In addition to the conducted correlational study, test results for cement, mortar with higher limestone content were compared to the requirements of

Australian Standard AS 3972 as shown in Figure 3. All properties of 12% limestone content cement complied with the requirements of Australian Standards.

**Figure 3: Compliance with Australian Standards requirements (a) SO<sub>3</sub> content, (b) Chloride content, (c) Soundness, (d) Setting time, (e) Compressive strength, (f) Sulfate expansion and Drying shrinkage**

The third part of analysis included an inferential statistical analysis of cement and mortar test results. Considering the standard deviation, variation and distribution of test results, the statistical significance of test results was calculated. The majority of properties for cement and mortar samples prepared by higher limestone content did not show significant change from the samples prepared with control Type GP cement. The only statistically significant drawback found was a 5% reduction in mortar 28-day compressive strength, explained by the constraints of the test method, and congruent with reported international findings.

In summary, the results of cement, cement paste and mortar samples prepared with a higher limestone content demonstrated comparable properties with the control samples and there is no technical evidence that should limit the manufacture of Type GP cement with up to 12% limestone mineral content.

**5.2. Concrete Results**

The testing of the cements containing 7.5%, 10% and 12% limestone mineral addition was carried out in conjunction with relevant control cements as benchmarks. In addition to the 34 sets of standard laboratory concrete mixes using in-house mix designs, a wide range of concretes were prepared using current commercial mix designs for specific types of concrete. 52 sets of durable concrete; 24 sets of high-strength concrete; plus 35 and 32 sets of normal concrete grades N32 and N20 respectively were prepared. Moreover, an additional 33 sets of different specific types of concrete were provided from actual field concrete supplied for testing. Testing included those specified for fresh, hardened and durability properties namely (where applicable) concrete slump, concrete spread test, initial and final setting time, air content, bleed water, 1 day to 56 days compressive strengths, 56 day drying shrinkage, chloride ion penetration at 28 and 56 days, chloride ion migration, volume of permeable voids, creep test to 112 days, and modulus of elasticity at 28 and 56 days.

The evaluation of the data indicates there is little difference in performance between concrete using cement containing 12% limestone mineral addition and the control samples. This is supported by a statistical evaluation of the test results. Full correlational study, compliance with requirements, and inferential statistical evaluation details are available in the project reports. A summary of major findings is addressed as follows:

#### **Laboratory Standard Concrete**

The results of testing concrete based on standard laboratory mix design showed almost the same performance for 12% limestone mineral addition concrete samples and control samples. A statistically significant observed change was a reduction in bleed with increasing limestone content.

#### **Durable Concrete**

The test results for durable concretes indicated similar performance for 12% limestone mineral addition samples and control samples. The 12% limestone content durable concrete complied with all the benchmark requirements of this specific grade. Statistically significant changes were the reduction of bleeding and final setting time with increase in limestone content. Results for chloride ion penetration and chloride ion migration showed a significant improvement in concrete performance for the higher limestone content concretes.

#### **High-Strength Concrete**

Test results for high-strength concrete samples indicated similar performance for 12% limestone mineral addition samples and control samples. The 12% limestone content high-strength concrete complied with all the benchmark requirements of the high-strength specific grade. Similar workability and creep characteristics were observed for 12% limestone cement samples. Statistically significant observed changes were in the reduction of 1 day and 56 days strength by 7% and 1.6%, respectively. Test results for the modulus of elasticity at 56 days showed a 4% reduction compared to control samples.

#### **Normal Concrete Grades N20 and N32**

Test results for normal grade concrete samples showed almost the same properties for 12% limestone mineral addition samples and control samples. Both grades N20 and N32 prepared with 12% limestone content complied with all the benchmark requirements for these grades.

A statistically significant observed change for grade N20 was a reduction in bleed. No other significant change was detected.

A statistically significant observed change for grade N32 concrete was a reduction in bleed. In addition, relatively to the control samples, slump and air content results were 5% and 6% lower, respectively. However, higher strength values of about 3% to 6% for early ages (1, 3 and 7 days) test results were observed, which were statistically significant.

#### **Field Concrete**

Test results from field concrete samples exhibited similar performance for 12% limestone mineral addition concretes and control samples. The 12% limestone content concrete showed similar strength, drying shrinkage and fresh properties except for setting times, which were reduced by about 3-4%.

In general, it can be concluded that the test results for different specific types of field concrete did not show significant differences to control samples and supported the proposition of increasing the allowable mineral addition level in General Purpose (Type GP) cement, up to 12% limestone mineral addition.

### ***5.3. Supplementary Cement, Mortar, Grout and Concrete Results***

Several members of the BD-010 Working Group expressed concerned with the experimental program for the original test program (2011-2014). Specifically, they sought to determine the effect of increasing limestone content in the cement used in a number of specific concrete materials. Therefore,

an additional suite of tests and statistical analysis was agreed among Committee members and carried out in 2014 [3].

Cement, mortar and concrete tests were conducted on a variety of mixes to evaluate the effect of introducing higher limestone mineral addition to cement. These were to be tested according to normal test methods used in Australia. The total number of prepared mixes was 61 which were distributed between different types of concrete and grout. There are major differences in the performance requirements and properties of these specific types of concrete. Therefore, it was decided to report the result of the studies for the different groups of specific types of concrete separately from the original program. In addition to the cement, cement paste and mortar testing, six specific types of concrete included grout, self-compacting, general purpose, durable, high strength and structural concretes were examined.

### Cement, Cement Paste and Mortar

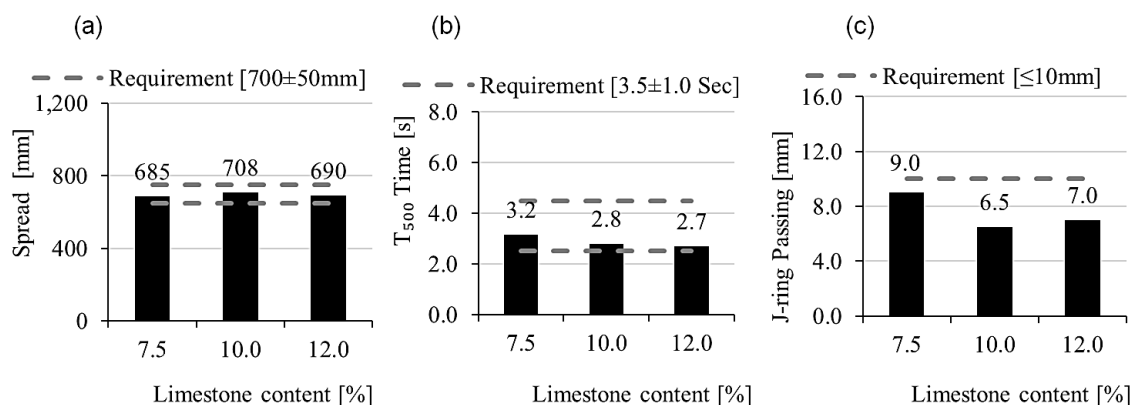

Some changes in chemical composition were noted due to a higher limestone content. In addition, there was a strong correlation between limestone content and surface area and the 45  $\mu\text{m}$  residue due to the influence of the manufacturing specifications. There was no correlation between cement limestone mineral addition content and the compressive strength or drying shrinkage of mortar.

### Grout

Grout test results include workability and strength results of three mixes prepared based on commercial mix designs. Results showed a significant improvement in the flow properties of grout made with cement containing the higher limestone contents in both the initial measurement and also after 45 minutes. The improvement may be due to the positive effect of higher limestone on the increase of water retention properties of grout. In addition, the better workability of mixes with higher limestone may be explained by softer and finer particles of limestone compared to the ground clinker particles. Literature supports the reported results for grout. Compressive strength tests were performed at different ages. Results revealed that there was no significant correlation between grout strength and limestone mineral addition content of cement.

### Self-Compacting Concrete (SCC)

The higher limestone content of cement did not result in a significant change in concrete flow. The results from additional tests such as  $T_{500}$  test and J-ring passing ability showed better workability of SCC with increased limestone content, however, the correlations were not strong.

**Figure 4: Self-compacting compliance with work-group requirements (a) Spread, (b)  $T_{500}$  time, (c) J-ring passing ability**

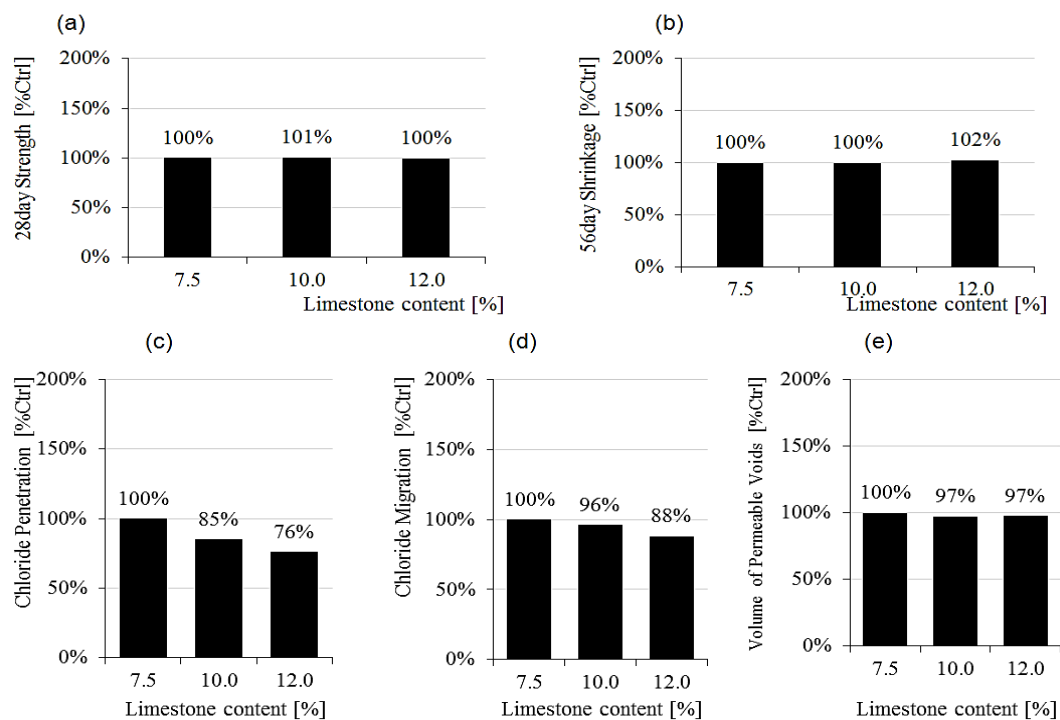

Considering results from all ages, slopes of trend lines and calculated values of  $R^2$ , it can be concluded that the increase in limestone content had no significant effect on the strength of SCC. SCC drying shrinkage results showed a slightly higher drying shrinkage for 12% limestone content, which may be due to the higher fineness of the cement, the increased limestone content or both factors. The correlations for chloride penetration and Volume of Permeable Voids (VPV) with limestone content of

cement were assessed for the SCC mix series. No significant correlation between limestone mineral addition content and chloride penetration or VPV was found.

### Normal, Structural, Durable and High-strength Concrete

In order to have a complete investigation regarding the effect of higher limestone on different types of concrete, 54 sets of concrete were prepared and tested by examining fresh, hardened and durability properties. It was found that the higher limestone content does not significantly affect the fresh properties of concrete. Results showed the air content decreased very slightly with the increase in limestone content. Moreover, the samples with increased limestone content did not have a significant effect on fresh concrete density or workability.

**Figure 5: Relative change of properties of concrete samples prepared with different limestone contents (a) Compressive strength (b) Drying shrinkage (c) Chloride penetration ASTM 1202 method, (d) Chloride penetration NT 492 method (e) Volume of permeable voids AS1012.21 method**

The test results showed that at very early ages, the compressive strength of concrete increased slightly with the increase of limestone content. For other ages, the compressive strength of concrete samples was not changed by the increase of limestone content.

An insignificant increase in the drying shrinkage was observed for the majority of concrete samples at different testing ages (Figure 5). Comprehensive analysis of drying shrinkage test results revealed that slightly higher drying shrinkage was observed only for concrete samples prepared with a combination of Type GP cement and fly ash. The higher drying shrinkage for 12% limestone content is possibly due to the higher fineness of the cements containing the higher limestone mineral addition levels.

Durability test results revealed that there were negative correlations between chloride penetration and the Volume of Permeable Voids with limestone content of cement. These lower Volume of Permeable Voids and chloride penetration results suggest improved durability of concrete using cement with higher limestone content. The observed improvements were more significant for concretes prepared with Type GP cement, while there were mild or insignificant correlations found for those prepared by Type GP cement and fly ash.

It was found that for most properties no significant change was found for up to 12% limestone mineral addition content (Table 1). The only drawback observed with 12% limestone mineral addition was a

higher drying shrinkage measured at 21 days compared to the control samples. However, the measured concrete drying shrinkage at 56 days did not show any significant increase. In addition, it is important to take into account that the reported repeatability of the drying shrinkage test is 8% at the 95% probability level. The measured shrinkage for 12% limestone samples was 7% higher than the shrinkage of control samples.

**Table 1: Overall evaluation of specific types of concrete test results for higher limestone cements**

Item	Correlation		Compliance		Inferential		Decision on addition		
	Trend	Condition	10% content	12% content	10% content	12% content	10% content	12% content	Consideration
Slump	neutral	insignificant	yes	yes	no effect	no effect	✓	✓	-
Air content	negative	insignificant	yes	yes	significant	significant	✓	✓	-
Mass per unit volume	neutral	insignificant	yes	yes	no effect	no effect	✓	✓	-
Strength 1day	positive	insignificant	-	-	significant	significant	✓	✓	improvement
Strength 3day	neutral	insignificant	-	-	no effect	significant	✓	✓	improvement
Strength 7day	neutral	insignificant	-	-	no effect	no effect	✓	✓	
Strength 28day	neutral	insignificant	yes	yes	no effect	no effect	✓	✓	-
Strength 56day	neutral	insignificant	-	-	no effect	no effect	✓	✓	-
Strength 91day	neutral	insignificant	-	-	no effect	no effect	✓	✓	
Shrinkage 21day	positive	insignificant	-	-	marginal	significant	✓	×	increased
Shrinkage 56dy	positive	insignificant	yes	yes	no effect	no effect	✓	✓	-
Chloride ASTM 1202	negative	mild	-	-	significant	significant	✓	✓	improvement
Chloride NT492	negative	mild	-	-	significant	significant	✓	✓	improvement
AVPV	negative	mild	-	-	marginal	significant	✓	✓	improvement

The test results showed an improvement in the chloride penetration (ASTM 1202 Method) and Volume of Permeable Voids (AVPV) for concrete prepared with 12% limestone mineral addition. The improvement was significant and confirmed at a 95% confidence level. The better durability performance of concrete prepared with 12% limestone GP cement suggests the potential to enhance concrete performance or service-life and reduce maintenance costs.

## 6. Conclusion and Recommendation

The results of this project supported the proposition of increasing the allowable mineral addition level in General Purpose (Type GP) cement. It was found that by increasing limestone content of cement to 12% most properties of cement, mortar and concrete were effectively unchanged. There were generally very limited performance reductions and these were statistically insignificant. It is concluded that variability in performance among the different tests was influenced more by concrete mix design and binder composition than by limestone content in the Type GP cement.

The result of this research supports the recommendation to increase the allowable limestone content of General Purpose (Type GP) cement up to a maximum of 12%.

# Steel, Concrete or Plastic? Support your Reinforcement!

Scott Munter<sup>1</sup>, Mark Turner<sup>2</sup>

<sup>1</sup>Executive Director, Steel Reinforcement Institute of Australia

<sup>2</sup>Chairman Committee BD-084 Steel Reinforcing and Prestressing Materials

**Abstract:** The construction industry is witnessing increased levels of failure of critical cover control elements. Moreover, the global supply market, lack of quality control and traceability through the current procurement cost reduction approach is a critical factor in this lack of the minimum expected performance levels.

Until recently, there has been no standard for performance requirements for bar chairs and spacers in reinforced concrete. Unsatisfactory manufacture and application of bar chairs may compromise structural strength and reduce durability of reinforced concrete. AS/NZS 2425 – Bar chairs in Reinforced Concrete has been developed in response to this need. The strength grade, performance and classification of the three main product types: steel wire; plastic; and concrete bar chairs have been considered.

The specification, methods of test and traceability requirements will assist designers and builders to select appropriate reinforcement supports to ensure maintenance of specified cover within tolerance under self-load and anticipated construction loads. The ability to place, compact and cure the concrete around the reinforcement is also a critical consideration.

The benefits and shortfalls of the main types of bar chairs are reviewed and the practical application of appropriate products is presented for a range of construction tasks. All types of complying supports are shown to deliver cost-effective achievement of design intent.

**Keywords:** Bar chairs, steel reinforcement, standards, cover, durability.

## 1. Performance Critical – Reinforcement Placement

The construction industry is witnessing increased levels of failure of critical cover control elements. Moreover, the global supply market, lack of quality control and traceability through the current procurement cost reduction approach is a critical factor in this lack of the minimum expected performance levels.

The structural and durability performance of reinforced concrete depends significantly on securing and maintaining the position of reinforcement during fabrication, concrete placement and finishing. The end result seeks to provide the specified cover within tolerances to ensure that the concrete is compacted around the reinforcement. The use of bar chairs and spacers is critical to ensure design intent.

Until recently, there has been no standard for performance requirements for bar chairs and spacers in reinforced concrete. Unsatisfactory manufacture and application of bar chairs may compromise structural strength and reduce durability of reinforced concrete. Figure 1 shows that in extreme circumstances, no support is provided for reinforcement at all!

**Figure 1. Where's the support?**

There are few standards throughout the world that specify the performance of bar chairs and spacers. Unfortunately consideration of the type, quantity and spacing of reinforcement supports is often an afterthought of the design and detailing process. AS/NZS 2425 – Bar chairs in Reinforced Concrete (1) has been developed in response to this need.

## **2. Introducing AS/NZS 2425**

### **2.1 What is covered**

Design Standards such as AS 3600 (2) and NZS 3101 (3) specify the cover to reinforcement and the tolerances, which need to be met in placing and fixing reinforcement. These covers and tolerances form the underlying principles upon which AS/NZS 2425 is written.

The standard for bar chairs and spacers specifies their strength, permanent deflection, accuracy of manufacture, identification and traceability and fixing. It applies to chairs made from plastic-tipped wire, plastic and concrete. While primarily focusing on load-carrying capacity, the standard specifies durability requirements for concrete bar chairs, because the durability performance of these products is intrinsic to their suitability and selection.

While this new standard covers the majority of commercially available products there are some products which escape its application. These include:

- Custom made or “engineer specified” chairs such as may be required for heavily reinforced sections or extreme exposure classifications.
- Exotic materials. Some developments such as carbon fibre composites are being used for limited applications.
- Specialised supports for concrete products covered by their own standards including precast concrete access chambers and precast concrete pipes.
- Post-tensioning duct chairs. Heights of these chairs vary considerably. However the principles of AS/NZS 2425 may apply but are not designed to support construction loads.

AS/NZS 2425 notes that “engineer specified” chairs and the like should always be designed to comply with the fixing tolerances of AS 3600 and NZS 3101 as appropriate.

### **2.2 Load carrying Capacity**

The key classification for all bar chairs is their load carrying capacity. Four strength grades are nominated: 60 kg, 120 kg, 200 kg, and >300 kg. When tested in accordance with the standard, products need to carry not only the specified load but also maintain deflections and permanent set within certain limits. These are summarised in Table 1. The deflection and permanent set limits have been based on roughly half the fixing tolerance of AS 3600: allowing other site factors to be accommodated within the fixing tolerance.

Strength grade 60 would typically apply to non-vertical load bearing spacers such as those for columns and walls. For most building structures strength grade 120 would commonly be specified. The load carrying capacity allows for the mass of steel reinforcement, construction personnel, heaped concrete and equipment such as pumps and vibrators. Strength grades 200 and >300 would typically be used in heavily reinforced civil structures. Bridges and power stations are likely users of these products. The >300 grade chairs are often made from fine aggregate concrete. There are minimum compressive strength and durability requirements for concrete chairs but they should also be greater than or equal to the strength specification of the surrounding concrete.

Continuous bar chairs are often supported from bottom steel reinforcement rather than horizontal formwork. The table advises that the cumulative effects of supporting top steel from already supported bottom steel be considered. See Figure 2.

**Table 1. General Product Requirements**

Test		Strength grade			
		60	120	200	>300
Minimum test load capacity, kg		60	120	200	>300
Dimensional tolerance					
Height of bar chair, measured at pre-load	<75 mm	±1 mm generally For concrete chairs, -1 + 2 mm			
	≥75 mm	±2 mm			
Deflection under load		±3.0 mm max.			
Permanent set		After removal of load, the final recovered position of the test specimen shall be less than 2.0 mm For concrete chairs, no cracking shall be evident			

**NOTES:**

- 1 Strength grade >300 kg bar chairs are typically manufactured from a fine aggregate concrete. Specifiers should ensure that the concrete in the chair is greater than or equal to the strength specifications of the surrounding concrete.
- 2 Continuous bar chairs with heights >90 mm should be designed to ensure that reinforcement is supported within the placing tolerances of AS 3600 or NZS 3101, taking account of any cumulative effect of deflection from being supported on already supported reinforcement.

**Figure 2. Top steel supported from bottom steel using “engineer specified” supports.**

### 2.3 Durability

Consideration was given to inclusion of durability requirements. However, the Committee resolved that specification of durability resided with the design Standards such as AS 3600 and NZS 3101 except for concrete bar chairs where impermeability is intrinsic to their performance and is not covered in the design Standards.

Concrete bar chairs are required to have a minimum compressive strength of 60MPa. They also need to be classified on the basis of chloride permeability determined by the charge passed in a modified sample tested in accordance with ASTM C1202 (4). See Table 2

**Table 2**  
**Chloride Permeability Based On**  
**Charge Passed**

Maximum charge passed Coulombs	Chloride permeability class
>4 000	High
2 000–4 000	Moderate
1 000–2 000	Low
<1 000	Very low

This is one of the more controversial aspects of this new standard. Main Roads Queensland provided a modified test method. While the results from ASTM C1202 can be quite variable both in terms of repeatability and reproducibility, the drafting Committee acknowledges the need for an economically feasible test method.

### 2.4 Testing and Traceability

The new standard set out a regime for sampling and testing of bar chairs on a batch-by-batch basis. The general testing procedure requires samples from each batch to be statically load tested and measured against the criteria shown in Table 1. The batch is deemed to comply where the load and deflection requirements comply with Table 1 for the specified strength grade.

Where the sample does not meet the load and deflection requirements of Table 1, a further five samples must be tested. The batch is deemed to comply where all five samples comply with Table 1 for the specified strength grade.

All bar chair packaging is required to identify the strength grade. Packaging for concrete bar chairs is also required to display the permeability class. Each pack of bar chairs must be traceable to manufacturer and batch.

## 3. Protective-tipped Wire Bar chairs

### 3.1 Applications

Protective-tipped wire bar chairs are an economical choice for many applications. They will usually be grade 120 chairs. Figure 3 shows a range of wire bar chairs ranging in height from 20 mm to 360 mm. Protective tipped bar chairs can be used in suspended slabs, beams, vertical walls and slab on ground applications. When used in slab on ground applications, the chairs require a base to prevent penetration of the polythene film or soil base.

### 3.2 Limitations and Precautions

While an economical choice for many applications, protective tipped wire chairs should be used with caution in some situations and completely avoided in others. These include:

- **Durability Category B2 and above.** The Steel Reinforcement Institute of Australia (5) has advised designers and detailers not to use wire chairs in durability categories B2 and above. Typically these are exposed concrete structures within 1 km of the coast. The potential for corrosion and subsequent staining of the concrete surface cannot be ignored.

- **Architecturally sensitive slab soffits.** The potential for the wire to penetrate the protective coating and cause staining should be considered. Compliance with AS/NZS 2425 will mitigate this being a problem as testing requires the absence of any penetration of the wire through the protective coating. Recent innovations with protective-tipped wire chairs include a push-on Teflon cap system.

**Figure 3. Plastic tipped wire bar chairs.**

## **4. Plastic Bar Chairs and Spacers**

### **4.1 Applications**

Plastic chairs and spacers are finding an increasing and economic role. Figure 4 shows a selection of plastic products. They are available from a number of reputable manufacturers. Typical applications include:

- **Slab on ground and pavements.** Plastic chairs with an integral base are most suitable for these situations. They provide a stable platform for reinforcing bar and mesh and are available in a range of heights.
- **Suspended slabs.** Plastic chairs for these applications often have a clipping mechanism to keep reinforcement in place; reducing the need for tie wire. They can be substituted for wire chairs in durability categories B2 and above as they will not corrode or stain.
- **Vertical element spacers.** Wheel type plastic spacers are often used in maintaining cover to reinforcement in vertical elements such as walls, columns and piles. Because they are not required to be load bearing they will usually be grade 60 products. Recent innovations have seen this type of spacer produced as a carbon fibre polymer. While not specifically covered by AS/NZS 2425, the general principles of delivering covers within the fixing tolerances of the design standards should apply to carbon fibre spacers.

### **4.2 Limitations and Precautions**

AS/NZS 2425 has additional requirements for plastic chairs. The standard requires that plastic chairs be tested at a temperature of 30<sup>o</sup> C compared to 22<sup>o</sup> C for other products. The potential for a plastic chair to soften at elevated temperatures needs to be considered. One of the authors had experience as a younger engineer where 85 tonne of reinforcement for an insitu bridge span was supported on plastic chairs. High temperatures within the form caused the chairs to soften and collapse just prior to concrete placement: an expensive and time wasting event!

The standard also requires that the design of plastic chairs allows 20 mm aggregate concrete to readily penetrate the chair openings. Without this provision, the generally thicker walls of plastic chairs could lead to voids occurring in the finished concrete. Caution should be exercised if larger aggregate concrete is contemplated.

**Figure 4. Sample selection of plastic bar chairs and spacers.**

## **5. Concrete Bar chairs**

Concrete bar chairs find their best application where support of large amounts of reinforcement is needed or where durability is a major consideration. They usually have a strength grade of >300. The additional durability provisions, noted above, seek to ensure that the solid chairs are not a source of chloride penetration to reinforcing steel. A variety of manufacturing processes have been employed to create concrete chairs including moulding and extrusion. See Figure 5 below. The standard does not apply to site-manufactured bar chairs where product quality, dimensional tolerances and performance cannot be assured.

Concrete bar chairs and spacers may also be the preferred choice for water retaining structures or where water pressure against a concrete surface is a factor. Generally their bond to the concrete and low permeability offer the desired performance. A very low chloride permeability class as listed in Table 2 should be specified.

**Figure 5. Concrete bar chair with cast in tie wire.**

## 6. Continuous bar chairs

Continuous bar chairs are covered in AS/NZS 2425. They are chairs that are used to support reinforcing in a continuous line of support, which includes soffit-supported as well as middle deck chairs supported from a lower layer of reinforcement. Continuous chairs can be made from wire plastic and even concrete. See Figure 6. They rely on the mat of reinforcement to spread the imposed loads across the nodes. They are tested for compliance by applying pairs of the specified load at mid-node. Where middle deck chairs are used, detailers and designers should be aware of the cumulative effect of load deflection to ensure that the top layers of steel are placed within tolerance.

Figure 6. Sample selection of continuous chairs.

## 7. Conclusion

The publication of AS/NZS 2425 is a welcome addition to the suite of Standards intended to assist the delivery of structurally sound, durable and cost effective concrete structures. The specification of strength grade and product specific performance requirements gives designers and builders a tool to specify the quantity and spacing of reinforcement supports with confidence.

The selection of the most appropriate chair: plastic tipped wire chairs; plastic; or concrete, depends not only on the mass of reinforcement to be supported but the imposed construction loads during fabrication and concrete placement.

A specifier should also consider the environmental and durability conditions to which the finished structure will be exposed. While AS/NZS 2425 focuses primarily on the load-carrying capacity of bar chairs, durability aspects of concrete chairs are considered, as these are not adequately covered by the design standards.

The application and limitations of the various types of support have been briefly considered. Further useful information will be found in the product literature of compliant manufacturers and suppliers.

The new standard will need to be referenced in design standards such as AS 3600 (2) to realise its full potential.

# Performance of Architectural Concrete: New Approach

Vyacheslav Falikman<sup>1</sup>, Vyacheslav Deniskin<sup>2</sup>, and Alexander Vainer<sup>3</sup>

<sup>1</sup>Professor of Material Science, Moscow State University of Civil Engineering

<sup>2</sup>Researcher, Scientific Research Center "Construction"

<sup>3</sup>Consultant, Scientific Research Center "Construction"

**Abstract:** Architectural concrete technology is known to provoke often the growth of shrinkage strains, increase in permeability and reduction in frost-resistance. Methods of modifying of architectural concrete are proposed that provide an opportunity to control its structure and durability, concrete mix workability and hardening rate at all stages of manufacture. Performance of architectural concrete belonging to compressive strength classes B30 - B80 is assured by using mechanically activated composite binders and effective superplasticizers. The increased hydraulic activity of binders and rational design of new architectural concrete predetermine their high physical and mechanical properties and durability, particularly under favorable conditions of structure formation, e.g. when shrinkage reducing admixtures are used. Concrete mixes, including self-consolidating ones (slump-flow 60-70 cm, V-funnel time 7-15 sec), are characterized by 0 to 0.4% bleeding. Architectural concrete frost resistance reaches 300-600 freezing-thawing cycles and more and the open integrated voids rating does not exceed 2-4% vol. The values of the prism strength factor and the initial tangent modulus of elasticity of modified concretes meet or exceed regulatory requirements. Durability of architectural concrete may be additionally improved by impregnation with the special organic silicate compounds.

**Keywords:** architectural concrete, composite binders, self-consolidating concrete, shrinkage reducing admixtures, durability, impregnation.

## 1. Introduction

Development of the high-performance concrete (HPC) concept has revolutionized the concrete technology. By combining high strength with optimum structural characteristics, higher values of physical and mechanical properties and durability, the HPC extends the areas of application of artificial mineral composites [1].

One of the most promising areas of the HPC implementation is manufacturing of architectural concrete with improved decorative properties and performance. Application of concrete technology in decorative façade elements, sculptural plaster, and other elements of buildings requires, as a rule, the use of highly workable and fluid mixes. Additionally, plain and colored cements are used to improve decorative properties of material, while fine aggregates are required to create complex textured and highly detailed surfaces. A combination of these factors leads to increased water requirements for cement mixes, which in turn instigate the growth of shrinkage strains, increase in permeability and reduction in frost resistance of concrete. The features of cement chemical, mineralogical, and material composition (for example, increased content of C<sub>3</sub>A, increased content of belite, introduction of bleaching mineral agents during grinding, e.g. diatomite, etc.) contribute to the problem.

Within the framework of implementing the HPC concept, an integrated control system for the structural characteristics, hardening rate and strength of concrete has been developed having in mind to obtain a material with set-up physical and mechanical properties and durability in specific operating conditions. It envisages the use of mechanically activated composite binders, multifunctional chemical modifiers for various applications. Thereby a directional impact is possible upon the processes of structure formation and hydration, hardening and strength gain, as well as on parameters of concrete structure and durability at all stages of its preparation: from selecting initial materials, specifying material constitution and activation parameters of composite binders, introducing chemical modifiers into a concrete mix at the preparation stage to improve its workability, including efficient superplasticizing admixtures of the new generation, and up to concrete placing and hardening in special forms.

Elimination of the specified contaminating impurities from front face of ornamental elements, and upgrading of architectural concrete and architectural elements is attained by their treatment with the various compositions reducing permeability to water and water absorption. Among wide choices of treating and coating compositions and systems (acrylic, urethane, epoxide, silicone, siloxanic, silaned, etc.) the greatest technical and economic efficiency possess materials such as silicate and organosilicate

compositions combining comparative cheapness and accessibility of a raw-material base with a large-scale of decrease of water absorption, and permeability to water, and raise of working life.

## 2. Experimental Program

### 2.1 Materials

The Portland cement of CEM I 42.5 grade (**Table 1**) produced by Stary Oskol cement plant and White cement of CEM I 52.5 R grade produced by Aalborg cement plant were used for the tests.

**Table 1. Bogue cement composition.**

Cement	C <sub>3</sub> S	C <sub>2</sub> S	C <sub>3</sub> A	C <sub>4</sub> AF	R <sub>2</sub> O
CEM I 42.5	62.84	12.31	8.5	12.5	0.63
CEM I 52,5 R	77,26	15,52	4,5	1,0	0,25

Washed crushed granite of 5-20 mm fraction as coarse aggregate and standard siliceous sand were used for concrete preparation.

A superplasticizer based on polymethylene polynaphtalene sulphonates (PNS) and a retarder based on sodium triphosphosphate (TPPh) were used in some tests.

Titanium dioxide produced by DuPont was used as pigment. Samples of photo catalytic TiO<sub>2</sub> were synthesized according to [2].

Organic shrinkage reducing admixture (OSRA) was synthesized on the basis of aliphatic alcohols and their ethers [3]. The well-known commercial OSRA by Takemoto Oil & Fat Co. Hibidan® on the basis of polyalkyleneglycol was used for comparison.

### 2.2 Methods

Spread tests of mortars were performed according to [4]. Fresh concretes and mortars (fine-grained concretes) were tested according to [5], and hardened concretes (mortars) – according to [6-8]. Compressive strength of hardened samples was measured in accordance with [9].

Shrinkage for concrete samples was measured also starting from the 1-day age (zero reading); 100 mm × 100 mm × 400 mm prisms, prepared according to [10], were used for the measurement. Each curve is the average of results obtained in three specimens.

The performance criterion of OSRA was shrinkage strain reduction for three mortar samples (40 mm × 40 mm × 160 mm prisms) as measured using the method described in [11]. Shrinkage deformations of each specimen were measured using a length comparator, sensitivity of 1 μm, and gage studs on the end sections of the prisms.

The OSRA were incorporated in the mortar mixtures with gauged water (1:3 mixture proportions, 150 -170 mm cone flow) in dosage of 2%, 4% and 6% of cement weight. For the first 24 hours after casting the specimens were stored in a normal hardening chamber ( $t = 20 \pm 2^\circ\text{C}$ ,  $\phi = 95 \pm 5\%$ ), then after demolding and throughout the test – in air-dry conditions ( $t = 20-25^\circ\text{C}$ ,  $\phi = 60-70\%$ ). The shrinkage strains were measured starting from the 1-day age (zero reading). To assess the OSRA effect on the hardening rate and mortar strength the appropriate tests were conducted at the age of 1, 2, 3, 7 and 28 days.

The effect of admixtures on the concrete void structure characteristics was explored studying the kinetics of their water absorption in conformance with the methods described in [9].

To investigate the parameters of the specimen porous structure, the optical method based on the Gallery software was applied.

## 3. Results and Discussion

### 3.1 Low water demand binders.

In accordance with the developed process one of the main aspects of HPC producing is the use of mechanically activated composite binders. They are produced by controlled grinding of Portland cement clinker or finished Portland cement with chemical modifying agents, including water-reducing admixtures, and mineral admixtures; their types and quantities are specified from operating conditions and with

account of hydration and structure formation process optimization. As a result of the solid-phase reaction on the clinker mineral surface in the process of mechanochemical activation, finished binders are forming that combine increased dispersivity and, accordingly, high hydraulic activity, with very low water demand. Variations in a wide range in types and quantities of mineral admixtures confer to the binders such special properties as sulfate resistance, dimensional stability, reduced hydration heat, etc. The cumulative result of all above peculiarities is obtaining the mechanically activated binders with high performance properties and durability. It should be noted that the organic mineral compounds formed on the clinker grain surface in the activation process determine such technological properties of composite binder-based mixes as resistance to bleeding, a high degree of thixotropic shear thinning and increased reproductive performance, i.e. the ability to reproduce the finest details of the relief or texture without the formation of the large air pores and defects on the front surface, that is being especially important for decorative elements made from architectural concrete [12-14].

Below the test results are given (**Table 2**) based on composite binders from LWDB-90 – LWDB-100 test batches that were produced in ball mill with 0.5 t/h capacity from white cements (for composite binders LWDB designation is used, i.e. the binder having low water demand, the numeral in the designation denotes the content of clinker component in %).

**Table 2. The impact of binders and admixtures used in concrete mixtures preparation on technological properties and strength of concrete.**

№№	Quality index, measuring unit	Indicator values

4.	Slump, cm	18,5	20	15	5-9	14	20	14	16	18,5
5.	Fresh concrete density, kg/m <sup>3</sup>	2326	2360	2450	2475	2490	2410	2288	2295	2338
6.	Air content, %	2,5	3,0	2,7	2,3	2,3	2,5	4,5	5,6	4,7
7.	Compressive strength, MPa, in age									
	1 day	20,5	25,7	55,0	69,7	72,8	16,5	39,8	9,6	8,8
	2 days	36,4	47,4	64,8	70,5	78,4	72,0	55,2	48,4	23,1
	3 days	40,2	51,0	72,1	76,7	83,0	76,1	59,5	68,1	40,9
	7 days	47,6	58,4	83,3	90,0	90,6	84,2	73,4	77,9	73,0
	28 days	55,6	67,3	93,7	103,8	112,6	107,3	81,0	84,0	84,5

The use of mechanochemical activation allows considerably increasing the hardening rate and strength of white cement, while obtaining on its basis the composite binders with 60-100 MPa activity depends on the initial cement quality; this corresponds to the strength rise by 41-53% at 28 days, by 30-70% at 2-7 days and over 2 times at 1 day. Alongside with the above, the essential reduction (by 17-25%) of cement paste water demand is provided in spite of the rise in binder dispersivity as compared to initial cements. Introducing at the stage of binder production of mineral additives, such as natural alumina-containing pozzolana to reduce shrinkage or granulated blast furnace slag to control heat release and to increase sulfate resistance, does not result in considerable reduction of binder activity.

### **3.2 *Fresh concrete and structure formation of concrete.***

In accordance with the reduced water demand of binders the making of flow (or self-compacting) fresh concrete on their basis is achieved at significantly lower – by 20-30% - mixing water consumption (**Table 2**). At the same time the specific rheological properties of composite binders associated with mechanochemical activation provide the minimum bleeding, reduction of air entrainment in concrete mixes and increase their density, suggesting improvements of concrete structural characteristics.

Control of structure formation processes as well as performance and decorative properties of architectural concrete envisages at the stage of concrete mix preparation, first of all, a regulation of their slump loss and introduction of various chemical and mineral admixtures (mineral pigments, shrinkage reducing admixtures, etc.) when mixing. Slump loss of concrete mixes with composite binders, i.e. the rate and time of initial flow reduction, as a rule, corresponds to slump loss of mixes with ordinary cements. However, it may not be sufficient when concreting complex elements, for example, large-scale sculptural reliefs. Besides, the rapid loss of flow is in line with accelerated structure formation of concrete and intensive heat release during the first hours after placement. Introduction of retarding agents allows avoiding it. The data given in **Table 2** and related to the use of the admixture on the basis of sodium tripolyphosphate show that in this case slump loss of concrete mixes essentially decreases, while the beginning of the intensive strength gain occurs in 36-48 hours after molding. This process is accompanied also by the more uniform heat development.

### **3.3 *Role of titanium dioxide.***

Along with admixtures controlling the rate of structure formation, the coloring agents, in the first turn, titanium dioxide  $TiO_2$ , are introduced when mixing. Even when using binders based on white cement, the introduction of  $TiO_2$  allows neutralizing the color distortion due to contamination of the fillers and aggregates, and making the mix color more susceptible to the introduction of small doses of mineral pigments for accurate reproduction of colors. Adding small amounts of  $TiO_2$  (up to 3-5% of cement mass) does not affect actually water demand and rheology of concrete mixes, while affects positively the concrete strength. The data presented in **Table 2** show that for all periods of hardening the strength of concretes increases with the growth of  $TiO_2$  dosage. At the 1-day age the addition of  $TiO_2$  in the amount of 3% of cement mass is accompanied by the strength gain from 65 to 81 MPa, i.e. by 25%, at 7 days - from 82 to 101 MPa, i.e. by 23%, and at 28 days - from 92.5 to 109 MPa, i.e. by 18%. In combination with PNS the introduction of  $TiO_2$  is accompanied by even greater increase in strength. Using titanium dioxide sensibilized through a nanotechnology gives additional benefits connected with self-cleaning properties of architectural concrete and possibilities of the control over urban pollution [2].

### **3.4 *Hardened concrete.***

The analysis of the data in Table 2 shows that the use of mechanically activated binders is accompanied in all cases by essential increase of the hardening rate as compared to concretes based on initial cements. Indeed, except for the cases, when a special aim was pursued to retard structure formation and hardening by using a retarder (**Table 2**, compounds 6, 8), the strength of modified concretes reaches 49-67% of the quality class strength as early as 1 day aging, while for concretes based on initial cements this value does not exceed 36-38%. These high hardening rates of concrete cured at ambient air confirm once more a possibility to produce architectural concrete articles without steam curing when used both sand and crushed stone (compounds 1-6) and graded sand mixtures as aggregates (compounds 7-9).

### 3.5 Control of shrinkage.

As already noted, at an early hardening stage the important factor of concrete defect-free structure formation is reduction of its shrinkage. The data given in **Figure 1** illustrate a possibility to control shrinkage of high performance architectural concrete owing to the use of OSRA. Being a product of chemical synthesis, the above admixture differs from mineral additives on the basis of sulfate and aluminat compounds by stability of its composition and properties. Besides, the OSRA admixture mechanism based on variation of water bond forms in concrete and regulation of mass-transfer processes presents a much lesser hazard for the concrete structure formed than appearance of calcium hydrosulfoaluminates, unbalanced conditions of hydration and composition of which alongside with reduction in shrinkage strains may also lead to structural failures. It follows from the data given in **Figure 1** that the reduction of their value is 22-45% by the moment of strain stabilization during hardening under air-dry curing when introducing OSRA in the amount of 2-6% of cement mass.

It should be noted that at equal dosages of admixtures OSRA and Hibidan based on polyalkylene glycol the equal degree of shrinkage reduction is reached thereby confirming efficiency of the admixture offered.

**Figure 1. Effect of admixtures on the shrinkage value of fine-grained concretes with the ratio of cement to sand 1:3,5 under air-dry curing.**

1 – no admixture; 2 – 2% OSRA; 3 – 4% OSRA; 4 – 6% OSRA; 5 – 4% Hibidan.

### 3.6 Mechanical properties and durability.

The increased hydraulic activity of mechanically activated binders and efficient mix design of architectural concretes predetermine their high physical and mechanical properties and durability, particularly under favorable conditions of structure formation, e.g. when introducing retarders or OSRA admixture. The data presented in **Table 2** show that show that the values of physical and mechanical properties of concrete correspond to high values of their strength.

The values of the prism strength factor and the initial tangent modulus of elasticity of modified concretes meet regulatory requirements or exceed them. Noteworthy increase of prism strength and modulus of elasticity of concrete with OSRA and sodium tripolyphosphate may be associated with reduction of the shrinkable nature microdefects in their structure, on one hand, and with the absence of structural changes connected with intensive heat development under fast strength gain at an early age, on the other hand.

The value of volumetric water absorption of modified architectural concretes may also serve as an indicator of improving of their structural characteristics. The data in **Table 3** indicate that mentioned value does not exceed 10%, thus allowing attributing the obtained concretes to materials with compact structure.

Combination of high density and strength of modified concrete determines, in turn, their high frost-resistance. As follows from the data presented in **Figure 2**, frost-resistance factor  $K_f$  of concretes based

on LWDB (i.e. the ratio of strength of key samples after a given number of alternate freezing and thawing cycles to the strength of control samples) is over 1 even after 300-400 test cycles, that indicates to the available reserve of durability and to the predominance of constructive processes in the concrete structure over destructive ones. In contrast, the frost resistance of concrete based on initial white cements does not exceed 100-250 cycles depending on the type of cement.

**Table 3. Main characteristics of architectural concrete depending on binder and admixture types.**

6. LWBD-90 (based on CEM I 52,5R + granulated blast furnace slag) + 3 % TiO<sub>2</sub> + 6 % OSRA + 0.6 % PNS.

### **3.7 Impregnation with the special organic silicate compounds.**

In real building practice ornamental concrete products are exposed to pollution to some extent even prior to the beginning of maintenance - during transportation, warehousing and especially at installation which is carried out frequently without appropriate protection of exterior surfaces. Surface treating of architectural concrete with special organic-silicate compounds, which partially or completely seal the pores with high density air-silica-gel, improves performance and durability of material, decreases water absorption up to 20-37% and increases freezing-thawing resistance up to 20-50% [15]. Penetrating sealant systems were developed on the basis of the soluble sodium silicate which silica module varied within 1.98-3.36. It has been found that technological parameters of organosilicate compositions for concrete impregnating can be essentially improved when surface active agents (SAA) of the various natures were introduced to soluble silicate, anionic and nonionic surfactants including. These additives make significant impact on state of soluble silicates in an aqueous solution at low concentration of SAA. The surfacing of concrete by specified sealing system improves essentially physical-mechanical parameters of the impregnated concrete that allows to raise considerably operate reliability and durability both new concrete made articles and reinforced concrete structures, and products and buildings which are under service conditions. With reference to architectural concrete it means also raise of durability of a surface of ornamental elements to foulings and makes easily the process of their cleaning, and also possibility of protective coating while in service that is confirmed by experience of practical application during restoration of some historical monuments and buildings in City of Moscow (**Figure 3**).

**Figure 3. The Center of Orthodox Heritage in Peredelkino near Moscow. More than 24,000 purpose-made details of outside architectural decoration.**

## **4. Conclusions**

Thus, the above mentioned methods of modifying of the architectural concrete provide an opportunity to control its structure and properties as well as concrete mix workability and hardening rate at all stages of its making – from selection of initial materials to surface treatment at the final stage of manufacture or even at the operational stage. Thereby an optimum combination of construction and technical characteristics of concretes and decorative properties of products is achieved that should considerably expand a field of architectural concrete application and on the whole facilitate the growth of its social significance and attractiveness.

# TORSIONAL BEHAVIOUR OF REINFORCED CONCRETE T-BEAM SECTIONS

*Douglas Anabalon, Bridge Design*

---

## ABSTRACT

The development of torsion design models has been primarily based on the analysis and behaviour of rectangular beam sections. With the exception of linear theory, the formulation of torsion design rules have based on empirical results, which are subsequently applied to non-rectangular sections.

An assessment of the response of an isolated beam and slab section is undertaken to identify the torsional behaviour of T shaped beam elements when subjected to pure torsion. A study of the torsional theory associated with the Softened Truss Model is discussed to demonstrate a comparison between the applied theory, design code rules and experimental tests results undertaken on T-shaped beams.

To demonstrate differences in torsional behaviour between rectangular and T-shaped sections, two finite element models are assessed to study the impact of flanges and web aspect ratios on concrete stress distribution, reinforcement stresses, structural response and torsional stiffness.

---

## INTRODUCTION

Early principles of torsion design define the linear elastic state of materials however its left to non linear models to define the post cracked behaviour of cross sections under torsion. Many of the design theories developed for non linear behaviour have been determined from empirical solutions, formulated to match the behaviour of rectangular sections observed in load testing of sections to failure. Design theories are then applied to non rectangular sections through simplified methods that approximate the torsional response of structures. This design approach can underestimate the behaviour of idealised T beam sections and the stiffening effect of the flange.

This paper seeks to present a discussion regarding comparative studies relating to the structural behaviour of rectangular and T-shaped beam sections subjected to pure torsion. Design theories adopted and review of experimental testing in torsion is discussed and reviewed relative to the study of T shaped beam sections. Four non-linear finite element models are assessed and discussed to identify behavioral differences observed in the structural performance of T-beams and rectangular cross sections subjected to torsion.

## DESIGN THEORY

Classical torsional theory, developed in the early 19th Century, was considered an adequate model for behaviour of concrete members in the pre-cracked state. For members such as T and L shape sections, the torsional strength of a section could be estimated by expressing the stiffness through the torsional modulus,  $J_t$ .

$$J_t = 0.33 \sum x^2 y \quad (1)$$

This function, defined as the torsional modulus, embraces the rigidity of each individual segment in a member and is commonly used in the 2004 Australian bridge code to evaluate the cracking torque.

In the post cracked state of concrete, the shear flow around the perimeter of a cross section is disturbed and engagement of reinforcement is achieved over an increasing rate of rotation. As a result alternative design theories have been established to describe the behaviour on concrete members after the onset of cracking.

One such theory is that of the Softened Truss Model (STM) developed by T. Hsu. The theory adopts the three principles of mechanics

- equilibrium
- compatibility and
- stress strain relationship of material

in much the same way as the Modified Compression Field Theory. The STM transforms the normal plane stresses into a rotated co-ordinate system which conforms to the angle of the twist rotation observed in crack patterns. The rotated angle assumes a changing angle of compressive struts and differs from the fixed angle model which assumes the compressive struts remain parallel to the direction of the initial cracks

The softened component of the model relates to a reduced stress-strain relationship of the concrete principal compressive stresses and equivalent strains. To account for the reduced concrete performance of the stress-strain relationship a softening coefficient was adopted to reflect the two dimensional softening effect experienced in the concrete under stress. Furthermore the relationship of the average stress and average strain of the reinforcement was adjusted to account for the potential of local yielding at the crack location.

## **EXPERIMENTAL STUDIES**

### **Testing of Rectangular beams**

Much of the early research undertaken on rectangular beams consisted in an attempt to vary structural properties. Although development of early design theories was based on the idealised linear response of circular hollow sections, the development of post crack torsional theories has been based on empirical solutions created to match test cases observed in understanding the post-crack behaviour.

- An increase in the aspect ratio for specimens with the same amount of reinforcement, led to a decrease in the extent of cracking observed albeit with larger crack widths. Furthermore the increased aspect ratio also led to a decrease in the ultimate strength of a reinforced section
- concrete strength affected the crack width, torsional stiffness and torsional capacity of rectangular sections. Increase in concrete strength increase torsional stiffness and capacity.
- crack widths were reduced and well controlled by an increase in longitudinal reinforcement at near ultimate torsional capacities.
- The proportion of reinforcement affects the behaviour of crack angles and crack width across shear planes in the diagonal struts. Figure 1 depicts an interaction diagram based on STM model identifying four modes of failure for different reinforcement ratios.
- Concrete sections were found to suffer significant loss in stiffness in the post crack range and as such affected the capacity of a section to resist torsional moment.

In assessing the degree of redistribution, the presence of the two types of torsion:

- Equilibrium Torsion: where torsion is required to maintain equilibrium in the structure; and
- Compatibility Torsion: where twist is required to maintain compatibility of the structure.

It was found that the ratio of torsion to bending stiffness significantly dropped causing a redistribution of torsion and bending moment. In adopting compatibility torsion design, it was deemed that elements should consider twist rotation and not torque and as such minimum reinforcement would be required to ensure ductility and crack control. A reasonable assumption of "zero torsional stiffness" was suggested to simplify torsional design.

Figure 1: Failure interaction curve for rectangular beams

## Testing on T- shaped beams

Research in the area of T-beams that reflect slab on beam sections has been at best sporadic and random with varying results. Most of the effects noted previously were also found applicable to flanged sections. The effect of flanges on section capacity was assessed and deemed significant by a study assessing the Moment - Torsion interaction of flanged sections. Two failure mechanisms were identified in the study, these consisting of the following:

- Partial cracking of the beam faces at high bending to torsion ratios
- Full cracking of the beam at low moment to torsion ratios.

The first mechanism of failure consistently occurred for M/T ratios greater than 4 where as the second mechanism consistently occurred at ratios less than 4. The effect of reinforced flanges was considered a significant factor in the increase of torsional capacity in terms of both width and depth of flanges. The interaction diagram shown in Figure 2 highlights the significant effect of flanges compared to the rectangular section, with torque capacity up to 2.6 times greater than rectangular sections.

Failure of most sections was uniformly identified to occur after cracking along the top face of the web/flange. As a result, the influence of the flange width on the torsional capacity of the section was considered to be effective at overhang widths equal to six times the flange thickness. It was concluded that the behaviour of the slab and beam behave as box sections that cross each other with shear flows on each element generally unequal.

Figure 2: Moment/Torsion Interaction diagram for flanges sections (2)

A recent evaluation of torsional stiffness in beam and slab bridges decks was carried out by the University of Rijeka. The study looked at direct load testing of bridge structures with no transverse diaphragms. The intention of the analysis was to determine the design value coefficient of torsional stiffness reduction for the verification of serviceability limit state design. There study concluded that cross sections experienced a 70% reduction of torsional stiffness under serviceability limit state conditions.

## DESIGN MODEL

Two design models were selected to simulate a typical beam size section encountered in service with beam aspect ratios between 1.0 and 2.1. The beams only consider conventional reinforcement so to observe the overall pre and post crack behaviour and distribution of stress across the surface plane of the member. The Analysis of typical section models were carried out on a Strand 7 with models based on the stress-strain relationship of softened concrete truss theory.

## Model Analysis

An ideal flange width overhang of 4 times the flange depth was adopted for this particular study in accordance with the ACI code and previous studies on effective flange widths. A standard length of 2.0m was adopted, with axis - symmetric boundary conditions on one side to allow crack propagation over the peak stress regions and thus identify changing section stiffness. The design models were constructed using 2 node line element (Truss type) and 8 noded Quadrilateral Brick element (Hex 8)

The study considered four different design sections consisting of two rectangular and two T-beam sections as shown in Table 1. The dimension of the main web was carried throughout the length of the T-beam section so to assess the impact of flange stiffness.

**Table 1 - Analysis of beam torsional Stiffness**

Tag	Type	Beam section	Flange width	Flange Depth
R1_450	Rectangular	600 x 450	-	-
R2_600	Rectangular	600 x 600	-	-
T1_450A	T-Section	600 x 450	1 800	150
T2_600A	T-Section	600 x 600	1 800	150

Table 2 shows the degree of reinforcement adopted in the construction of the FE models. Two additional modifications were introduced into the T1\_450A beam to assess the impact in changing stirrup spacing and absence of reinforcement in the flange sections.

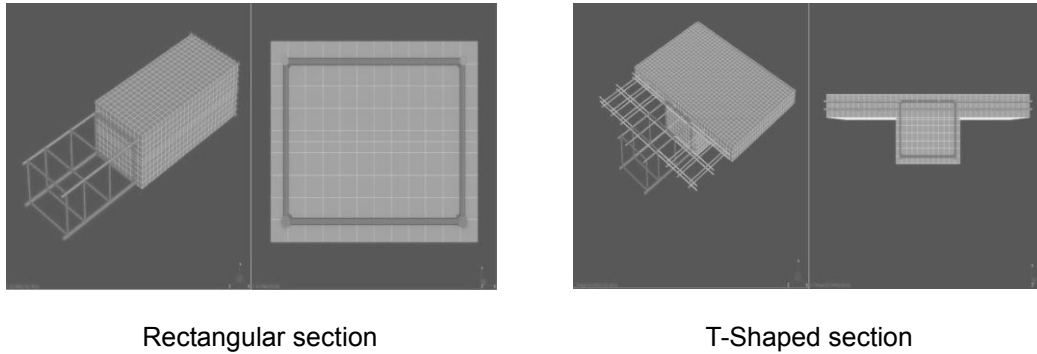

**Table 2 - Reinforcement details in finite element models**

Reinforcement Type	Location	Beam	Flange
Longitudinal	Top	2 - Ø20	Ø12 @ 200
	Bottom	2 - Ø28*	Ø12 @ 200
Transverse	Stirrups	Ø16 @ 300*	-
	Top	-	Ø12 @ 300
	Bottom	-	Ø12 @ 300

\*Reduced to 2-Ø20 bars longitudinally & Ø12 bars at 200 centers on 1 test beam.

The behaviour of reinforced concrete elements under shear stress was identified to differ from the normal constitutive laws of concrete in normal compression hence a softening of concrete strength in the truss model theory using redefined constitutive laws were adopted.

Defined boundary conditions reflecting rigid fixity at one end and axis symmetric conditions on the opposite end were adopted to reflect free end movement at midspan. Warping of the internal end face was restrained by the use of a loading beam on the end of the section and a coupling force was applied to a loading beam connected to the end of the beam segment.

**Figure 3: Typical section of FE models**

## Results

General observations identified regarding the response behaviour included:

- no vertical or horizontal displacement about the center of the beam rotation
- Flanges tips displayed a hyperbolic deformation with internal curvature.
- Shear flow path within the web was consistent with rectangular sections however demonstrated a change in direction at the web - flange interface flowing through the flange. No shear flow between web-flange interfaces.
- Maximum shear stress zones around re-entrant corners and the middle of each surface element.

**Figure 4: Flange deformation**

Inspection of the diagonal strut angles found that the introduction of flange members resulted in keeping fairly uniform compressive strut angles between reinforcement nodes. No compressive strut was observed between web-flange interfaces. Increasing torque past the point of cracking caused strut angles to become steeper due to failure of beam elements and subsequent interruption of shear flow paths

The impact of flange reinforcement was found to improve the behaviour and response of a T-beam subjected to torsion. Members with no flange reinforcement behaved similar to reinforced flange sections up until the onset of cracking at which point they behaved like rectangular sections. Strain distribution was observed in areas over the top and bottom of the flange. After cracking the extent of failure increases at the interface between the beams and flange until brittle failure results in the webs and flanges behaving as individual members. The use of flange reinforcement was found to:

- improve the ultimate torsional capacity;
- increase the level of ductility due to greater rotation tolerance;
- transfer shear stresses across the beam – flange interface thus enabling distribution of forces; and
- provide an effective bond between beam and flange sections after cracking has propagated through the interface.

Analyses of the concrete stresses present in a rectangular section were found to coincide with the location of maximum shear flow around the perimeter of the cross section. Concrete stresses of T-shaped members demonstrated similar behaviour with peak stress concentrations associated with the maximum shear flow path identified on the member surface. Differences identified between the two shapes are identified in Table 3.

**Table 3 - Observations in Concrete Stress**

Rectangular Beams	T-Shape Beams
<ul style="list-style-type: none"> <li>• Uniform distribution over length</li> <li>• Minimum stress in the core</li> <li>• Minimum stress on the corners</li> <li>• Maximum stress on long length at shortest distance to centroid</li> <li>• Stress propagates uniformly over length with applied torque</li> </ul>	<ul style="list-style-type: none"> <li>• Diagonal distribution of stress</li> <li>• Uniform distribution of stress disturbed by flange</li> <li>• Stresses at mid length are lower but peak within the web sides</li> <li>• Stress concentrations near beam/flange interface</li> <li>• Peak tensile stresses at beam/flange interface located on beam ends and opposite faces</li> </ul>

**Figure 5: Concrete compressive stresses (post crack)**

Figure 5 demonstrates two main features associated with the compressive stresses which differ from that shown on rectangular sections. These include the non-uniform and uneven distribution of stress along the side face and change in distribution resulting from the flange.

**Figure 6: Concrete compressive stresses (post crack)**

Figure 6 highlights peak stress concentrations on the bottom re-entrant corners in addition to the stress distribution through the section near ultimate failure. Prior to failure, similar stress patterns are observed between each flange overhang and central beam. As the torque load increases to failure the stress disruption results in form of that shown in Figure 7. Each segment maintains connectivity to allow shear flow to remain present and thus distribute stress over the full cross section.

The shear center of the cross section was found to shift with increasing torque. In the pre-cracked state, the position of shear center was in accordance with theoretical assessment. . After cracking the shear center displaces vertically downwards ceasing midway between the original location and the shear center of the rectangular web section near ultimate failure. It is deemed that the transverse reinforcement across the flange assists in maintaining the distribution of shear flow across the T shaped cross section.

Stress levels in reinforcement were not found to significantly increase until after the onset of cracking. The depth of crack was also found to effect the stress increase. It was noted that the stress levels in the reinforcement depended on the location within the beam and the tensile forces acting on the truss elements.

The main areas where increased levels of steel stress were encountered included:

- Tensile face of the intersection between web and flange overhang
- main bottom longitudinal reinforcement and
- varying length of stirrup (subject to strut angle)

The degree of steel stress in the reinforcement was considered to be strongly associated with two factors:

- the deformation of the T-beam section and
- the stress distribution in the concrete

**Figure 7: Flange Reinforcement (loaded end)**

*i) Rectangular beam section*

ii) T-beam section

**Figure 8: Beam Longitudinal Reinforcement (Bottom face)**

Analysis of the torsional behaviour was carried out by generating two types of curves:

- Torque Vs Twist
- Stiffness Vs Torque

Based on the profiles observed on both graphs curves the following results can be obtained from the strength analysis of the beam section with an aspect ratio of 1.33.

- The rectangular beams experience increased rotation due to the lack of stiffness provided by the flanges
- The T-beams have greater torque capacity of than rectangular sections.
- The cracking torque of T-beams is relative to the cracking identified on the web. The stiffness of the flanges allows an increase in strength when compared to the rectangular section.
- Beams with unreinforced flanges have less ultimate torque capacity yet provide similar cracking torques.
- The torsional stiffness of T-beams has a flatter gradient after the onset of cracking resulting in increased degree of capacity.

**Figure 9: Load response graphs for 450 deep beams**

As shown in the graphs, the stiffness of the T-beam section at the point of cracking in the flange was closer to 90%. The results for cracking in the web of the T-beam sections clearly show a 30% loss in stiffness at first crack however suffer a significant loss of stiffness at ultimate torque limits. The torsional stiffness of beams in the ultimate limit state also appear to reduce with increasing aspect ratios of the web, although it is considered that this may have been the result of the FE models failing to converge before engaging full tensile capacity in the steel truss. In contrast with rectangular sections, the ultimate capacity of T-beam section can be seen to significantly increase with increasing aspect ratios of the web.

**Table 4 - Analysis of beam torsional Stiffness and strength**

Aspect ratio of Web	$GJ_{cr} / GJ$ (%)		$GJ_{ult} / GJ$ (%)		Torsional Capacity Ratio
	Rectangular	T-beam	Rectangular	T-beam	$Tu_{T-beam} / Tu_{rect}$
1.0	90	53	25	28	1.17
1.33	91.7	72	20	22	1.50
2.1	83	76	10	13	2.75*

## CONCLUSIONS

The study of the FE models found that the deformation of the structures was consistent with application of the applied torque. The key findings identified in the analysis and comparison of sections included the following:

- Shear stresses in T-beams reflected the behaviour of the shear flow around the typical cross section. Distribution was found to be diagonal along flange surfaces and not in a constant circulatory flow as identified in rectangular sections
- Maximum shear strains resulted in early cracking of the flange followed by the interface of the flange with the main web. The web surface was found to be the last of the elements to crack
- Flange reinforcement in T-beams was deemed important in maintaining compatibility between flange and web sections. It also increases torsional capacity of the beam at ultimate limit state conditions.
- Longitudinal stresses in the web reinforcement were found to behave differently between top and bottom bars, which were not consistent with rectangular beams
- Cracking torque of the main web was found to be 30% to 50% greater in T-beam sections when compared to equivalent rectangular sections.
- The relative torsional stiffness of T-beams with aspect ratios greater than 1 was greater by 12% to 16% in comparison with equivalent rectangular sections
- Ultimate torque levels were found to decrease with increasing aspect ratios of the main webs however torque capacities of T-beam sections are greater in T-beams relative to equivalent rectangular beam sections.
- Although initial flange cracking was observed at 90% of the torsional stiffness, the theoretical assessment to cracking torque coincided with cracking of the web. Torsional stiffness of sections at cracking torque was found to be equivalent to 70% of gross stiffness and 90% for rectangular sections.
- At ultimate torque, torsional stiffness was found to be between 10% to 25% of their gross torsional stiffness for both rectangular and T-beam sections.
- Principal failure mode consisted of surface yield lines located diagonally over the flange emanating from the point of load application and also located at the flange and web interface.

**Abstract:** In recent years, the use of polymer concrete have become a promising choice in outdoor applications such as repair concrete structures, beams and slabs of small cross section and coating of railway sleepers, is subjected to degradation caused by photochemical reactions from solar ultraviolet (UV) radiation. Any small damage in polymer matrix can be detrimental to the overall mechanical performance of the structure as it binds and transfers load to the reinforcement. This paper deals with the effect of UV radiation on the physical and mechanical properties of epoxy resin based polymer matrix. Seven different mixes containing filler materials from 0 to 60% with an increment of 10% were exposed to UV radiation using accelerated laboratory testing. Specimens were subjected to 2000 hours of UV radiation by Xenon 2200 watt air cooled lamp in the sunset XLS chamber and subsequently weighed, examined by microscope and mechanically tested. Surface degradation in the form of discoloration were observed by microscopic observation. It was found that, the loss of specimen's weight decreased with the increase of filler materials in the mix. Significant decrease of flexural strength were observed in the mixes containing filler volume up to 20%. However, no reduction of flexural strength were noticed for the higher filler ( $\geq 30\%$  filler) containing mixes indicating the filler can helps to preserve the structural performance by absorbing or blocking UV radiation before it reaching the chromophores in polymer matrix.

**Keywords:** epoxy resin, polymer matrix, ultraviolet radiation, physical and mechanical properties.

## 1. Introduction

The use of polymer concrete in outdoor structures such as bridge decking, pavement overlays, hazardous waste containers, waste water pipes and composite railway sleepers [1-3] are commonly exposed to ultraviolet (UV) radiation. UV radiation is found highly damaging to organic polymeric materials [4]. The solar UV radiations absorbed by the polymer are responsible for photolytic, photo-oxidative, and thermo-oxidative reactions that can degrade the polymer [5]. This photo-oxidative reaction reduces the molecular weight and makes the polymer brittle. Therefore, a special attention need to be provided for the application of polymer matrix in such kind of infrastructures. The wavelengths of UV radiation that reaches the earth's surface are ranged from 290 nm to 400 nm and most of the polymers have bond dissociation energies in that range of wavelength [6]. The UV ray caused by sunlight frequently combined with atmospheric oxygen, moisture, temperature, wind-borne abrasives, freeze-thaw and other environmental factors, and their photo-oxidative degradation can break the polymeric chains [6]. Due to photo-oxidation, the polymer matrix greatly affected by UV radiation and its effect on the physical and mechanical properties are essential to investigate for their widespread applications. Unfortunately, so far, a very limited research have been conducted on the performance of polymer matrix under UV radiation.

The effect of UV radiation are usually confined to the top few microns of the surface [6] that can reduce the mechanical properties which results in embrittlement, discoloration and an overall reduction in its physical and electrical properties [7]. This effect is severe for transparent polymer that allows UV ray to break the molecular bond of structure [8]. To reduce the transparency of epoxy resin, a non-transparent filler such as fly ash can be added. In contrast with the traditional concept of using fly ash as filler, this study incorporates two other filler materials, a fire retardant filler and hollow microsphere to improve the fire and shrinkage performance, respectively. However, the addition of filler can reduce the mechanical strength of polymer matrix as the flexural strength of polymer primarily depends on the amount of resin, the more resin in the mix- the more strength is.

The effect of different UV exposure time (500, 1000 and 1500 hrs) on fibre reinforced polymer composites have been studied by Yan et al. [9]. They found the deterioration of tensile and flexural properties after 1500 hrs of UV exposure. Chin et al. [10] investigated the UV radiation on thin polymer films that was exposed to a 1000 watt xenon arc source for 1200 hrs at 30 °C in an Oriel solar simulator. They observed surface oxidation results surface erosion and cracking for both vinyl ester and iso-polyester samples.

Peng et al. [11] studied the accelerated weathering on polypropylene composites reinforced with wood flour, lignin and cellulose at different loading levels from 0 to 960 hrs. They observed large cracks and delamination of polypropylene layer after 960 hrs of UV exposure. Cao et al. [12] investigated the degradation of polymer coating systems under 2000 hrs of UV exposure. The present study decided to expose the polymer matrix under UV radiation up to 2000 hours to achieve the more reliable results.

The lack of comprehensive knowledge on the effect of UV radiation on epoxy polymer matrix restricts their applications to the practicing civil engineers and designers. This paper explore some aspects related to physical and mechanical properties of polymer matrix under UV radiation and contributes to the scientific knowledge in the field.

## 2. Materials and Method

### 2.1 Materials

The materials employed in this investigation were epoxy resin and light-weight filler. Epoxy provides a high level of bonding properties compare to the traditional paste style glue. Generally two components of resin are required to get the gluing properties and need to be mixed together before use. In this study, two main components of the epoxy resin were DGEBA type (Part-A) and an amine based curing agent (Part-B). Epoxy resins are blended, filled, or modified with reactive and nonreactive components. It is then necessary to adjust the concentration of the curing agent to cure only the portion of the mix that is reactive. The resin producer furnishes the Epoxy Equivalent Weight (EEW) of 190 gm for Part-A and Amine Hydrogen Equivalent Weight (AHEW) of 60 gm for Part-B. To make the resin mix reactive, one equivalent weight quantity of amine curative will require for one equivalent weight quantity of an epoxy resin. Therefore, 32 gm of Part-B is required to react with 100 gm of Part-A, and otherwise it will not work properly.

Resin is the most expensive ingredients in polymer matrix and to minimise the cost and improving durability light weight filler materials were added in the mix. Three different filler materials such as Fire Retardant Filler (FRF), Hollow Microsphere (HM) and Fly Ash (FA) were mixed together by a certain percentage to get the effective filler mix. The mixing formulation of these three filler materials was established after several trial mixes. The fire retardant used is non-toxic and has low abrasiveness, acid resistance, chemically inertness, electric arc resistance and smoke suppression properties. On the other hand, hollow microspheres can contribute in reducing weight, controlling shrinkage, increasing thermal insulation of the polymer matrix. The by-product fly ash can improve the performance of matrix by resisting UV and reducing permeability of water and aggressive chemicals.

(a) ingredients before mixing

(b) solid polymer matrix after mixing

**Figure 1. Polymer matrix ingredients and specimens casting.**

## 2.2 Method

The addition of UV absorbers or UV stabilizers into the polymer is one of the best methods for protecting polymeric matrix against UV radiation [7]. In this study, filler materials were incorporated as UV absorbers for targeting the absorption of UV light and dissipating the absorbed energy harmlessly. The specimens were cast in plastic cups (Fig. 1b). Seven different mixes were prepared with an increment of 10% filler by volume starting from pure resin mix (0% filler) to the mix with 60% filler content. The detail mixing proportions are given in Table 1.

**Table 1. Details of mixing proportion.**

Identity of mix	Mix-1	Mix-2	Mix-3	Mix-4	Mix-5	Mix-6	Mix-7	
% Resin/Filler (by volume)	100/0	90/10	80/20	70/30	60/40	50/50	40/60	
Resin	Part A, (gm)	124	112	100	87	75	62	50
	Part B, (gm)	40	36	32	28	24	20	16
Filler (FRF+ HM+ Fly Ash), (gm)	0	30	59	89	119	148	178	

Specimens were demolded in the next day of casting and cut it to a nominal dimension of 80 × 10 × 10 mm using machine. The initial flexural properties of the specimens were determined and recorded before exposed to the UV radiation. The effect of UV can be determined either by accelerated laboratory testing or actual outdoor exposure. The latter is obviously time consuming method and therefore accelerated laboratory testing was conducted. UV-chambers basically consist of a UV-light source(s) and a specimen rack. A variety of artificial light sources including carbon arc lamps, xenon arc lamps, fluorescent sun lamps and mercury lamps can be used to simulate the natural sunlight. However, xenon arc and fluorescent lamps are the two most popular UV-sources for photo-degrading materials that can emit a similar type of harmful radiation [5]. In this study, specimens were subjected to 2000 hours of UV radiation by xenon 2200 watt air cooled lamp in the sunset XLS chamber. The exposure was carried out in an ambient atmosphere where the temperature was varied between 22 to 24 °C, with a relative humidity between 30 to 50%. After the specified time, the specimens were taken out from the UV chamber and subsequently weighed, examined by microscope and mechanically tested. Flexural test of the affected samples were conducted under three-point bending (Fig. 2b) set-up and compared the results with unaffected one.

(a) ultraviolet chamber

(b) bending test of polymer matrix

**Figure 2. Bending test of the UV affected samples.**

## 3. Results and Discussion

The polymer matrix usually generate heats while mixing two resins together and the maximum temperature was generated in the mix containing 0% filler. The addition of filler can absorb heat and maintain the temperature to the comfortable range for working. The physical properties in terms of

discolouration, depth affected by UV and loss of weight, and mechanical properties in terms of bending strength were examined once the samples were removed from the UV chamber.

### 3.1 Physical properties

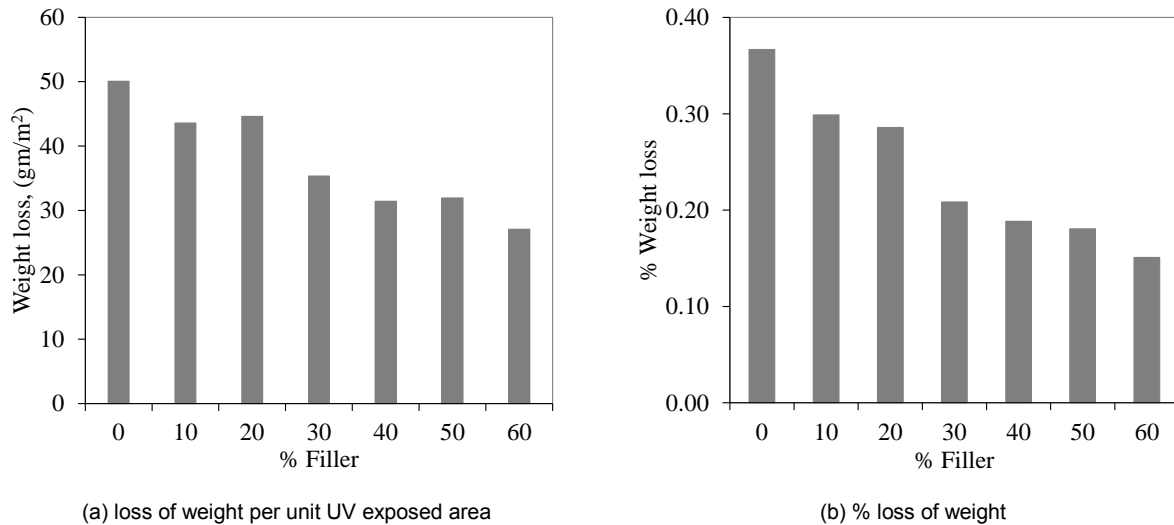

The mixes containing high resin or low filler (Mix 1 to mix 3) were severely affected by UV and surface degradation in the form of discoloration were observed by microscopic observation (Fig. 3 a-c). The discoloration is due to interaction between epoxy molecules on the exposed surface and the photons from UV radiations results in photo-oxidative reactions that alter the chemical structure [13]. No significant changes in colour were noticed for the mix having filler 30% or more (Fig. 3 d-g). It is noted that the Mix-1 which contains 100% resin or 0% filler is more transparent than the other mixes. This transparency is due to the physical properties of resin and the addition of filler can increase the darkness in the succeeding mix because the colour of fly ash which is grey or light dark in nature. Significant improvements were observed in 30% filler mix. Therefore, it can be concluded that the mix containing filler less than 30% is more prone to UV radiation. No significant variations were observed in the higher filler content mix (Mixes 4 to 7) because the darkness of filler can block the UV ray and protect the samples from physical and mechanical degradation. However, a minor changes in surface roughness were also visible by naked eye for all UV exposed specimens.

**Figure 3. Discoloration of UV affected samples after UV exposure.**

The weight of the specimens were measured immediately after taken out from UV chamber. As the UV lamp focused the specimens from the top, the top surface of the specimens were mostly affected by the UV light [14]. The loss of specimen's weight per unit UV exposed area was determined and it was found that the loss of weight follows a decreasing trend with the increase of filler in the mix (Fig. 4a). The highest loss of weight was found 50 gm/m<sup>2</sup> in 0% filler mix (Mix-1) and it decreased to 27 gm/m<sup>2</sup> for 60% filler mix (Mix-7). The loss was found more for the mix containing 0 to 20% filler and suddenly decreased from 45 gm/m<sup>2</sup> to 35 gm/m<sup>2</sup> when the filler increased from 20% to 30%. This sudden drop is expected because the depth of the specimen affected by UV for 20% filler mix was found significantly higher than 30% filler mix (Fig. 5b) and consequently the expulsion of moisture was higher. Moreover, the improvement rate is quite slow from 30 to 60% filler mix. The percentage loss of weight based on the initial weight of the specimens (before UV exposure) shown in Figure 4(b). It was also found that the loss of weight decreased from 0.37% to 0.15% with the increase of filler from 0 to 60%. This result is somewhat comparable with the loss of weight of carbon fibre reinforced epoxy composites after 500 hrs of UV exposure studied by Kumar et al. [13] where they found an average loss of 0.27%. The decrease of weight loss is due to the gradual improvement of UV resisting properties with the increase of filler which can protect the samples from deterioration.

**Figure 4. Loss of weight of polymer matrix after 2000 hours of UV exposure.**

The affected depth of the specimens due to UV light were measured using electronic microscope. There was a clear distinction of colours between the affected and unaffected layers (Fig. 5a). The affected depth was found higher for the mix containing filler up to 20%. The maximum depth was measured 4.58 mm for 0% filler mix and it was slightly decreased to 4.45 mm for 20% filler mix. However, a sudden decrease of the affected depth was found when the mix contained 30% filler (Fig. 5b). This indicates, the transitional polymer matrix that has superior resistance to UV radiation contains filler between 20 and 30%. The affected depth was gradually decreased from 1.11 to 0.40 mm for the mix having filler from 30 to 60%. Overall, the addition of filler in the epoxy polymer matrix can increase the resistance against UV radiation as the fillers block the penetration of UV thus only the resin near the surface is affected.

**Figure 5. Depth of the samples affected by UV light.**

### 3.2 Mechanical properties

The flexural strength of the UV unaffected group of specimens were measured before placing the identical second group in UV chamber. After 2000 hours of UV exposure, the flexural strength of the second group of samples were measured using three point bending test. To ensure the effect of UV on flexural strength, the specimens were placed in the testing machine in such a way that the UV affected side subjected to tension in bending. Results were compared with the unaffected samples and observed a significant

reduction of flexural strength up to 48% for zero filler mix (Mix-1). The reduction of strength was found 34 and 32% for the mixes containing filler volume of 10 and 20% respectively (Mix-2 and Mix-3). The reduction of strength due to the effect of UV should not be more than 10% in outdoor application [15], thus the mixes containing filler up to 20% is vulnerable to UV. However, no reduction of flexural strength were noticed for the higher filler containing mixes indicating the filler can help to preserve the structural performance by absorbing or blocking UV radiation before it reaching the chromophores in polymer matrix (Fig. 6).

**Figure 6. Effect of UV radiation on flexural strength of polymer matrix.**

Surprisingly, a slight increase of the flexural strength was found in the UV affected mix containing filler volume from 30 to 60%. It is previously mentioned that the effect of UV is only significant for the mix having filler less than 30% and no major change in colour was observed for the mix containing 30 to 60% filler (Fig. 3). Therefore, the slight increase of strength is probably due to the age of UV specimens which was at least 2000 hours (in-chamber period) longer than the unaffected samples.

#### 4. Conclusions

In this paper, the effect of UV radiation on some of the physical and mechanical properties of epoxy polymer matrix was studied by accelerated UV weathering. Microscopic observation was performed to analyse the change of colour and measuring the affected depth of the specimens under the effect of UV radiation. The loss of weight and the reduction of flexural strength was compared with unaffected samples. Some conclusions drawn from the investigation are listed as follows:

1. Significant surface degradation in terms of discoloration was observed in the mix containing filler up to 20%. However, no noticeable change in colour were found for the mixes containing 30 to 60% filler. The increase of filler reduces the transparency of the mix that can increase the UV resistance.
2. Specimens were affected up to a maximum depth of 4.58 mm when the mix contained pure resin without filler. A slight improvement was observed up to 20% filler mix (affected depth 4.45 mm). However, the addition of 30% filler can significantly improve the UV resisting properties as the affected depth drastically reduced to 1.11 mm indicating the transition polymer matrix containing filler between 20 and 30%. A minor variation was observed among 30 to 60% filler mix.
3. The loss of specimen's weight per unit UV exposed area decreased from 50 gm/m<sup>2</sup> to 27 gm/m<sup>2</sup> or 0.37 to 0.15% with the increase of filler from 0 to 60%. However, the loss of weight suddenly decreased from 45 gm/m<sup>2</sup> to 35 gm/m<sup>2</sup> or 0.29 to 0.21% when the filler increased from 20 to 30%. This is due to the significant improvement of UV resistance by the later when comparing with the former.

4. Reduction of flexural strength was observed for the UV exposed specimens containing filler from 0 to 20%. However, the addition of filler from 30 to 60% can protect the polymer matrix from mechanical degradation by improving the UV resisting performance.

# Self-healing of Cementitious Composites via Coated Magnesium Oxide/Silica Fume Based Pellets

Rami Alghamri<sup>1</sup> and Abir Al-Tabbaa<sup>2</sup>

<sup>1</sup> PhD Student, Department of Engineering, University of Cambridge, Cambridge, UK

<sup>2</sup>Professor of Civil & Environmental Engineering, University of Cambridge, Cambridge, UK

**Abstract:** Many studies have reported the use of mineral admixtures as an approach for the self-healing of cementitious composites. However, research has consistently shown that it is difficult to apply this approach because there could be a significant loss in workability of fresh concrete as well as the occurrence of early reactions with cementitious materials, which would lead to a decrease in the self-healing efficiency. Therefore, this work aims to improve the self-healing capabilities of concrete by developing pellets, which possess semi-capsulation effects, from powder materials. In this research, self-healing pellets were fabricated from a mix of magnesium oxide (MgO) and silica fume (SF) as potential self-healing agents and encapsulated within a cement paste coating. The produced self-healing pellets with a diameter range of 0.6-4.75 mm were added to mortar concrete samples in three dosages of 5%, 10%, and 15% by weight as partial sand replacement and all mortar specimens were then cured in water. The results indicated that the addition of up to 10% pellets increased the compressive strengths at 7, 14, 28, and 56 days. Same proportions presented promising results in both the flexural strength and its recovery. For instance, the addition of only 5% of pellets shows ~ 60 % and ~ 51% strength recovery in 28 days and 56 days respectively. The designed concrete samples containing the developed self-healing pellets possessed a promising crack self-healing performance.

**Keywords:** Self-healing, cementitious composites, pellets, Magnesium oxide, Silica fume.

## 1. Introduction

Concrete is the most used construction material worldwide and in comparison to many other materials it is cheap, can be moulded in any required shape easily, and has a high compressive strength [1]. Also, concrete has a greater durability than the majority of other building materials, for instance, it is very effective at fire resistance [2]. One drawback, however, is that concrete is a material sensitive to crack formation because of its limited tensile strength. Therefore, concrete is often combined with steel reinforcement to carry the tensile loads. These rebars restrict the crack width but cannot prevent crack formation completely and the propagated cracks may endanger the durability and functionality of concrete structures [3]. For instance, concrete cracks lead to an increase in the number of pathways open to the ingress of saline water, acid rain, and carbon dioxide. Depending on the type of concrete, the environmental conditions, and the chemical makeup of the infiltrating fluid, various degrading processes can occur which cause further cracking and substantially reduce the durability of the structure. These processes include freeze-thaw action, aggregate alkaline reaction, and reinforcement corrosion [1]. Additionally, cracking is aesthetically unsightly which is considered very important aspect in many structures [4]. Therefore, repairing of these cracks is very essential and indispensable.

The conventional repair methods increase the life-cycle cost of concrete, have a significant environmental impact, and need long time and intensive labour [5]-[6]. Therefore, it inspires the possibility that; if concrete were designed with a sufficient healing capability, cracks in concrete could be self-healed after cracking under specific conditions without human intervention. This may lead to a material with reduced lifetime costs and with improved durability and service life, both in terms of money and environmental impacts. In order to achieve this goal, many scientists and researchers have recently turned their attention to investigating this topic. Different approaches and materials have been proposed by research groups all over the world [7]. Among those some approaches are aimed at improving the natural mechanism of autogenous crack healing, which is generally attributed to the hydration of unhydrated cement grains and may be aided by carbonation of Portlandite (calcium hydroxide) [8]. Others are designed to modify concrete by embedding microcapsules or hollow fibers with a suitable healing agent, to heal the cracks autonomously [3].

A further approach used for healing concrete cracks is the incorporating of mineral admixtures [9–12]. For instance, Ahn (2008) [13] added some specific mineral and chemical admixtures in terms of swelling, expansion and precipitation to concrete mixture in the form of powder as partial cement replacement. Generally, concrete shows a promising healing capability with some mineral admixtures. However, it has been difficult to apply this approach to the construction industry as there has been a significant loss in workability of fresh concrete and self-healing efficiency, due to further reactions between the self-healing powder and mixing water during concrete casting. To control the reactivity of embedded materials, self-healing granules having a semi-capsulation effect, in which the inner material containing self-healing materials were closed by a coating layer of a cement compound, were proposed by Koide & Morita (2010) [14]. To date, few attempts in this area have been carried out and the application is still in its experimental steps.

On the other hand, pelletisation is a worldwide known technique in many industries including mineral processing, agricultural products, pharmaceuticals, and some chemicals [15]. However, it has not been widely used in the construction sector [16]. Few attempts have been made to produce lightweight aggregates (LWA) by using pelletisation technique and the developed pellets showed promising results to use them as artificial LWA in concrete structures [16,17].

Therefore, this paper focuses on introducing pellets from some self-healing powder minerals enclosed by a coating layer to produce self-healing pellets with semi-capsulation technique. These minerals may have the potential to heal concrete cracks, meanwhile, avoiding the problems in term of workability and early reactions with the existing cementitious materials.

## 2. Materials and Methods

### 2.1 Materials

The main materials used in this work were Portland cement, magnesia, and silica fume. Portland cement (PC) was the principal material for the concrete mixes while magnesium oxide (MgO) and silica fume (SF) were utilised as cargo for the developed self-healing pellets. CEM 1 (52.5N) which was supplied by Hanson, UK has been selected as PC cement. The MgO 92/200 was obtained from RBH Ltd., UK. The SF, which was adopted in this study, is undensified microsilica (MS) (from Elkem, UK), typically used in cement and concrete industries as an additive. The physical properties and chemical compositions of the raw materials, as provided by the suppliers, are listed in **Table 1**

**Table 1: Chemical and physical properties of PC, MgO, and SF as provided by the suppliers**

Chemical composition/properties		PC	MgO	SF
Chemical composition	CaO %	63.6	0.87	1.20
	SiO <sub>2</sub> %	19.50	2.25	93
	Al <sub>2</sub> O <sub>3</sub> %	4.90	0.22	1
	Fe <sub>2</sub> O <sub>3</sub> %	3.10	0.53	1
	MgO %	0.90	93.18	0.50
	SO <sub>3</sub> %	3.30	-	1
	Na <sub>2</sub> O %	-	-	0.50
	C %	-	-	2
	K <sub>2</sub> O %	-	-	-
Properties	Loss on ignition LOI %	2.10	2.59	≤ 3

	Reactivity* (sec)	-	136	-

(\*) As measured at the laboratory.

## 2.2 Pelletisation and coating

The cargo materials of the pellets were MgO and SF with 50% for each from the total solid. Water was used as a binder. The device used in this study is DP-14 “Agglo-Miser” which is a disc pelletiser supplied by Mars Mineral, USA, as shown in **Figure 1**. All the pelletisation trials were performed at room temperature. The two solid raw materials, i.e., MgO and SF, were dry-mixed together using Breville SHM2 Twin Motor Compact Mixer at the lowest speed for 3 minutes until a homogenous blend was achieved by visual inspection. Then the dry mix was loaded in the pelletiser drum wherein it was left to mix for 1 min  $\pm$  5 sec. Subsequently, the appropriate quantity of tap water was uniformly added by a venting bottle or spray gun within 1 min  $\pm$  5 sec. During the pelletisation process, the pelletiser was intermittently stopped to scrap the materials stuck to the pan and on the blades by spatula. Thereafter, the green pellets were dried in an oven at 60°C for one day. After that, the particle size distribution (PSD) analysis was performed. Then the pellets were stored in airtight plastic containers until the coating process.

**Figure 1: DP-14 “Agglo-Miser” pelletiser**

The produced pellets with diameters of 600  $\mu$ m to 4.75mm were selected for coating. Excluding the finer particles was due to the difficulty of coating them and their agglomerating while spraying the coating solution. While, the larger pellets with diameter  $\geq$  4.75mm were excluded because the pellets were used in concrete mixes instead of natural sand. The sand used in this study is a sharp natural sand with particles less than 4.75 mm. The coating solution was prepared by dissolving Portland cement in deionized water by a percent of 1 PC to 5 water. The spray gun used in the coating process is Gravity Feed Mini-HVLP gun with 1mm nozzle size. During rotation of the disc pelletiser, the pellets were sprayed with the coating solution. After that, the coated pellets were dried in the oven at 60°C for 3 days to raise the rate of cement hydration. Thereafter, the cured coated pellets were stored in an airtight plastic container until tested. Sample of these pellets from different sizes were examined under the microscope to ensure if they were coated or not. Typical images of the coating process are shown in **Figure 2**.

(a) (b) (c)

**Figure 2: (a) Preparation of cement solution for coating using a lab homogenizer, (b) Gravity Feed Mini-HVLP spray gun, and (c) Spraying the pellets while the disc pelletiser rotates.**

### 2.3 Mortar concrete mixes

Mortar concrete samples with water-to-cement ratio (w/c) of 0.5 were prepared for this study. The produced self-healing (S-H) pellets were incorporated as a partial sand replacement in four different ratios. The proportions of the four mixes are illustrated in **Table 2**. For each mix 12 cube samples (40 mm X 40 mm X 40 mm) were prepared for compressive strength analysis and 6 prism samples (40 mm X 40 mm X 160 mm) were prepared for crack forming through a three point flexural test, and crack healing analysis overtime. The samples were demoulded after 1 day of curing and then cured in a water tank at temperatures of 20°C ±2°C and a relative humidity 60°C ±2°C until the designed testing age.

**Table 2: Mix design of mortar samples by percentage weight**

Mix ID	PC (%)	Water (%)	Natural sand (%)	S-H pellets (%)
G1	22.2	11.1	66.7	0
G2			61.7	5
G3			56.7	10
G4			51.7	15

### 2.4 Tests to verify self-healing performance

Three-point flexural test was carried for prism samples from different mixing groups in order to examine the healing of the crack after certain periods and to evaluate the recovery of the flexural strength and study the effect of incorporating S-H pellets by comparing with the reference samples. Cracks were introduced in the prism samples instantly after de-moulding. Thereafter, the cracked samples were vertically setup into the water tank in order to keep the crack surface in contact. Digital microscope image analysis was used to analyse the crack healing of specimens at different ages (7 days, 14 days, 28days, and 56 days).

In order to study the effect of the addition of S-H pellets on the mechanical properties of concrete, the compressive strength testing was carried out using CONTROLS ADVANTEST9 with a maximum capacity of 250 KN and with a loading rate of 2400N/s. Three cubes (40 mm X 40 mm X 40 mm) were taken out for compressive strength test at ages of 7, 14, 28, and 56 days.

## 3. Results and Discussion

### 3.1 Pelletisation and coating

The PSD of the produced S-H pellets used in preparing mortar samples and the natural sand are shown in **Figure 3**. It is noticed that  $D_{50}$  and the gradation of particles of the both are very close. To examine the coating thickness, random samples from each size of coated pellets were selected for crushing and testing under microscope. **Figure 4** shows microscope images of some crushed pellets. It can be inferred that the thickness of the coating represents 20 to 35% from the total diameter of the pellets for most of the pellets that examined. Nevertheless, the un-coated pellets in all tested samples ranged between 30-40%.

### 3.2 Three-point flexural strength

A three-point flexural test was carried out on six prism specimens from each of the four mortar groups just after de-molding with age of 1 day and before water curing. After 28 days of water curing for three specimens from each group, the crack was induced once again in each one by the same test to monitor their mechanical strength recovery. The other specimens were re-cracked after 56 days.

**Figure 3: PSD of the S-H pellets and natural sand used in preparation of mortar samples**

**Figure 4: Samples of crushed coated pellets**

**Figure 5** illustrates the average flexural strength of the samples on 0-day curing and the average regain strength after 28-days and 56-days for each group. The graph reveals that there is a sharp decrease in the regained flexural strength of the control samples (G1) where it is (794 N) 59% from the original strength at 28 days and it is (666 N) 40.3% after 56 days. Meanwhile, the addition of S-H pellets up to 10% achieved promising results. For example, the addition of only 5% of S-H pellets shows 60.3% and 50.5% strength recovery in 28 days and 56 days respectively. Similarly, G3 demonstrates 56.31% in 28 days and 47.4% in 56 days. However, G4 shows a dramatic decrease in the original flexural strength. Nevertheless, the samples of this group had a significant recovery compared with original strength i.e. 79.4% in 28 days and 81% in 56 days. The decrease in flexural strength with increasing the proportion of pellets is believed to be attributable to the increase of the uncoated pellets in the mix which adversely affects the workability and accordingly on the strength development.

Figure 5: The flexural strength recovery for mortar specimens after 28 days and 56 days

### 3.3 Unconfined compressive strength (UCS)

Compressive strength was measured to find out the effect of partial replacement of sand by S-H pellets as presented in **Table 2**. The UCS values of mortar cube specimens at different ages (7, 14, 28, and 56 days) with their standard deviations are presented in **Figure 6** and **Table 3**. It is noticed that the addition of S-H pellets up to 10% increase the UCS values in all ages. In contrast, the addition of S-H pellets in 15% reduced the UCS for all ages in comparison with the control samples, although it had increased the self-healing capacity significantly. The main cause of the drop in the UCS values of G4 may be due to loss of workability. This is because some of uncoated pellets may be presented in the mix and this leads the free SF and MgO to consume large amounts mixing water. G2 and G3 samples show a significant increase in the UCS values at late ages particularly at 56 days. Therefore, it can be concluded that the replacement of natural sand by S-H pellets up to 10% has a positive influence on UCS.

Figure 6: UCS of mortar samples with different proportions of pellets

**Table 3: Average UCS of mortar groups in different ages**

Age (days)	G1 (R)	G2 (5%)	G3 (10%)	G4 (15%)
7	39.2	45.6	51.0	34.4
14	42.6	45.9	56.2	34.6
28	48.3	48.0	59.5	39.1
56	49.6	61.4	64.3	44.7

### 3.4 Analysis of digital microscope images

The microscopic image analysis was conducted to monitor the change in the crack widths, which were induced in the prism mortar specimens. The crack-sealing process is used as an indication for efficiency of the self-healing cementitious composites [5]. The crack widths were measured in different ages (0, 7, 14, 28, and 56) days. **Figure 7** presents digital microscope images of cracks for the mentioned ages meanwhile **Figure 8** demonstrate the average crack widths for all groups in these ages. The results show that the average cracks for all groups ranged from 43 to 83.3  $\mu\text{m}$ . Variations in self-healing have been found in different mixes and generally, the crack width varied markedly overtime, as there were no reinforcing bars or fibers in the mixes. The average crack widths in G3 were approached to close earlier than other groups. However, all samples with S-H pellets showed promising results compared to the pristine samples.

**Figure 7: Digital microscope images of cracks at 0, 7, 14, 28 days**

Figure 8: Average crack widths for all groups in different ages

#### 4. Conclusions

The following conclusions can be drawn from this study:

- The designed concrete samples containing S-H pellets of MgO and SF possessed a promising crack self-healing performance with the elapse of time in comparison to control samples. This includes both the sealing of the cracks and the recovery of flexural strength.
- Pelletisation of mineral admixtures is a cost-effective and a simple approach for self-healing of cementitious composites. This contributes to the possibility of applying broadly later.
- The major challenges of this investigation are increasing the efficiency of coating process and development the mechanism of realising the powder materials from the pellet to the surface of crack upon the crack occurrence.
- There are many other aspects need to be addressed in the future work to make this approach practically applicable.

**Abstract:** Shrinkage of concrete may lead to cracking and ultimately to a reduction of the service life of concrete structures. Among the known methods for shrinkage mitigation, internal curing with porous aggregates was utilized in the last couple of decades for decreasing autogenous and drying shrinkage. In this paper, the internal curing performance of different types of lightweight aggregates (LWA) and porous mineral admixtures is evaluated in terms of impact on the internal relative humidity and on shrinkage. In particular, next to expanded shale/expanded clay aggregates, results on zeolite, bottom ash and LWA produced from biomass-derived waste are presented. For all these porous aggregates, it is shown that the internal curing performance is directly linked to their pore structure, which determines both their water absorption kinetics and their desorption isotherm. Most of the LWA and the bottom ash examined in this research had a substantial amount of pores larger than about 50-100 nm when measured with mercury intrusion porosimetry. They showed a rapid absorption under water, a steep desorption isotherm (they lost most of the water already at 98% RH) and were efficient internal curing agents. On the contrary, the zeolite aggregates absorbed most of the water in nm-sized pores, retained the water at low relative humidity levels and were unsuitable as internal curing agents.

**Keywords:** high-performance concrete; internal curing; porous aggregate; pore structure.

## 1. Introduction

In high performance concrete (HPC), even when water evaporation is prevented, self-desiccation of the cement paste results in high capillary stresses that cause autogenous shrinkage. Restrained shrinkage may result in cracking and loss of durability of concrete structures. For HPC with low water-to-cement ratio ( $w/c$ ), low porosity and permeability, external curing may not avoid self-desiccation because the curing water penetrates only the surface layer of the concrete (only several mm). On the contrary, internal curing consists in distributing small water reservoirs into the concrete mixture [1,2], which release the water locally and limit self-desiccation. The most common water reservoirs are porous lightweight aggregates (LWA) [3], followed by superabsorbent polymers (SAP) [4].

The efficiency of LWA as internal curing agents depends on their water absorption and desorption characteristics. Preferably, they should take up water rapidly before mixing when they are stored underwater and release it during concrete hardening, while the internal relative humidity is still high. Most porous aggregates absorb significant amounts of water (about 10–30% by mass) thanks to their high porosity [5]. However, not all of them are able to release rapidly a sufficient amount of absorbed water during self-desiccation of HPC. This issue of water availability has been discussed in [6], where the concept of thermodynamic and kinetic availability of water in the hydrating cement paste was introduced. Although it has been shown recently that the water has high mobility in hydrating cement paste in the first few days of hydration (see e.g. [7,8]), the water needs first to be rapidly released at high RH. The desorption behavior of porous aggregates depends critically on their pore size distribution. LWA with coarse pore structure perform better for internal curing [9].

In this paper, the internal curing performance of different types of LWA and porous mineral admixtures is evaluated in terms of impact on the internal relative humidity and on shrinkage. In particular, next to expanded shale/expanded clay LWA, results on zeolite, bottom ash and LWA produced from biomass-derived waste are presented. The results presented in this paper derive from published [9,10] and current [11] research of the authors. This comparison between different types of internal curing reservoirs allows drawing general conclusions about pore structures that are effective for internal curing.

## 2. Materials and Methods

### 2.1 Materials

#### *Internal curing agents*

LECA (Lightweight Expanded Clay Aggregate) is a porous expanded clay aggregate that is widely used in internally cured concretes [9]. The particle size was between 1 and 4.75 mm. Zeolite (clinoptilolite) is a natural porous aggregate with high absorption capacity [9]. The particle size was between 0.1 and 4.75 mm. LWA produced from pelletization of sugar cane bagasse fly ash (bio-LWA) had particle sizes between 0.5 and 1.4 mm [10]. Finally, bottom ash (BTA) derived from a stoker burning process had particle sizes between 63  $\mu\text{m}$  and 1.4 mm [10]. In this paper, only the water absorption, the pore size distribution and the sorption isotherms of LECA and zeolite are shown, while for their performance as internal curing agents reference is made to [9]. For the bio-LWA and the BTA, internal relative humidity and autogenous deformation data of internally-cured mortars are also shown [10,11].

#### *Mortars*

An ordinary Portland cement CEM I 42.5N was used. A polycarboxylate-based superplasticizer (SIKA Viscocrete 1S) replaced part of the mixing water (deionized water) in an amount allowing for obtaining similar spread (~170 mm after 15 shocks of the table) for all analyzed mixtures. The mixture composition is shown in Table 1. Different amounts of either bio-LWA or BTA were used based on their absorption (see Table 1) in order to introduce into the mixture the same amount of water. The bio-LWA or the BTA replaced part of the NWA and the total aggregate volume was fixed at 40%. The NWA was alluvial sand composed of (by weight): sandstone 37%, limestone 37%, dolomite 18% and metamorphic rocks 8% with grain sizes 0.25 – 1.0 mm.

**Table 1. Mix compositions of mortars.**

Material	Mass [kg/m <sup>3</sup> ]			
	REF w/c 0.30	REF w/c 0.35	bio-LWA	BTA
Cement	973.4	899.7	973.0	973.7
NWA (sand)	1063.8	1063.6	555.9	665.8
LWA	-	-	324.3	221.3
Mixing water	281.3	310.4	286.1	278.5
Water in LWA	-	-	48.6	48.7
Superplasticizer	10.7	4.5	5.8	13.6
w/c basic	0.30	0.35	0.30	0.30
w/c entrained	-	-	0.05	0.05
w/c total	0.30	0.35	0.35	0.35

### 2.2 Methods

#### *Density and water absorption*

Density and water absorption in saturated surface dry (SSD) conditions was determined according to the standard ASTM C1761/C1761M–12. In this method, LWA are immersed in water for 72 h before the SSD condition is determined using a cone. The water absorption is referenced to dry state obtained after 24 h oven drying at 110°C.

#### *Pore structure – MIP*

In order to relate the desorption properties with the microstructure of the aggregates, Mercury Intrusion Porosimetry (MIP) was performed, which allows determining the equivalent size distribution [12]. The dry aggregates were inserted into the sample holder, which was first filled with mercury at pressures up to 200 kPa in a low pressure porosimeter (Pascal 140). At this pressure range, mainly the intergranular spaces

were filled by the mercury. The sample was then moved to a high pressure porosimeter (Pascal 440) which reached intrusion pressures up to 200 MPa.

#### *Desorption isotherms*

The water desorption isotherms were determined with a VTI+ Dynamic Vapor Sorption (DVS) analyzer. Before performing the desorption tests, the samples were saturated with water for  $24 \pm 2$  h. 30-100 mg of saturated LWA were placed in a sample holder and changes of mass due to water desorption were monitored continuously at different RH steps. At the end of each test, the sample was dried to constant mass at  $105^\circ\text{C}$  and 0%RH in order to obtain the reference mass for water-content calculations. The equilibrium condition for proceeding to the next RH step was set as 0.001% of the initial mass per 5 min.

#### *Internal relative humidity*

Measurements of internal RH in reference mortars and mortars with BTA and bio-LWA were performed using water activity HC2-AW sensors by Rotronic. Each mortar obtained from a single mixing was measured at two stations in parallel. The nominal accuracy of the sensors was  $\pm 0.8\%$  RH. The sensors were calibrated at the beginning and at the end of each measurement with three saturated salt solutions with equilibrium RH in the range 98–85%. This procedure allowed reducing the difference between two sensors measuring the same mortar to below 0.5% RH. The temperature of the sample and the sensor was maintained at  $20 \pm 0.02^\circ\text{C}$  by means of tempered water circulating in the casings of the measuring chambers.

Right after mixing, the mortars were cast in sealed plastic containers. At the age of approximately 24 h the mortars were crushed into pieces of 2–5 mm. About 8 g of crushed mortar were inserted into sealed measuring chambers. The measurement continued until the age of 7 days.

#### *Linear autogenous shrinkage*

The linear autogenous shrinkage of mortars was measured using the corrugated tube method [13,14]. The length change was measured on a stainless steel bench, which can accommodate three specimens in parallel, with two linear variable differential transformers (LVDTs) for each specimen. The measuring bench was placed in a tempered silicone oil bath at  $20 \pm 0.1^\circ\text{C}$ . Duplicate samples from independent mixings were measured for each mixture; average results are presented in the graphs. Automatic measurements allowed recording the deformation starting approximately 1 h after mixing. Nevertheless, the results were zeroed at final set [13]. The setting times were estimated by Vicat needle on corresponding cement pastes (same composition as the mortars, but without aggregates).

## **2.2 Results and discussion**

#### *Density and water absorption*

The density and the water absorption of the LWA determined at SSD conditions are presented in Table 2. While LECA and BTA aggregates had similar density, the absorption of the BTA was double that of LECA. This might indicate the presence of closed pores in the LECA, or of pores into which water can be absorbed only slowly. The zeolite had the highest density, though the water absorption was comparable to the bio-LWA and substantially higher than for LECA.

**Table 2. Density and water absorption of LWA**

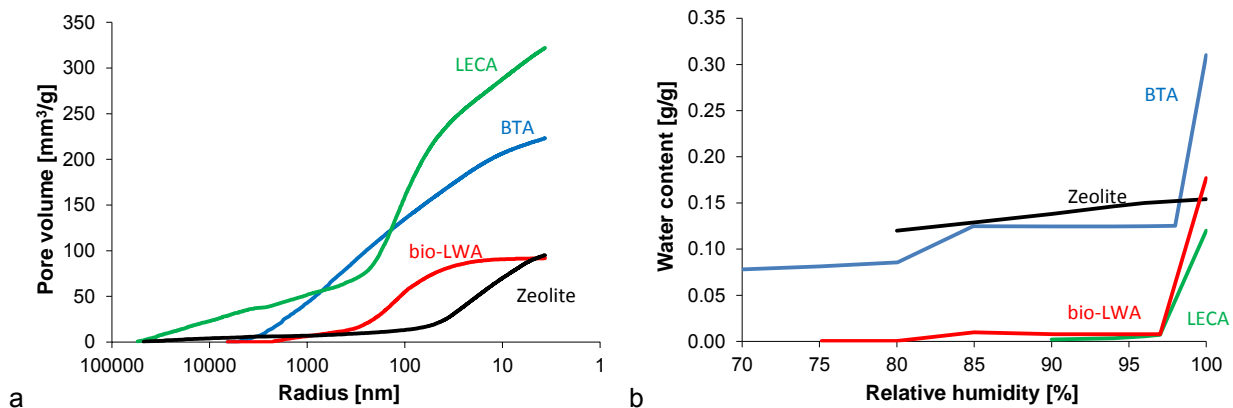

LWA type	Dry density [kg/m <sup>3</sup> ]	Absorption at 24 h [g/g]
LECA	1470	0.11
Zeolite	2250	0.16
bio-LWA	1700	0.18
BTA	1492	0.22

### Pore structure and desorption isotherms

The pore size distributions and the desorption isotherms of LWA are shown in Fig. 1. LECA had the highest porosity measured by MIP, followed by the BTA and by the bio-LWA and the zeolite with almost the same porosity (Fig. 1a). It should be noted that the 200 MPa used as maximum intrusion pressure allowed accessing pores of equivalent radii larger than approximately 4 nm. Depending on the LWA type, this may have not allowed to intrude the whole pore volume (consider also that for LECA, BTA and zeolite aggregates the pore size distribution did not reach a plateau at the highest intrusion pressures, Fig. 1 a). In LECA and BTA, a substantial amount of pores had equivalent entrance radii larger than 100 nm. The bio-LWA had slightly finer pores, with a majority between 100 and 30 nm. In the zeolite aggregates, instead, almost all the porosity were accessed through radii smaller than about 20 nm. A further analysis based on multi-cycle MIP [12] (results shown in [9-11] reveals that most of the pores in the LECA and the bio-LWA were ink-bottle pores, accessed only through pores with smaller radius. Also the BTA had a majority (about 70%, against the 90% of e.g. bio-LWA) of ink-bottle pores. It is expected that only the pore volume accessed through larger pores (larger than about 50-100 nm) might be useful for storing internal curing water. In fact, smaller pores would not be able to release the water at the high RH levels needed to avoid or limit autogenous shrinkage.

The results of the desorption isotherms presented in Fig. 1b appear to support this hypothesis. Whereas LECA, bio-LWA and BTA released a substantial amount of water already at 97-98% RH, this is not the case for the zeolite aggregate, which retains almost all the absorbed water down to 80% RH (when the experiments were stopped). Moreover, while LECA and bio-LWA were almost empty by 97% RH, the BTA retained a part of the absorbed water down to 70% RH and below. This could be explained by the presence of both large and small pores in the BTA, as suggested by MIP. The smaller pores of LECA were apparently not filled by water during the 24 h absorption period.

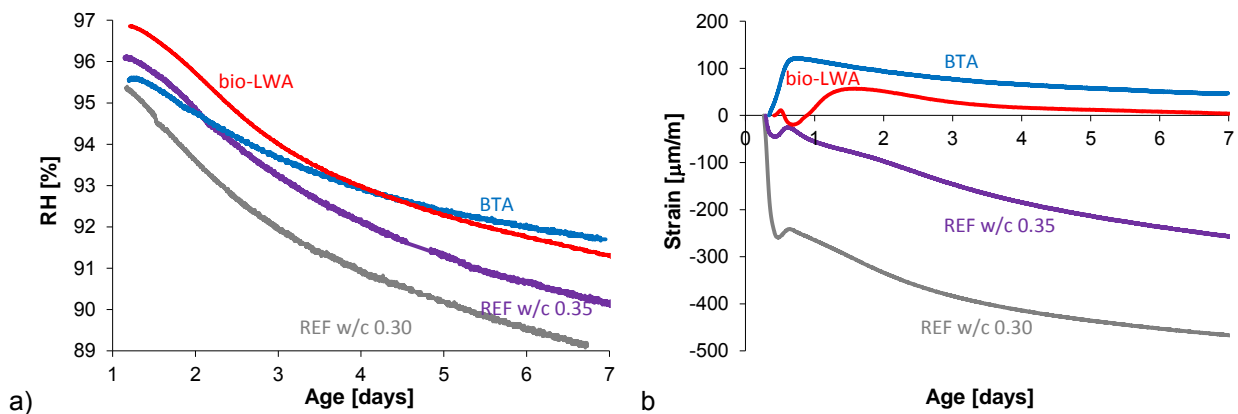

**Figure 1. a) MIP equivalent pore size distributions (cumulative curves); b) desorption isotherms.**

### Internal relative humidity and autogenous shrinkage

In Fig. 2a, the internal RH evolution in the mortars is presented, while the deformation in autogenous conditions, referred to the length at final set determined with the Vicat needle, is shown in Fig. 2b. The addition of both BTA and bio-LWA is keeping the internal RH considerably higher (especially in the first few days) compared to the reference mortar with w/c 0.30 (Fig. 2a). The RH is also higher than in the mortar with the same total amount of water, which is a confirmation of the principles of internal curing [1,2]. The autogenous shrinkage is strongly reduced in both mortars with BTA and with bio-LWA (Fig. 2b). It is noticeable that the two reference mortars differ only in the first day but have similar shrinkage rate afterwards, while the mortars with internal curing both show an initial expansion and a subsequent lower long-term shrinkage rate. Based on these results and others shown in [10,11], it is possible to conclude that both BTA and bio-LWA are efficient internal curing agents.

Results for LECA and zeolite presented in [9] show that LECA was able to delay and reduce drying shrinkage of mortars compared to the reference, while the mortars containing zeolite experience even higher shrinkage than the reference. This indicated that due to their small pores, the water absorbed in the zeolite aggregates was not available for internal curing.

**Figure 2. a) Evolution of internal RH in reference mortars and mortars with BTA and bio-LWA. b) autogenous deformation of mortars with BTA and bio-LWA.**

### 3. Conclusions

In this paper, the water absorption, the pore structures and the desorption isotherms of four different types of porous aggregates (LECA, BTA, bio-LWA and zeolite) were examined in view of their use as internal curing agents.

The principal conclusion is that the water absorption alone is not a good indicator of the internal curing efficiency. While e.g. BTA had high water absorption and was effective in keeping the internal RH high and reducing autogenous shrinkage in high-performance mortars, zeolite aggregates were not suitable as internal curing agents, despite their comparatively high absorption (16% by mass). The reason for this difference could be found in the pore structure of the different LWA. In particular, the zeolite aggregates had a majority of pores smaller than about 20 nm, which did not release the absorbed water even down to 80% RH. The other LWA types had larger pores (most of them in the range 50 nm – 1 µm) and were able to release a substantial amount of the absorbed water already at 97% RH.

A practical conclusion of this work is that MIP can be used instead of desorption isotherms measurements for a first evaluation of the suitability of a LWA for internal curing. In fact, for LWA, thanks to the prevalence of larger pores, it is possible to calculate a sorption isotherm from the MIP pore size distribution (see for example [10]). Depending on the availability of laboratory equipment and on measuring time, this approach can be more efficient than measuring a sorption isotherm.

# Reinforcing ordinary Portland cement mortar using carbon nanotubes

Shu Jian Chen<sup>1</sup>, Xiang Yu Li<sup>1</sup>, Tong Bo Sui<sup>2</sup> and Wen Hui Duan<sup>1</sup>

<sup>1</sup>Department of Civil Engineering, Monash University, Clayton, VIC, 3800, Australia

<sup>2</sup>Sinoma International, Beijing, China

**Abstract:** Carbon nanotubes (CNT), as the strongest fiber ever manufactured, are promising reinforcements in ordinary Portland cement (OPC) based materials. In this study, by dispersing CNTs with ultrasonication and polycarboxylate based surfactants, CNT-OPC mortar composites were made. The compressive strength of the material was increased by up to 20% for 28-day samples and the flexural strength of the sample was found to increase by 31%. The effect of CNT concentration was studied and it was found that 0.0375 wt% of CNTs in terms of the weight of cement gave the best results.

**Keywords:** cement, carbon nano tube, mortar, strength, ultrasonication.

## 1. Introduction

Ordinary Portland cement (OPC) based material is the second most consumed material in the world. However, its production consumes a huge amount of energy and releases greenhouse gases. The weak tensile property of OPC is one of its main limitations. Carbon nanotubes (CNTs), the strongest fibers ever manufactured, have the potential to improve the mechanical performance of cement based materials. Studies of CNT-reinforced OPC paste have shown improvements in compressive and flexural strength, fracture toughness, Young's modulus [1], porosity [2], electrical resistance [3], and piezoresistivity [4, 5] of the composite. However, little research into CNT-reinforced OPC mortar has been published. In this paper, CNT-OPC mortar composite is fabricated by dispersing CNTs with ultrasonication and surfactants. The compressive and flexural of the composite are tested.

## 2. Experimental Program

### 2.1 Materials

Type GP OPC, conforming to the requirements of Australian Standard AS 3972 [6], was used as the binder material. Multi-walled CNTs functionalized with COOH groups were purchased from Nanocyl s.a., Belgium. The physical properties of the nanotubes are shown in **Table 1**. The sand was provided by Sibelco Australia. The particle size distribution is shown in **Table 2**. A commercially available polycarboxylate-based concrete superplasticizer (PC) ADVA 210 (supplied by Grace Australia Pty. Ltd.) was used. The PC contains both active non-polar groups for adsorption on the surface of CNTs and polar groups to attach on cement particles/water in aqueous solution, thereby assisting the dispersion of both cement and CNTs [7-9].

**Table 1 Properties of functionalized CNTs**

Aspect ratio	Average diameter (nm)	Average length ( $\mu\text{m}$ )	Carbon purity (%)	-COOH functionalization (%)	Specific surface area ( $\text{m}^2/\text{g}$ )
150	9.5	1.5	>95	<4	250-300

**Table 2 Particle size distribution of silica sand**

Mesh size (mm)	% retained
0.710	0.1
0.600	1.5
0.500	20
0.425	32.5
0.355	24.5
0.300	12.3
0.250	5.6

## 2.2 Preparation of CNT suspensions

CNT suspensions were prepared by mixing CNT powder with PC in aqueous solutions under ultrasonication using a horn sonicator (VCX 500W) with a cylindrical tip (19 mm end-cap diameter). The input power of the sonicator was fixed at 150 watts. To prevent the temperature rising, the suspensions were placed in a water-ice bath during sonication. The ultrasonication energy was adopted from a previous study as 100J/mg of CNTs [10].

## 2.3 Preparation and testing of CNT-OPC mortar specimens

The mixing of the CNT aqueous dispersion, OPC and sand followed ISO 679 :1989, using a planetary mixing in compliance with ISO 681 :1989. A water-to-cement mass ratio of 0.5 was used for all the mixes. The sand-to-cement mass ratio of 3 was adopted. The mix design, as shown in Table 3, was based on the workability of CNT-OPC paste reported in a previous study [10] in order to produce very workable and consistent mortars. Based on a flow table test according to ASTM C1437 – 13, the three mixes had similar workability, yielding a flow diameter of 210±10 mm.

**Table 3 Mix proportion of CNT-OPC mortar specimens**

	Cement/g	Sand/g	CNTs*	Water/Cement ratio	SP*
Control	300	900	/	0.5	0.55%
CNT-0.0375%	300	900	0.0375%	0.5	0.85%
CNT-0.0758%	300	900	0.7058%	0.5	1.05%

Note:\* by weight of cement

The fresh mortars were poured into molds and vibrated to release residual air bubbles. The specimens were then covered under polyethylene sheets for 24 hours in the laboratory environment with temperature controlled at  $20 \pm 2^\circ\text{C}$  before demolding. After demolding, specimens were cured for 14 and 28 days in a tank of saturated limewater at  $23 \pm 2^\circ\text{C}$  as the moist-curing regime to satisfy ASTM C192 requirements [11]. Subsequently, the specimens were stored in a controlled environment maintained at relative humidity  $50 \pm 3\%$  and temperature  $23 \pm 2^\circ\text{C}$  for 1 hour before testing. This environment met the ISO requirements as a standard atmosphere for conditioning and testing of materials known to be sensitive to variations in temperature or relative humidity.

Following hardening, the mechanical properties of the hardened mortar were evaluated by compressive and bending tests to obtain the compressive and flexural strength. Cubes 20 mm in height were used in

compressive testing and 15 × 15 × 75 mm prisms were used in the three point bend tests. 50 and 2 kN load cells were installed on an Instron 4204 50 kN loading frame for compressive and bending tests, respectively. All the specimens were loaded to failure at a constant loading rate of 0.01 mm/min to maintain stable crack growth.

### 3. Test Results

Table 3 shows the strength of the CNT-OPC mortar in comparison with pure OPC mortar. Both batches of specimens containing CNTs show higher compressive and flexural strength than pure OPC specimens. It is found that 0.0375 wt% of CNT is the more effective, producing 18% improvement in compressive strength and 7% in flexural strength. The degree of improvement in the CNT-OPC mortar is lower than that obtained in CNT-OPC pastes [10], when 0.075wt % of CNTs was found to be more effective (with about 50% percent improvement in flexural strength). This might be due to the more complex nature of the mortar, where interfacial transition zones (ITZs) play important roles in the mechanical properties of the composite. The effect of CNTs on ITZs is still unclear and requires future investigation to optimize the enhancing effect of CNTs.

**Table 3. Compression (A) and bending (B) test results of CNT-OPC mortar (14 days) with different amounts of CNT incorporated (wt% is expressed in terms of the weight of dry OPC).**

### 3. Conclusions

CNT-OPC mortar composites were fabricated by dispersing CNTs with ultrasonication and a surfactant that was a polycarboxylate based superplasticizer. From the authors' previous research on CNT-OPC paste, the optimum ultrasonication energy and CNT-to-surfactant ratio for paste were used. The compressive strength of the material was increased by up to 18% and 20% for the 14-day and 28-day samples respectively. Greater improvement in flexural strength was obtained, 22% and 31% for 14-day and 28-day samples respectively. The improvement of strength in the mortar was found to be lower than that in paste, that was higher than 50%. This difference is due to the effect of ITZs in the mortar, indicating that more work is required for better understanding of CNT-ITZ interaction.

# The Significance of the Alkali Aggregate Reactivity Provisions in the VicRoads Structural Concrete Specification Section 610

Fred Andrews-Phaedonos<sup>1</sup>, Dr Ahmad Shayan<sup>2</sup>, Dr Aimin Xu<sup>3</sup>

<sup>1</sup>Principal Engineer – Concrete Technology, VicRoads, Australia

<sup>2</sup>Chief Research Scientist, ARRB Group Pty Ltd, Australia

<sup>3</sup>Senior Engineer, ARRB Group Pty Ltd, Australia

**Abstract:** Alkali aggregate reactivity (AAR) has been identified as a durability problem affecting a number of VicRoads concrete bridges since the late 1980s. At that time a number of bridges, built in the 1950s exhibited signs of distress in the form of cracking of various concrete elements, presenting costly rehabilitation requirements for these structures. Some of these bridges are situated inland and in moderate exposure conditions, whereas some others are exposed to salt water in coastal areas. VicRoads work into AAR continued throughout the 1990s and early 2000s with further investigation of additional structures for the presence of AAR. Extensive research work was also conducted on a relatively large number of aggregates, covering a wide range of aggregate types which established a strong correlation between the results of the accelerated mortar bar test (AMBT) (VicRoads RC376.03) with both the Concrete Prism Test (CPT) (VicRoads RC376.04) and field performance of the aggregates studied in a number of in-situ structures. As a consequence of the earlier investigation work, AAR testing of aggregates and mitigation measures were introduced into the 1996 version of the VicRoads structural concrete specification Section 610. This was followed by further improvements which culminated in the more recent AAR upgrade of Section 610 in 2013. The significance of the preventative AAR provisions in Section 610 is highlighted by the AAR investigation in 2014 of a relatively young bridge which was constructed some 5 years earlier in 1991, identified with AAR and premature cracking some 10 years later, and shown to have developed considerable amount of cracking and high residual expansion potentials as a result of AAR. In contrast, many VicRoads bridges monitored since the inclusion of the initial AAR provisions in Section 610 in the mid 1990s have not exhibited any signs of AAR related damage. The paper presents the updated AAR provisions in Section 610 and considered effectiveness in contrast to the investigation results of the young AAR affected bridge which will lead to further expansion and cracking and possible reduction in mechanical, structural and durability properties if costly protective measures are not undertaken.

**Keywords:** alkali aggregate reactivity (AAR), cracking, AAR damage, residual expansion, AAR provisions, cost protective measures

## 1. Introduction

Deterioration of concrete is of both internal and external origin. Deterioration of an internal origin is closely linked to the nature and chemical composition of the various constituents of concrete (cementitious materials, aggregates, water, admixtures etc), and to the internal chemical reactions in which they participate, particularly alkali aggregate reaction (AAR). The extent and rate of deterioration can also be controlled by the natural environment in which the concrete structure is situated (i.e. various exposure conditions of water etc), the technology and mechanical properties of the concrete and the construction practices adopted (1).

AAR occurs in a number of forms, the most common in Australia being that of alkali silica reaction. AAR can cause expansion and subsequent cracking of concrete, thus further compromising its durability by exposing the concrete to the easier ingress of aggressive agents such as moisture, carbon dioxide, oxygen, other gases, and salt solutions which lead to premature corrosion of the steel reinforcement(1,2,3,4). AAR also has important implications in the management of bridge assets and other concrete structures (2, 3).

AAR is a disruptive chemical reaction within the concrete matrix. The reaction, in susceptible aggregates and in the presence of moisture, is between the alkali hydroxides (sodium and potassium) and free or unstable, volatile silica minerals. It produces an expansive sodium or potassium rich (alkali) silica gel which has the ability to absorb further amounts of moisture and expand. When this expansive gel completely fills the pore system within the concrete it exerts excessive expansive stresses which can overcome its tensile capacity of the concrete. The result is severe cracking of the concrete (1, 4).

For deleterious AAR to occur in a structure, the concrete must contain aggregate with a high proportion of

reactive silica; the concrete pore solution must have a sufficiently high alkali hydroxide content; and there must be sufficient moisture, typically >85% internal relative humidity. The absence of any one of these inhibits the reaction.

The alkali aggregate reaction is normally a slow process which may take many years to manifest itself in a structure that contains the necessary ingredients for the reaction, with older bridges taking 20 to 30 years to exhibit visible signs of AAR damage. However, it has been observed over recent years that even much younger structures of less than 10 years can exhibit significant signs of AAR. This is mainly due to the higher amounts of cement content and more refined pore system, if appropriate preventative measures have not been taken, such as the incorporation into the concrete mix of adequate amounts of fly ash, slag or silica fume or combinations of these Supplementary Cementitious Materials (SCMs), as is the case with VicRoads structural concrete specification Section 610 (5).

## **2. Sources of Alkali and Moisture and Types of Potential Reactive Rocks**

The alkali hydroxides are mainly derived from the cement as they are present in its raw materials. Other possible sources include chemical admixtures, SCMs (i.e. fly ash, slag, silica fume), water and alkali released from some aggregates. Ground water, sea spray and sea water can also supply alkali. Mixing water in excess of that required to hydrate the cement can be retained as moisture within the pore system. More moisture can become available from rain and runoff, condensation, seasonal increases in humidity, leaking joints and inadequate drainage scuppers. Structures in moist environments, with surfaces immersed in water or exposed to regular cycles of wetting and drying, are particularly vulnerable.

Rocks must contain free or unstable fine-grained silica such as glass, quartz and quartz derivatives to be potentially reactive to alkalis. Potentially reactive aggregates include some originating from basalt, rhyolite, dacite and andesite, hornfels, granite and quartzite. Potentially reactive sedimentary aggregates include those originating from river gravel and sandstone (1, 4).

## **3. Visible Signs of Damage**

The visible signs of AAR damage are characterised by a network of cracks known as map cracking. Cracking can be directional, influenced by the direction of the largest applied stresses, such as in the case of prestressed concrete components. This may also be the case where significant amounts of steel reinforcement are present in a concrete component, as cracking tends to be more prominent in the direction parallel to the steel reinforcement. Other visible signs of damage include damp patches, usually at crack junctions, and discolouration due to the calcium rich alkali-silica gel which migrates to the surface of the concrete.

A greater awareness of AAR and its potential damage to concrete in recent years has made it easier to identify the problem. Previously, AAR induced cracking of 20 to 40 year old bridges may have been attributed to other factors such as drying and plastic shrinkage, surface crazing or structural movements or loadings. Shrinkage cracks and surface crazing normally develop early in the life of the structure (i.e. within hours, or days/weeks after casting the concrete and certainly within the first year), whereas AAR induced cracking may appear after about 5 to 8 years, with further deterioration taking place in subsequent years.

## **4. Durability Considerations**

The main deleterious consequences of AAR are essentially related to potentially significant reductions in compressive strength (up to 30%), tensile strength (up to 50%), flexural strength, elastic modulus (up to 60% to 80%), bond strength of the steel reinforcement and increased creep strain for concrete affected by AAR. Although not much evidence exists of significant reductions in structural capacity, reductions in the above physical properties does have the potential to adversely affect structural capacity with subsequent rehabilitation and strengthening requirements. The issue of greatest concern is the long term durability of concrete structures due to the network of cracks which substantially increase the permeability to aggressive agents. This can further accelerate deterioration mechanisms such as carbonation, chloride attack and corrosion of the steel reinforcement. Very porous and low strength concrete may be less susceptible to AAR induced damage as the gel products will tend to fill the porous microstructure first before they start cracking the concrete.

## 5. Management of Structures Affected by Cracking caused by AAR

Given the potential durability consequences it is important that AAR affected structures are inspected on a regular basis by experienced personnel. Monitoring of cracks should be undertaken using suitable measuring devices. Concrete cores are extracted from structures and subjected to petrographic analysis by viewing thin sections with a petrographic microscope. Alternatively, a more detailed examination of polished sections of concrete can be done by scanning electron microscopy (SEM). An assessment is made of the existing and predicted level (magnitude of residual expansion) of AAR expansion to enable determination of the timing and type of remedial options. Measurement of residual expansion of AAR affected concrete may show that for some elements of a structure the reaction has been exhausted and they would not develop any further AAR related cracking (1, 4).

Remedial measures to prevent moisture ingress may include:

- the injection of cracks with flexible epoxy or elastomeric chemical grouts;
- the application of flexible epoxy, elastomeric acrylic or cementitious coatings; and
- silane impregnations where appropriate.

In severe cases, concrete encasement or concrete repairs and strengthening in combination with the above may be required whereas in the more severe cases, even propping and strutting may be required.

At present there is some precedent for extensive AAR repairs including the rehabilitation of Mitchell River and Tallangatta bridges undertaken by VicRoads some 15 years ago. More repairs will probably be carried out as AAR affected bridges and other concrete structures age and given the greater awareness of the problem by asset owners, especially State Road Authorities. Bearing in mind however, that cracking and subsequent deterioration occurs in the presence of water, cracks greater than 0.2 mm in width should be chased out and filled (injected) with a suitable flexible epoxy resin to prevent further ingress of water.

In atmospheric or splash zones, the structure should subsequently be coated with a pore-lining penetrant such as pure silane to dry it out (or in combination with acrylic top coats), a flexible urethane or epoxy coating or a suitable cementitious coating. Where cracks are less than 0.2 mm, an application with a pure silane, crack bridging or crack filling epoxy, urethane or flexible acrylic coating may be sufficient. In tidal or submerged zones flexible epoxy or urethane coatings, or polymer modified cementitious coatings may be the most appropriate. Re-application of these coatings will be required at regular intervals (in the order of 10 to 20 years) depending on the type of coating and exposure conditions until the problem is effectively controlled.

Based on the extent of cracking and other AAR related durability deficiencies, the required treatments may represent a significant ongoing cost to asset managers, given the expectation to significantly increase the service life of concrete bridges and other structures (1, 2, 3, 4).

## 6. VicRoads Specification Section 610 AAR Provisions

The AAR provisions of the 2013 version of VicRoads Section 610 (5) are aimed to further enhance and augment the momentum and knowledge already generated on the subject in the previous two decades including the initial AAR measures.

VicRoads Section 610 requires that a petrographic examination of aggregates be undertaken in accordance with ASTM C295. This is to characterise the aggregate source and to determine the presence of potentially reactive silica minerals.

The specification also requires that the potential alkali silica reactivity of the coarse and fine aggregates is determined using either the accelerated mortar bar or the concrete prism test methods in accordance with VicRoads test methods RC 376.03 and RC 376.04 respectively (6,7), as a minimum on a 3 yearly basis. Regular testing of aggregates for AAR is a very important requirement as the reactivity level of aggregates does change over time as influenced by the location within the bedrock deposits from which the aggregates are quarried. This is also strongly supported by AAR research work which shows several batches of low reactivity gneiss, dacite, hornfels and granite aggregates becoming more reactive than the batches tested some 5 and 10 years ago. Monitoring over time of AAR test results from the same source during concrete mix design assessment work also supports this.

Establishing the alkali reactivity of aggregates is fundamental to the long term management of VicRoads

concrete bridges which must be based on up to date knowledge of the actual reactivity of aggregates that are used in a particular bridge, to assist with any future condition assessments and to avoid limiting the range of options and adverse influence on the cost effectiveness of remedial measures that may have to be undertaken to ensure the 100 year design life requirements.

For the accelerated mortar bar test (RC 376.03), the average expansion should not exceed 0.1% at 21 days in the case of coarse aggregates and 0.15% at 21 days in the case of fine aggregates, when tested with straight Type GP cement. Where potentially reactive aggregates are used, the total alkali content within the concrete mix must not exceed 2.8 kg/m<sup>3</sup> and SCMs must be used to ensure that expansion does not exceed either 0.1% at 21 days for coarse aggregates or 0.15% for fine aggregates.

As an alternative, for a longer term evaluation of aggregates using the less aggressive concrete prism test method (RC 376.04), the average expansion at 12 months is to be less than 0.03%, when tested with straight Type GP cement. Aggregates classed as reactive by the concrete prism test method in a concrete mix design, cannot be used in that particular concrete mix design. Alternative aggregates and/or alternative concrete mix designs must be used subject to compliance with the requirements of the specification.

The specification requires that where blended aggregates are used, the aggregates from different sources must be tested individually, and where fine and coarse aggregates are procured from the same source, only one alkali silica reactivity evaluation per source is required to be undertaken.

Further to the minimum testing requirements above, where it is proposed to use aggregates that have been classed as reactive, the specification requires the use of concrete mixes which contain as a minimum the proportions of supplementary cementitious material as stated in Table 1 (5).

**Table 1 - Minimum proportion of supplementary cementitious material (SCM) combination with Portland cement in the concrete mix to mitigate alkali aggregate reactivity (%) (5).**

Supplementary cementitious material (SCM)	Minimum proportion of SCM in single combination with portland cement in the concrete mix to mitigate alkali aggregate reactivity (%)	Minimum proportion of SCM in double combination with portland cement in the concrete mix to mitigate alkali aggregate reactivity (%)		
		Fly Ash	Slag	Amorphous Silica
Fly Ash	20	-	-	-
Slag	50	-	-	-
Amorphous Silica	8	-	-	-
Fly ash + Slag	-	15	15	-
Fly Ash + Amorphous Silica	-	15	-	5
Slag + Amorphous Silica	-	-	40	5

Where it is proposed to deviate from the minimum blended cement requirements stated in Table 1, the specification explicitly requires that further testing is undertaken to demonstrate compliance with both the maximum mortar bar and concrete prism expansion limits as determined by VicRoads test methods RC 376.03 and RC 376.04.

In addition to the above provisions, reference in Section 610 to the ATIC-SPEC SP43 (Cementitious Materials for Concrete published by ATIC (Australian Technical Infrastructure Committee)), limits the amount of alkali content within the concrete mix in order to prevent or minimise the risk of AAR. These include:

- (a) General purpose cement and Portland cement clinker to AS 3972, plus additional acceptance criteria within ATIC-SPEC SP43, including the total alkali content (Na<sub>2</sub>O equiv) not to exceed 0.6%.
- (b) Fine grade fly ash to AS 3582.1 and the following acceptance criteria. 'Significant oxides', defined as silicon oxide (SiO<sub>2</sub>), aluminium oxide (Al<sub>2</sub>O<sub>3</sub>) and iron oxide (Fe<sub>2</sub>O<sub>3</sub>), to be greater than 70%, plus the total and available alkali (Na<sub>2</sub>O equiv) to meet either of the following criteria:
  - Total alkali content to be less than 3.0%, or
  - For total alkali content greater than 3.0%, but less than 4.5%, the available alkali not to exceed 2.0% for any single determination.

- (c) Slag to AS 3582.2 plus additional acceptance criteria within ATIC-SPEC SP43, including the available alkali content (Na<sub>2</sub>O equiv) not to exceed 0.5%.
- (d) Amorphous silica (silica fume) to AS/NZS 3582.3 plus additional acceptance criteria within ATIC-SPEC SP43, including the available alkali content (Na<sub>2</sub>O equiv) not to exceed 0.5%. For slurried and densified (i.e.: condensed or microsilica) amorphous silica, sampling and testing to be done from the raw silica used to make these products.

Minimum sampling and testing as appropriate for both available alkali content and total alkali content within the cement, fly ash, slag and amorphous silica is prescribed within ATIC-SPEC SP43.

The use of SCMs as cement replacements has proven to be very effective in reducing the negative effects of AAR. SCMs reduce the availability of alkalis for expansive reactions and make the concrete more water tight. Depending on the type of aggregate and magnitude of potential reactivity the minimum effective cement replacement levels are as indicated in Table 1.

It must be emphasised that from ongoing monitoring of VicRoads bridges constructed since the introduction of the AAR provisions into VicRoads Section 610 in 1996, no bridges have been found to exhibit any signs of AAR.

## 7. Influence of Fly Ash in reducing the AAR Effect

Fig. 1 demonstrates the effectiveness of fly ash in reducing AAR induced expansions (4). However, what Fig. 1 also shows is that whereas, 25% fly ash would definitely suppress the AAR expansion, 15% fly ash is unlikely to suppress the AAR reaction into the longer term and especially in-situ, as it appears to be taking off when the test actually ceased at 21 days. As such insufficient amounts of SCMs may show up as being adequate to suppress AAR, whilst in reality could lead to expansion and cracking of concrete structures in-situ. The minimum proportions of supplementary cementitious material as stated in Table 1, aim to address this deficiency.

A research project currently undertaken by the ARRB on behalf of Austroads is studying the appropriateness of both the test methods and current test limits to be able to evaluate the effectiveness of SCMs to effectively suppress AAR. In addition, it is studying, the efficiency of the SCMs concerned and the optimum amount to be used in concrete to suppress AAR. These findings will be reported in a future technical paper. Based on these findings further improvements and refinements may also be undertaken in VicRoads Section 610 with respect to its AAR provisions including the requirements of Table 1.

Figure 1. Comparative Mortar Bar Expansion - Results of Aggregate X with and without Fly Ash (4).

## 8. Testing for Potential Alkali Reactivity of Aggregates

The assessment of concrete aggregates for potential alkali reactivity can be undertaken using a number of laboratory test procedures.

- (a) **Petrographic examination:** an optical examination and analysis of the aggregate. This is undertaken to identify the types of minerals present and any suspect mineral phases. This is done using test method ASTM C295. Additional examination can be undertaken using scanning electron microscopy (SEM) and energy-dispersive X-ray (EDX) analysis.
- (b) **VicRoads accelerated mortar bar test method RC 376.03 (6):** Mortar bars are stored in caustic soda solution at 80°C and expansion is monitored for the required period. The test is rapid and provides results in about 3 to 4 weeks. The average expansion should not exceed 0.1% for coarse aggregate and 0.15% for fine aggregate at 21 days.
- (c) **VicRoads concrete prism test method RC 376.04 (7):** This test is considered to be less severe on the test samples and can be used to evaluate the aggregate performance over a 12 month period. The concrete prism test is appropriate when a longer period of time is available. Concrete prisms are produced using the actual concrete aggregates, with a minimum cement and alkali content, and are stored in sealed containers at 100% relative humidity and 38°C. The length of the prisms is measured at prescribed intervals for the 12 month period. Average expansion exceeding 0.03% at one year is considered deleterious.
- (d) **Determination of residual expansion (2):** Demec measuring studs are bonded onto the concrete cores with epoxy. Following the curing of the epoxy resin adhesive cores are soaked overnight in 0.5M NaOH solution at room temperature to allow them to absorb water without significant dilution of alkali in the pore solution of the concrete. The initial length is then measured, after which the cores are wrapped in moistened cloth and stored over water in sealed containers and transferred to a room kept at 38°C. The length change of the cores is measured periodically after equilibration at 23°C for a period of 12 months.

It should be noted that two new Australian standard test methods were published in 2014, namely, AS 1141.60.1 (Accelerated mortar bar test) and AS 1141.60.2 (Prism test). However, these test methods still require validation in practice with actual testing and a reliable performance correlation established with the respective VicRoads test methods, namely, RC 376.3 and RC 376.4, for local aggregates before acceptance by VicRoads.

## **9. 23 Year old Concrete Bridge affected by Alkali Aggregate Reaction (8, 9)**

### **9.1 General**

The investigation, assessment and associated results of this young bridge for AAR, highlight the significance of the AAR provisions in the VicRoads Section 610 introduced and further enhanced between 1996 and 2013. Importantly this bridge which was constructed in 1991 with a concrete comprising reactive aggregates and Type GP cement with a total alkali content exceeding 0.6%, and without the inclusion of any supplementary cementitious materials, was identified with AAR and premature cracking some 10 years later.

The two-span bridge which consists of a PSC box girder and a monolithic pier wall and the two abutments was identified with premature cracking some 10 years after construction. A brief examination undertaken in 2003, of cores taken only from the south east abutment, indicated that alkali aggregate reaction (AAR) was present in the concrete. However, no other concrete investigation was conducted at the time and it is unclear whether the pier wall had exhibited cracking in 2003, although at present cracking is clearly evident in the pier wall.

In 2014 an investigation (9) was commissioned into the concrete cracking at both the pier wall and the southern abutment crosshead. The aim of this investigation was to assess the concrete for AAR and its future expansion potential and to determine the relevant mechanical properties of concrete which may influence the bridge integrity.

### **9.2 Scope of investigation work (9)**

The investigation was limited to visual inspection and the extraction of five concrete cores taken from each of the pier wall and the southern abutment crosshead for the determination of the following properties:

- Visual features of cores
- AAR-related properties:
  - Petrographic examination
  - SEM examination
  - Available alkali content (soluble)
  - Residual expansion
- Compressive strength
- Modulus of elasticity
- Volume of permeable voids (VPV)

### 9.3 *Field Investigation*

#### 9.3.1 *Concrete Cores*

Five cores were drilled from each component; one 95 mm diameter core and four 74 mm diameter cores. Cores were drilled from the southern side of the pier wall adjacent to cracks and cores from the abutment were taken from near the west end of the element, where cracking was seen a few years ago. The abutment crosshead has been coated since that time and the cracks are no longer visible.

Examination of the cores showed that the coating was elastic and was about 140 µm thick. Additional cores which stopped as they intersected the steel reinforcement showed no corrosion on the exposed bars.

#### 9.3.2 *Cracking in Components*

Examination of the pier wall showed extensive cracking on all four faces. A few cracks were present on the side wall of the box girder and on the parapet near the abutments, where the components were accessible. Cracks in the abutment crossheads were covered over by the 140 µm grey elastic coating.

##### 9.3.2.1 *Cracking on Pier Wall*

Long vertical cracks have developed from top to bottom of the pier wall surfaces, which are visible on enlargement of photographs due to the masking effect of the concrete coating. The crack width was about 0.3 to 0.4 mm for finer cracks and 0.5 to 0.6 mm for the wider cracks (Fig. 2).

**Figure 2. (L) Crack (0.6 mm) pier wall; (C) Crack on box girder wall; (R) typical reaction rim (9)**

##### 9.3.2.2 *Cracking in Box Girder*

Horizontal cracking was observed on the side face of the box girder over the west end of the southern abutment, which was highlighted in previous investigation (Aug' 03). The widest part of the box girder crack was measured at 0.25 mm (Fig. 2).

##### 9.3.2.3 *Cracking in Parapet*

Cracking was noted in the lower part of the parapet, above the abutment crosshead, and in the kerb below the safety barrier. The vertical cracks are of regular space, which may be caused by shrinkage.

### **9.4.3 Visual Examination of cores**

#### *9.4.3.1 Cores from Pier wall*

Concrete Core 1 was noted as dense, with no cracking evident. One aggregate particle at the fracture surface showed signs of AAR gel formation. The coarse aggregate contains a dark variety of 7-20 mm size and white/cream variety of a small particle size. Some of the white aggregate pieces show faint signs of gel impregnation at the cement paste interface. Core 2 and Core 4 were noted to be very similar to Core 1.

Core 5 was found to be similar to Core 1 with dark aggregate particle exhibiting definite signs of AAR and a nearby void filled with AAR product. Some white aggregate particles also exhibit signs of gel impregnation at their boundaries with the cement paste. Weak to moderate AAR may be present in the concrete.

The coarse aggregate in Core 3 is also largely of the darker variety and the white aggregate is largely in the fine fraction. A few of the white particles of 7-10 mm show mild signs of gel formation at their interface with cement paste. Several dark aggregate pieces show stronger signs of gel impregnation at their boundaries with the paste. Some AAR seems to be present in the concrete.

#### *9.4.3.2 Cores from abutment crosshead (Surface coating on the outer face of cores)*

Both types of dark and white aggregate are present in Core 6. Two pieces of steel (16 mm dia.) are cut at depth of 60 mm and the edge of another bar is cut at 80 mm depth. A crack is present at the outer end of the core, which penetrates about 50 mm into concrete. A large pore and some small pores are filled with AAR products. Some aggregate pieces show AAR gel impregnating in the paste around them. Moderate AAR has occurred in the concrete. Internal aggregate cracking is present in some pieces.

The interior fracture surface of Core 7 shows several aggregate particles with AAR rims and a 5 mm diameter void was filled with AAR product. Many aggregate particles exposed at the drilled surface of core exhibited a sweating look indicating AAR gel impregnation in the surrounding mortar. Both the dark and cream/brown aggregates have reacted. Moderate AAR is present in the concrete.

The features of Core 8 are similar to Core 7, but there is also a crack at the outer end of the core (beneath the surface coating) which penetrates about 80 mm on one side and 60mm on the opposite side. Finer cracks also extend to 80 mm depth. Some aggregate pieces show internal cracking. Another Core 9 has features similar to Cores 7 and 8 but the AAR signs are milder. There is no cracking at the outer end of the core.

Core 10 has features are very similar to those in Core 9. Cores 9 and 10 are from the middle of the crosshead which appears to have weak AAR.

Overall, the visual examination of cores indicated that moderate AAR is present in the concrete. This is illustrated by the typical, white reaction rims around some aggregate particles (Fig.2).

### **9.4.4 Petrographic examination of cores**

#### *9.4.4.1 Pier wall*

The coarse aggregate in Core 3 is a mixture of metamorphic rock types of schist and gneissic rock types and all the particles exhibit strong signs of deformation and orientation, as indicated by elongated quartz grains and bands of micaceous minerals in parallel orientation. Some particles comprise a fine matrix of microcrystalline quartz and highly birefringent amphibole type minerals. Another variety includes a similar mineral assemblage, but with larger quartz crystals and the quartz also exhibits elongation. Some other particles resemble hornfels rock type. Particles of quartzite and quartz gravel with highly deformed quartz crystals are also present in which quartz shows patchy extinction and large undulatory extinction angles and sutured boundaries. All of these rock types are considered to be susceptible to AAR.

The fine aggregate fraction is a mixture of monomineralic quartz and feldspar crystals as well as finer fragments of the coarse aggregate particles. Some of the single quartz crystals also show moderate undulatory extinction angles. A portion of the fine fraction may be susceptible to AAR.

The cementitious matrix shows a considerable number of microcracks at the aggregate periphery, extending into the cement paste. AAR gel is definitely identified in some microcracks around the aggregate and in the microcracks within the paste. This concrete has clearly undergone AAR.

#### 9.4.4.2 Abutment crosshead

The coarse and fine aggregates in Core 6 are similar to those described for Core 3. In addition, one dark brown and one black particle with cryptocrystalline matrix were present, comprising very fine quartz and probably micaceous minerals. These particles could be of rhyolitic nature. Carbon may be present in the black particle. Similarly to the previous core, the coarse aggregate and part of the fine aggregate are considered to be prone to AAR. The cementitious matrix exhibits considerable microcracking and AAR gel is clearly identified in the concrete, even to a greater extent than in Core 3 from the pier wall.

The petrographic examination clearly shows that AAR is present in the pier wall and abutment crossheads concrete.

#### 9.4.5 Scanning electron microscopy (SEM) and energy-dispersive X-ray (EDX) analysis

The SEM/ EDX examination of both the pier wall and abutment crosshead cores provided strong evidence of the presence of AAR products in the concrete, both in and around aggregate particles, and in the microcracks in the cement paste. Some products were highly enriched with alkali and some contained aluminium, which indicated that in addition to the silica minerals, feldspar minerals may also have been involved in the reaction. Overall Core 7 from the abutment crosshead appeared to contain more extensive reaction products than the cores from the pier wall.

#### 9.4.6 Compressive Strength

The average value of compressive strength was 41 MPa, and there is no difference in the level of strength for the pier wall and abutment crosshead (Table 2). The strength indicates that the concrete may be of VR400/40 strength grade, although it is just on the borderline of the required 40 MPa for characteristic strength. These values of compressive strength may overestimate the actual strength of the element as cores are drilled in sound portions of concrete away from cracks, whereas the element itself would contain a considerable extent of cracking.

**Table 2 - Compressive Strength (9)**

ID	Component	Strength (MPa)	Mean ± 95% confidence range
Core 1	Pier wall	43.1	41.2 ± 4.0 MPa
Core 4	Pier wall	37.7	
Core 7	Abutment Crosshead	42.9	
Core 10	Abutment Crosshead	41.3	

#### 9.4.7 Volume of Permeable Voids (VPV)

VPV is a measure of porosity and permeability of concrete and influences several durability properties of concrete. VicRoads Section 610 states that cores drilled from a concrete of VR400/40 grade must not exceed a VPV value of 16%.

The VPV results for the cores taken from the pier and abutment crosshead were 15.4% and 15.6%, respectively. These values can be considered acceptable with respect to VicRoads requirements.

#### 9.4.8 Modulus of Elasticity

Cores 5 and 9 were subjected to modulus of elasticity testing, in accordance with AS 1012.17, *Methods of Testing Concrete. Method 17: Determination of the Static Chord Modulus of Elasticity and Poisson's Ratio of Concrete Specimens*.

Testing was conducted in accordance with AS 1012.17-1997 Appendix A, where compressive strain measurements were recorded by two bonded 120-Ohm strain gauges attached at 180° along the central 60mm of the cylinder. The cylinders were installed between the platens of a calibrated universal testing machine and load was applied until a stress of about 40% of the nominal compressive strength was achieved. At this point the load was released before repeating the loading cycle two more times. A fourth load cycle was then applied until a peak compressive stress was achieved. All testing was conducted in an enclosed environment at an ambient temperature of about 25°C and 50% humidity.

When tested, core 9 (abutment crosshead) achieved the lowest static chord modulus value (19 GPa). The static chord modulus value for Core 5 was of the order of 27 GPa (reduction of about 20% compared to design requirements for this type of concrete). The lowest modulus of 19 GPa (reduction of about 45%) for the abutment crosshead in young bridge is attributed to the more extensive occurrence of AAR in this concrete.

#### 9.4.9 Water soluble Alkali Content

The water soluble alkali content in the cores from the pier wall and the abutment crosshead was 3.78 kg/m<sup>3</sup> and 3.06 kg/m<sup>3</sup> (> than permitted maximum of 2.8 kg/m<sup>3</sup>), respectively, as shown in Table 3. Assuming that the concrete was of VR400/40 grade, the water soluble alkali as a percentage of cement mass would be 0.94% and 0.76% in the concrete of the pier wall and abutment crosshead, respectively. These values are higher than the 0.6% permitted, which may indicate that a local GP cement which is no longer available was used in the concrete, which had alkali contents in the range of 0.9 – 1.1 %. If the cement alkali content was actually lower than in the local cement, then the additional alkali may have been contributed from the Aggregate phase.

It is generally accepted that an alkali content of greater than 2.8 kg/m<sup>3</sup> is required to sustain AAR in concrete. Therefore, it can be expected that AAR will continue in the concrete, particularly if the aggregate phase releases alkali into the concrete. Petrographic features of the aggregate suggest that this may be possible.

**Table 3 - Water Extractable Alkali Content (9)**

ID and Component	Alkali per weight of concrete (%)				Alkali per volume of concrete (kg/m <sup>3</sup> )			
	CaO	Na <sub>2</sub> O	K <sub>2</sub> O	Na <sub>2</sub> O eq.	CaO	Na <sub>2</sub> O	K <sub>2</sub> O	Na <sub>2</sub> O eq.
Core 3, Pier	0.2494	0.1121	0.0859	0.1686	5.59	2.51	1.92	3.78
Core 8, Abutment Crosshead	0.2688	0.0899	0.0708	0.1365	6.02	2.01	1.59	3.06

#### 9.4.10 Residual Expansion

Cores 3 (pier wall) and 6 (abutment crosshead) which had a diameter of 95 mm were fitted with Demec studs and exposed to conditions of 100% RH, 38°C to enhance AAR expansion, which would reflect the residual expansion potential of the concrete. The expansion of the cores is being measured by using Demec gauge. The residual expansion potential is determined by the value of expansion measured at the age of one year, when the expansion usually flattens out.

The expansion results are presented in Figure 3 and at 365 days of exposure the expansion of both cores is relatively large and far exceeds the allowable limit of 0.03%. Core 6 from the abutment crosshead exhibits significantly higher expansion at the age of one year. The trend for both cores indicates that further reaction and cracking is likely in these elements.

Figure 3. Residual expansion of concrete. Core 3 from pier wall. Core 6 from abutment crosshead(9)

## 10. Discussion

The 23 year old post-tensioned box girder bridge referenced in this paper (constructed in 1991) situated in a moderate environment (exposure classification B1), was constructed with a concrete comprising reactive aggregates, Type GP cement with a total alkali content exceeding 0.6%, and without the inclusion of any supplementary cementitious materials. Within 10 years in service it was identified as suffering from premature cracking. A brief examination undertaken in 2003, of cores taken only from the south east abutment, indicated that alkali-aggregate reaction (AAR) was present in the concrete. A more detailed AAR investigation undertaken in 2014 established that both the pier wall and the abutment crosshead of the bridge are suffering from AAR. Both elements have developed considerable amount of cracking as a result of AAR. Crack widths in the pier wall are in the range of about 0.4 mm to 0.6 mm. The cracks previously reported for the abutment crosshead have been masked by the newly applied, grey surface coating. In addition both elements have exhibited high residual expansion potentials as judged by measurements for up to 365 days of exposure. This trend is expected to continue and indicates that the concrete would develop further expansion and cracking. This is further supported with the water extractable alkali content in the concrete of 3.8 and 3.0 kg/m<sup>3</sup> (> than allowable of 2.8 kg/m<sup>3</sup>) in the pier wall and abutment concrete, respectively, which is adequate for AAR to continue.

The elastic modulus of the concrete in the pier wall at this stage was determined at around 27 GPa (about 20% lower than design requirements for this type of concrete) and that in the abutment crosshead 19GPa (about 45% lower than design requirements for this type of concrete), which suggest that the latter element was more seriously damaged by AAR. This is in agreement with other microstructural observations.

It is important to emphasise that given the high alkali content within the concrete to sustain further reaction and expansion and the confirmed high residual expansion potential into the future, further cracking and reductions in strength and modulus of elasticity and possibly flexural and bond strengths will occur.

Based on these results an effective coating should be maintained to reduce the rate of AAR induced expansion. It was also considered that suitable strengthening and/or durability measures may be required for the bridge in the longer term to reduce the rate of expansion. The box girder of the bridge was not tested. However, given its importance it is considered that the bridge box girder also required testing given the likelihood that it may be made from similar concrete. In addition, it was considered that other bridges in the area that used similar concrete would also need to be assessed for AAR induced deterioration.

The unsatisfactory results of this 23 year old freeway overpass bridge, the significant AAR investigation costs over the past 10 years and the expected high repair costs highlight the importance of the AAR provisions, the concrete mix design (aggregate and other ingredient properties change over time) requirements and the overall integrated durability provisions in Section 610 progressively introduced and further enhanced since 1996. The AAR provisions in Section 610 which would have prevented the AAR damage in the 23 year old bridge presented in this paper can be summarised as follows:

- Petrographic examination of aggregates.
- Alkali silica reactivity testing of both the coarse and fine aggregates on a 3 yearly basis.
  - AMBT testing has shown that low reactivity aggregates were found to be significantly more reactive than the same aggregates tested over a 10 year period.
- AAR expansion limits for both fine and coarse aggregate.
- Provision for both accelerated mortar bar test method (RC 376.03) and concrete prism test method (RC 376.04).
- Concrete mixes to contain minimum proportions of supplementary cementitious material to mitigate AAR.
- Limitations on alkali content within the cement and the various cementitious materials.
- Alkali content in the concrete mix not to exceed  $2.8 \text{ kg/m}^3$  ( $\text{Na}_2\text{O}$  equiv).

Finally, it should be noted that in contrast to the condition of the 23 year old freeway overpass bridge (which showed AAR affected cracking some 10 years after construction), ongoing monitoring of a number of VicRoads bridges constructed since the mid 1990s in various in-service exposure conditions have not exhibited any signs of AAR related damage, demonstrating so far the effectiveness of the AAR preventative measures included in VicRoads Section 610. It is considered that these preventative measures will ensure the long term durability performance of VicRoads bridges and minimise unnecessary and costly maintenance needs.

**Abstract:** This paper presents an experimental study investigating the long-term behaviour of seven floor slab samples prepared with recycled coarse aggregate (RCA). In particular, three specimens consisted of slabs cast on steel-bars truss decks, while the remaining four samples were composite slabs poured on profiled steel sheeting. The slab specimens were tested in a simply-supported static configuration and monitored for a period of over five months. Separate concrete samples were prepared and tested to measure the occurrence of the non-uniform shrinkage profile through the slab thickness (developed due to the inability of the slabs to dry from their underside). Experimental results showed that the use of RCA produced increases in the measured long-term deflections when compared to the natural aggregate concrete (NAC) samples. It was also noted that time-dependent deflections were influenced by the shrinkage gradient and that the latter increased with RCA contents. The experimental measurements collected in this study are expected to contribute towards the development of adequate design guidelines for slabs prepared with RCA by providing benchmark data for the validation of numerical and design models.

**Keywords:** Recycled coarse aggregate, Recycled aggregate concrete, Floor slabs, Long-term deformation, Non-uniform shrinkage, Creep, Steel deck.

## 1. Introduction

Crushing waste concrete as aggregates for new concrete (recycled aggregate concrete) production represents an alternative to reduce the carbon footprint of natural aggregate concrete (NAC) [1-2]. Recycled aggregate concrete (RAC) has been commonly used to date for the casting of non-structural members, such as pavement, roadwork foundations, piles and mass concrete pours [3-6], because of its lower compressive strength and elastic modulus when compared to NAC [7-9]. Despite this, RAC has the potential to be applied over a broad range of structural applications and this has already been demonstrated from experimental work, for example, for RAC beams and columns, e.g. [10-17]. Full-scale tests were conducted by Sato et al. [10] on nine simply-supported beams to quantify the differences of flexural behaviour between RAC and NAC beams. They reported that the differences in the flexural capacities of beams made of NCA and RCA with the same reinforcement ratios were negligible. Etxeberria et al. [11] investigated the influence of RCA contents on the shear behaviour of twelve RAC beams with and without transverse reinforcement, and highlighted that beam specimens with transverse reinforcement and concrete with 50% and 100% RCA achieved approximately the ultimate shear load of NAC samples. Choi et al. [15] reported that the axial behaviour exhibited in RAC columns was comparable to that found in conventional reinforced concrete columns, and RAC could be effectively used as a structural material. A number of international design specifications regulate the use of RAC in reinforced concrete structures according to the quality of recycled coarse aggregate (RCA) [18-22]. In China, for example, the Type-I RCA with similar physical properties to NCA is permitted to be used in any reinforced concrete structure by JCJ/T 240-2011 [22], while the low-quality Type-III RCA is conservatively recommended for low-strength concrete applications (<25 MPa) which do not undergo freezing and thawing cycles. Due to the support of experimental research and international design specifications, increasing applications of RAC in reinforced concrete structures can be found worldwide, e.g. [23]. In the case of composite floor systems, recent research highlighted the ability for RAC composite slabs to obtain similar flexural capacity and longitudinal shear behaviour to NCA samples [24-26].

In this context, this paper intends to investigate how the use of RCA influences the long-term behaviour of composite steel-concrete slabs. Particular attention is devoted to the development of the non-uniform shrinkage profile which occurs due to the inability of the slabs to dry from their underside [27, 28]. As part of this study, seven full-scale slabs were prepared and tested. These included three specimens cast on steel-bars truss decks and four samples poured on profiled steel sheeting considering different levels of RCA replacement and slab thicknesses. Companion samples were subjected to shrinkage effects only and to the combined effects of external loads and shrinkage. Separate concrete samples were prepared and monitored to measure the development of non-uniform shrinkage through the slab depth. It is envisaged that the experimental measurements collected as part of this project will provide useful benchmark data for the validation of numerical and design models for RAC composite slabs.

## 2. Experimental program

### 2.1 Test overview

The experimental program involved the testing of seven full-scale slab samples with different RCA contents and slab depths for a period of five months. Two different decking profiles were considered and these consisted of steel-bars truss decks and profiled steel sheeting. Corresponding small-scale concrete samples were prepared to evaluate the development of non-uniform shrinkage through the thickness of the slab. Standard tests were carried out to determine the material properties of the components forming the cross-section. Details of the tests and measurements are reported in the following.

### 2.2 Aggregate properties

ASTM I Portland cement (with specific density of 3.17) was used as binder for the concrete prepared for this study. River sand (0-5 mm) with fineness modulus of 2.58 and limestone (5-25 mm) were used as natural aggregates. The RCA was sourced from a real demolition project of a 19-year-old building whose concrete properties consisted of a water-to-cement ratio of 0.45 and cubic compressive strength of about 30 MPa.

The demolished concrete underwent a two-stage crushing process. The first crushing treatment was carried out on the demolition site with clamp mechanical excavators and jackhammers, while the second crushing process was held in the laboratory with jackhammers and jaw crusher, during which the size of the waste concrete was reduced to less than 25 mm. The RCA was then sieved with square mesh to achieve a proper size fraction in accordance with the European Code UNE-EN 933-1 [29]. For comparison purposes, similar coarse aggregate gradations were used for the preparation of the RCA and NCA specimens and these are outlined in Table 1 (based on which the adopted RCA was graded as Type-I RCA and complied with the requirements of Chinese code JCJ/T 240-2011 [22]). Material properties measured during the experiments, e.g. density, water absorption, residual mortar content and index of crushing, are also reported in Table 1.

**Table 1. Basic properties of aggregates**

Properties	Size of test sieve (mm)	Cumulative passing by weight (%)		
		NCA	RCA	NFA <sup>a</sup>
Sieve analysis	26.5	100.0	100.0	—
	19.0	66.7	66.7	—
	16.0	50.0	50.0	—
	9.0	16.7	16.7	—
	4.75	0.3	0.4	—
Density (kg/m <sup>3</sup> )	Oven-dried	2777	2588	2623
	Saturated surface-dry	2792	2650	2714
Water absorption (%)		0.55	2.40	3.40

Index of crushing (%)		4.3	15.2	—

<sup>a</sup> NFA—Natural Fine Aggregate.

### 2.3 Recycled aggregate concrete and steel properties

Three concrete mixtures were prepared in the laboratory and their details are provided in Table 2. A superplasticizer with specific density of 1.2 g/cm<sup>3</sup> was used to achieve a sufficient workability for the fresh concrete mix (Table 2). These were used for the preparation of three concrete mixes based on three RCA amounts, i.e. 0%, 50% and 100% of the coarse aggregate by weight, respectively. The effective water-to-cement ratio, the sand ratio and the cement content were kept constant at 0.45, 0.36 and 400 kg/m<sup>3</sup>, respectively. The effective water-to-cement ratio and workability of the RAC were controlled by pre-soaking the RCA in water for 24 hours and by draining it for about 1 hour before batching. Slump tests were carried out and slump values ranged between 140 and 190 mm. All samples, including full-scale slab samples, small-scale slab samples, and concrete samples for material tests, were wet cured for seven days from casting and then permitted to dry in air. Cubic compressive strength (150×150×150 mm<sup>3</sup>), splitting tensile strength (150×150×150 mm<sup>3</sup>) and elastic modulus (150×150×300 mm<sup>3</sup>) of all hardened concrete mixtures at 7, 28, and 90 days were measured, as summarised in Table 3.

**Table 2. Concrete mixture design and fresh concrete properties**

Mix designation	Replacement ratios (%)	Mix proportions (kg/m <sup>3</sup> )					Slump (mm)	
		Water	Cement	Sands	Coarse aggregates			SP <sup>a</sup>
					NCA	RCA		
NAC-0%	0	180	400	680	1208	0	4.0	170±20
RAC-50%	50	180	400	650	578	578	4.0	160±20
RAC-100%	100	180	400	620	0	1102	4.0	170±20

<sup>a</sup> SP—Superplasticizer.

**Table 3. Mechanical properties of hardened concrete**

Mix designation	Compressive strength (MPa)			Splitting tensile strength (MPa)			Elastic modulus (GPa)		
	7 days	28 days	90 days	7 days	28 days	90 days	7 days	28 days	90 days
NAC-0%	33.2	40.9	45.9	4.3	4.9	4.6	31.8	35.5	33.8
RAC-50%	28.0	39.9	43.4	3.8	4.8	4.7	28.7	29.1	28.8
RAC-100%	27.3	36.3	42.1	3.1	3.4	3.6	25.1	26.3	26.3

As expected, when the RCA replacement levels increased from 0% to 100%, a decrease in compressive strength was observed. The corresponding reductions in the 28-day compressive strength were 2.4% and 11.2% for concrete made with 50% and 100% of RCA, respectively, when compared to the NAC measurements. Similar trends were noted for the splitting tensile strength, in which case concrete with 50% of RCA reduced by 2.1% the splitting tensile strength. This variation significantly decreased to 30.6% when using the 100% RCA replacement ratio. Only 74.1% of elastic modulus was achieved in RAC with 100% RCA replacement ratio compared to that of NAC, while 82.0% of elastic modulus was observed in RAC with 50% RCA replacement ratio.

The experimental arrangements used for the evaluation of the shrinkage properties of the concrete are illustrated in Figure 1. DEMEC gauges were used to measure the long-term shrinkage on both surfaces of the prisms (100×100×400 mm<sup>3</sup>) and of the small-scale shrinkage samples (600 mm×600 mm× 120 mm or 180 mm), while deformations taking place within the slab thickness of the small-scale shrinkage samples were monitored with embedded strain gauges, as shown in Figures 1 (a). The timber formwork was removed at 24 hours after casting, after which both four side edges and the bottom surface of the small-scale shrinkage samples were covered with epoxy to reflect the sealing condition provided by the steel deck without inducing its restricting action. Small-scale shrinkage samples were located on three roller supports vertically to eliminate any restraint due to friction between the specimen and the laboratory floor. Details of the small-scale shrinkage samples are listed in Table 4. The creep tests were conducted on concrete specimens (100×100×400 mm<sup>3</sup>) subjected to a sustained load ( $\approx 0.2 f_{cm}A$ ) applied at 28 days from casting. Figure 2 shows the temperature and relative humidity data that were recorded regularly for the duration of the experiments. The mean temperature and relative humidity measured during the tests were 19.0°C and 55.1%, respectively.

(a) Instrumentation for shrinkage

(b) Overview of the shrinkage test arrangement

**Figure 1. Instrumentation arrangement and long-term setup for small-scale shrinkage samples**

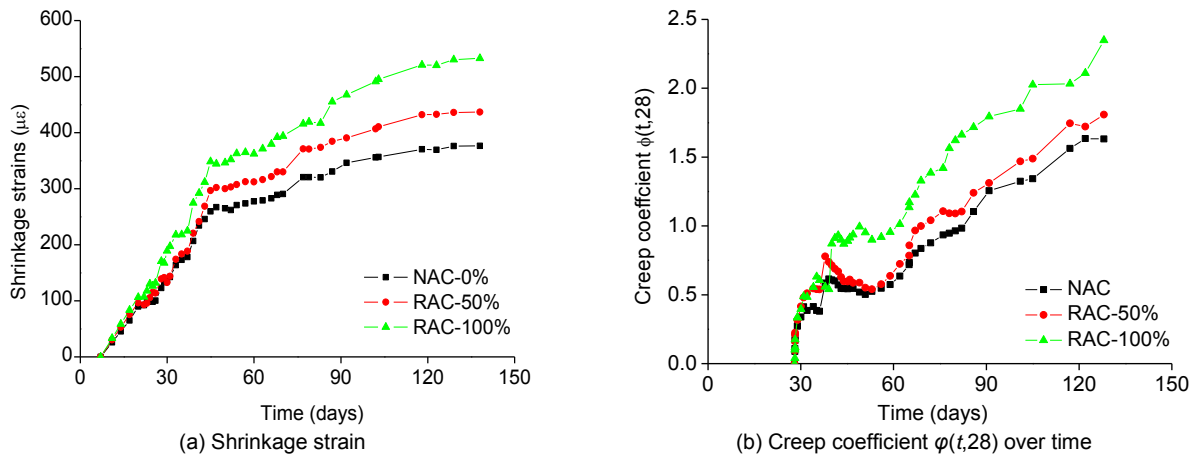

**Table 4. Detail of non-uniform shrinkage samples**

Shrinkage sample ID	Replacement ratio	Dimensions of samples (mm)	Exposed condition
SS-120-0%	0%	600×600×120	Only top surface exposed to the chamber condition, the other five sides sealed with epoxy
SS-120-50%	50%		
SS-120-100%	100%		
SS-180-100%	100%	600×600×180	

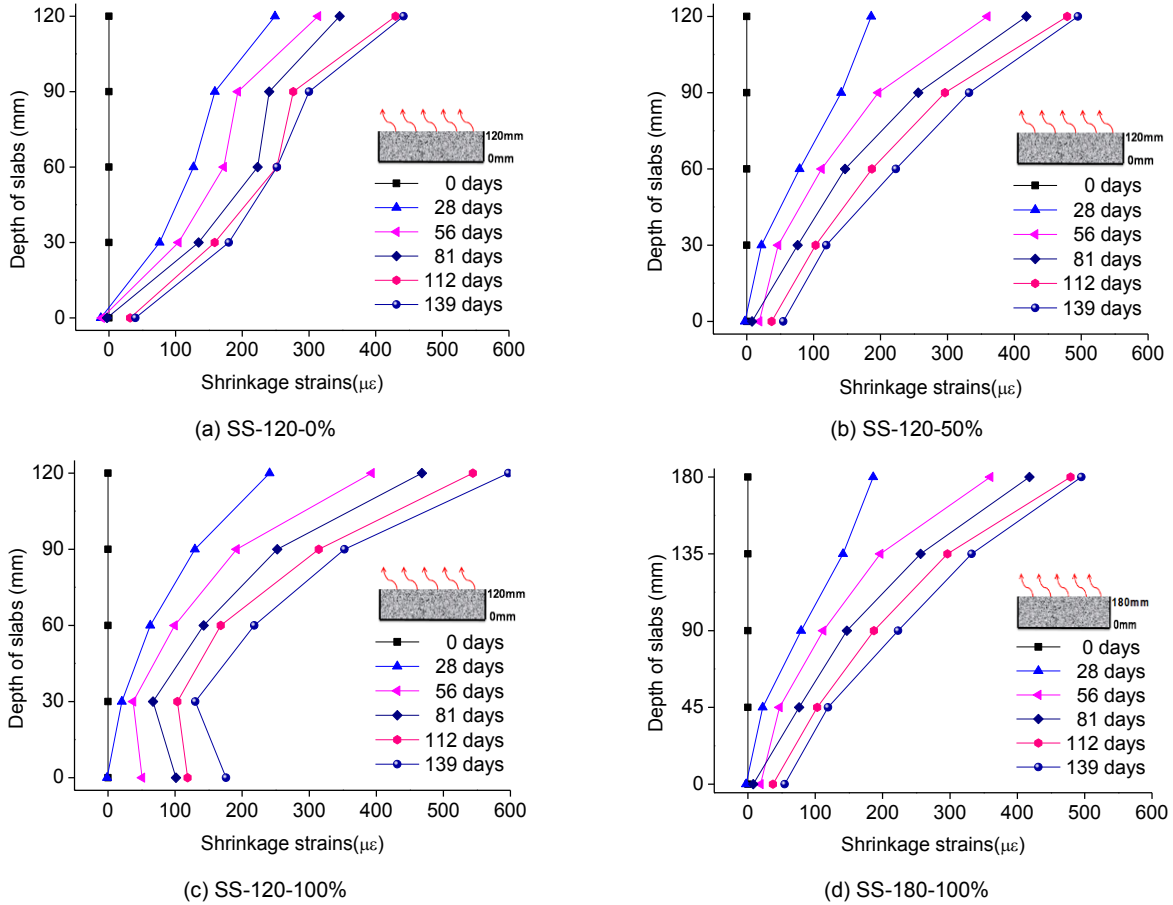

**Figure 2. Environmental conditions measured during the long-term tests**

Shrinkage deformation and creep coefficient measurements obtained from the 100×100×400 mm<sup>3</sup> samples are reported in Figures 3 (a) and (b). Significant increases of 41.5% and 52.9% for the shrinkage strains and the creep coefficients were observed for the concrete prepared with 100% RCA when compared to the measurements collected for NAC. Smaller increases (i.e. 16.0% and 12.2%) were recorded for concrete made with the 50% RCA replacement ratio.

**Figure 3. Long-term properties of hardened concrete**

The total deformations measured in the small-scale shrinkage samples are assumed in the following to reflect the shrinkage profile. As the purpose of this study is to develop adequate design guidelines, the simplifying assumption of using a linear distribution for the shrinkage profile is regarded as acceptable, even if more complex distributions develop in reality [30]. The shrinkage slab samples were sealed on one slab face (and on the four edges) to reflect the real condition in which the composite slab cannot dry from its underside due to the presence of the profiled sheeting. Typical strain profiles measured through the depth of the small-scale shrinkage samples at different instants in time are illustrated in Figure 4.

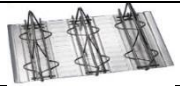

**Figure 4. Total deformations through the slab thickness of slab samples**

The strains measured on the top fibres increased with increasing percentages of RCA. In particular, maximum shrinkage strains on the top surfaces increased to  $495 \times 10^{-6}$  and  $597 \times 10^{-6}$ , respectively, when 50% and 100% of RCA were adopted, which were 12.0% and 35.1% larger than the NAC measurement (equal to  $442 \times 10^{-6}$ ). This was attributed to the residual mortar presented in RCA, which increased the porosity and reduced the volume of coarse aggregate in RAC. The non-uniform shrinkage gradient increased with RCA contents. At the age of 139 days, the shrinkage gradients were 2.91, 3.94, and  $5.19 \times 10^{-6} \text{mm}^{-1}$  for specimens SS-120-0%, SS-120-50% and SS-120-100%, respectively. A comparison of the shrinkage distributions in SS-120-100% and SS-180-100% showed that only 62.0% of the shrinkage gradient for SS-180-100% was observed compared to that of SS-120-100% after five months.

The section properties of steel-bars truss decks and profiled steel sheeting used in this study are provided in Table 5. The mechanical properties of the steel deck and reinforcement were obtained from standard tensile tests carried out in accordance with [31] and are reported in Table 6. Yield strength and elastic modulus of the profiled steel sheeting were 440.3 MPa and 199.7 GPa, respectively, while the corresponding measurements observed for the steel-bars truss decks were 414.3 MPa and 206.3 GPa, respectively. The yield strength of the 10 mm and 8 mm diameter reinforcing bars were 503.0 MPa and 510.0 MPa, respectively, with elastic modulus of 189.0 GPa and 166.3 GPa, respectively.

**Table 5. Geometric properties of steel-bars truss decks and profiled steel sheeting**

Deck profile ID	Depth $d$ (mm)	Width $b$ (mm)	Thickness $t$ (mm)	Dimension of reinforcement (mm)	$A$ ( $\times\text{mm}^2$ )	$I$ ( $\times 10^5\text{mm}^4$ )	Decking profile
Steel-bars truss decks	80	590	0.5	10/8/4.5 <sup>a</sup>	830	7.99	
Profiled sheeting	65	510	1.2	—	1200	7.75	

<sup>a</sup> 10/8/4.5—The diameters of reinforcing bars for compressive reinforcement, tensile reinforcement and stirrups.

**Table 6. Mechanical properties of reinforcement bars and steel deck**

Diameter or Thickness (mm)	Elastic modulus (GPa)	Yield strength (MPa)	Ultimate strength (MPa)	Samples from
10	189.0	503.0	648.0	Steel-bars truss decks
8	166.3	510.0	661.3	
0.5	206.3	414.3	469.3	
1.2	199.7	440.3	517.0	Profiled steel sheeting

**2.4 Description of long-term experiments of the full-scale specimens**

Three steel-bars truss slabs and four composite samples with profiled steel sheeting were prepared and tested as shown in Figure 5. All specimens were maintained propped during casting, after which the props were removed and the specimens were placed in a simply-supported static configuration. In this manner, the self-weight of the slabs was supported by the steel deck. Based on this, it was assumed that no creep developed in the concrete due to the slab self-weight. This condition was used to monitor the development of shrinkage only in two of the samples prepared which were kept unloaded for the entire duration of the long-term tests. The timber formwork was removed at 24 hours after casting, and then four side edges of the full-scale specimens were sealed with epoxy to prevent drying to take place from these locations as it would occur in a real slab due to its continuity.

(a) Instrumentation arrangement for long-term full-scale specimens

(b) Specimens with steel-bars truss decks

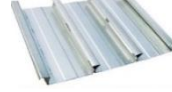

(c) Specimens with profiled steel sheeting

**Figure 5. Long-term test setup for full-scale specimens**

All slab samples were simply-supported with a total length of 3.3 m and a distance between roller supports of 3.0 m. The steel-bars truss samples had a thickness of 120 mm and were prepared with 0%, 50% and 100% RCA replacement ratios (Table 7). They were subjected to a sustained load of 4 kN/m applied at 28 days from casting. These samples have been referred to as SBTS-120-0%, SBTS-120-50% and SBTS-120-100%, respectively. The four composite slabs were poured with 100% RCA replacement ratio (Table 7). Two samples had a slab thickness of 120 mm and two specimens were 180 mm thick. One sample for each thickness was subjected to a sustained load at 28 days from casting. The two loaded samples were referred to as CS-120-100% and CS-180-100%, and were subjected to sustained loads of 4.5 kN/m and 9.0 kN/m, respectively. The remaining two specimens, referred to as CS-120-100%-SH and CS-180-100%-SH, were only exposed to shrinkage effects. Details of the full-scale specimens are provided in Table 7. The time-dependent deflections at mid-span, at quarter-span and at the supports of the slab samples were measured with dial gauges for the entire duration of the long-term tests.

**Table 7. Construction details of the full-scale slab samples**

Specimens	Replacement ratio $r$ (%)	Depth $d$ (mm)	Width $b$ (mm)	Length $L$ (mm)	$t_0$ (days)	Loading $w_{\text{SUS}}$ (kN/m)	Decking profile
SBTS-120-0%	0	120	590	3300	28	4.0	
SBTS-120-50%	50						
SBTS-120-100%	100						
CS-120-100%-SH	100	120	510	3300	—	—	
CS-120-100%		120			28	4.5	
CS-180-100%-SH		180			—	—	
CS-180-100%		180			28	9.0	

### 3. Experimental results

#### 3.1 Long-term experimental results for the steel-bars truss slab samples

The steel-bars truss samples exhibited greater mid-span deflections for increasing levels of RCA, as reported in Figure 6 (a). At the age of 139 days, the mid-span deflection was 8.78 mm ( $\approx L/340$ ) for SBTS-120-100%, which was about 14.5% and 35.5% larger than the measurements in the specimens prepared with 50% and 0% RCA replacement ratios, respectively. This was mainly caused by the shrinkage gradient and by the decrease of elastic modulus produced by the use of RCA, as the instantaneous mid-span deflections at 28 days were 1.72, 1.95 and 2.49 mm for SBTS-120-0%, SBTS-120-50% and SBTS-120-100%, respectively (Figure 6(b)).

It is worth mentioning that the slab samples presented initial upward deflections for the first few days when RCA was used. This was attributed to the expansion occurred in RAC at the beginning of the test caused by the additional water absorbed by RCA, as highlighted in [32]. This initial expansion was also observed in the RAC composite slabs, as shown in Figure 7.

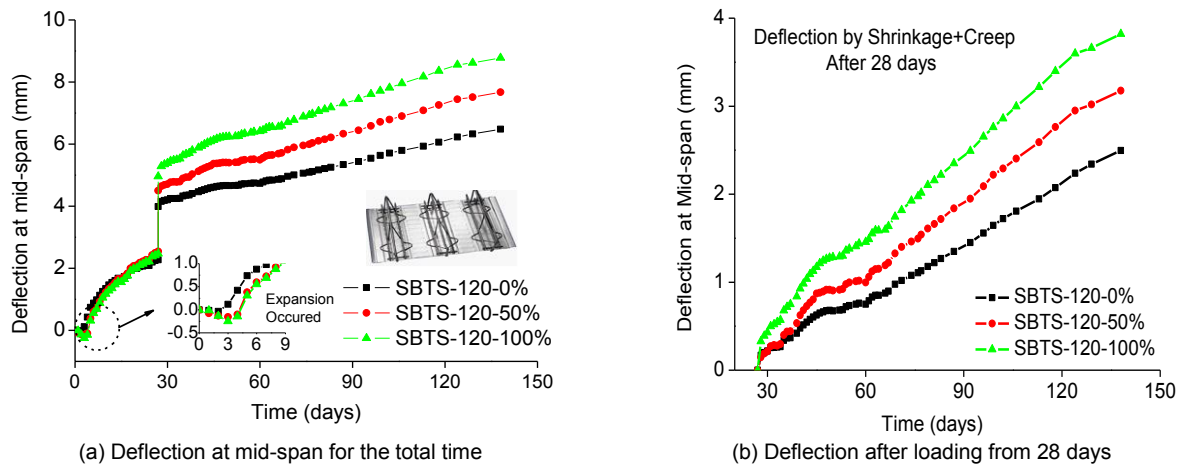

Figure 6. Mid-span deflection of slab samples with steel-bars truss decks

### 3.2 Long-term experimental results for the slab samples cast on profiled sheeting

Before the application of the external loads, the slab specimens with the same depth presented similar mid-span deflections, as reported in Figure 7. At the age of 139 days, the mid-span deflections of CS-120-100% and CS-180-100% under the combined effects of external loads and shrinkage were 8.33 mm ( $\approx L/340$ ) and 5.38 mm ( $\approx L/560$ ), respectively, while the mid-span deflections caused by shrinkage gradient were 5.33 mm and 3.22 mm for CS-120-100%-SH and CS-180-100%-SH, respectively. A comparison of the deflection composition of CS-120-100% showed that the deflection caused by shrinkage was about 64.0% of the total deflection. A similar influence was observed for the 180 mm thick samples (with the shrinkage deflection being equal to 59.9% of the total deflection).

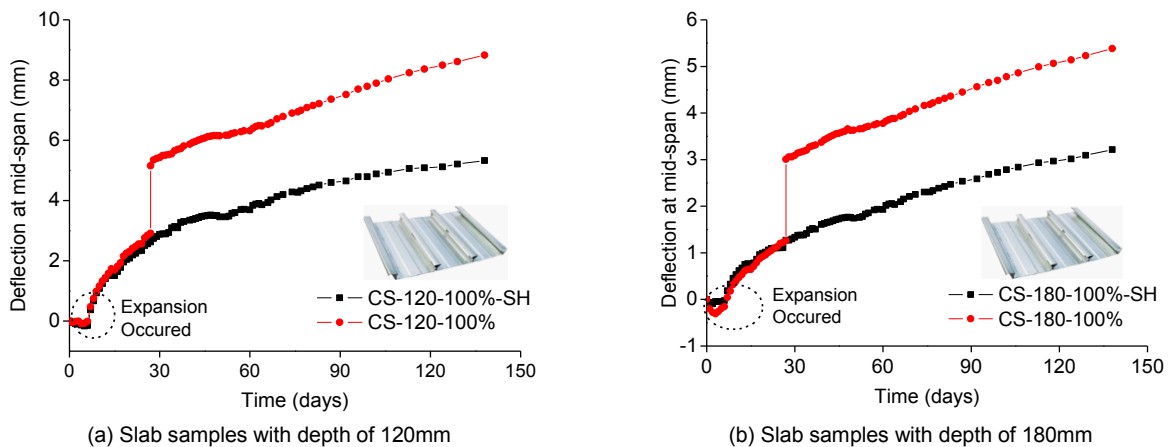

Figure 7. Mid-span deflection of composite slabs with profiled steel sheeting

## 4. Conclusion

This paper presented an experimental study on the time-dependent behaviour of seven floor slabs prepared with recycled coarse aggregate. These consisted of three steel-bars truss slabs and four composite slabs, and were tested in a simply-supported static configuration for a period of five months. Separate concrete samples were prepared and measured monitoring the shrinkage profile through the thickness of slabs. Experimental results showed that similar workability and compressive strength were achieved for RAC to corresponding NAC, due to the high quality of RCA used in this study, however, the decrease of elastic modulus and the increase of shrinkage and creep were still remarkable, when 100% RCA was selected. The non-uniform shrinkage gradient developed due to the inability of the slabs to dry from their underside and increased with RCA contents. The deflections of the RAC composite slabs were influenced by the non-uniform shrinkage gradient and increased with RCA contents. It is also expected

that more experiments should be carried out to quantify the non-uniform shrinkage profile though the thickness of the RAC composite slabs.

**Abstract:** Alkali-aggregate reaction (AAR) can cause damage to concrete structures, which can vary from serious reductions in structural capacity to less serious maintenance problems, or minor durability effects. New cases of AAR continue to be discovered in different concrete structures in Australia, and exhibit different visual effects. The affected concrete needs to be characterised in order to determine the extent of damage caused by AAR, and to establish appropriate rehabilitation strategies.

Recently, three bridges were diagnosed with AAR and were characterised using petrography, scanning electron microscopy, measurement of residual alkali content and residual expansion potential, compressive strength and elastic modulus. The results show that AAR has impacted the three bridges differently, and the paper discusses the consequences of AAR and appropriate treatments for each case.

**Keywords:** AAR, Expansion, Cracking, Corrosion, Microstructure, Strength properties

## 1. Introduction

The most visible sign of alkali aggregate reaction (AAR) in concrete is cracking, which takes different forms and can occur to different extents, depending on the severity of reaction, and design details of the affected element. The severity of reaction, in turn, is a function of the type of aggregate, alkali content of concrete and exposure environment. The cracking adversely affects the durability of concrete by exposing the concrete interior to aggressive environmental agents.

In Australia, several major cases of deleterious AAR have been reported in dams and bridges (for example, 1-8), which have resulted in significant repair and rehabilitation expenditure, amounting to many millions of dollars in each case. Many more cases of AAR damage in concrete structures have been included in the updated version of HB70 (2015), "Guidelines on minimising the risk of damage to concrete structures in Australia", which may have suffered less severe damage.

The AAR-induced cracking of concrete is also often associated with reductions in the strength properties of concrete (8-11), the extent of which depends on the severity of the reaction. Some authors have reported that despite the reductions in strength properties of concrete, the load capacity of the affected element was not adversely affected (8, 9, 12-15). Deterioration of mechanical properties was found to be more severe in smaller elements than in larger elements, due to larger ratio of crack depth to dimension of element (16). The above indicates that several parameters influence the effect of AAR on the behaviour of affected elements, and that each case needs to be considered individually. This paper details the different impacts of AAR on three different structures, which require different treatments.

## 2. Structures investigated and methodology

The AAR-affected structures investigated are listed in Table 1. They represent structures incorporating different reactive aggregates, subjected to different exposure conditions.

Bridge A is 54 years old and carries freeway carriageways over a fresh water creek. Figure 1 shows the mild nature of cracking in the column and more extensive cracking in the crossheads of the bridge.

Bridge B is 24 years old and carries a State Road over a freeway. The concrete has been coated with heavy duty anti-carbonation coating, thereby masking the cracks. Figure 2 shows examples of cracks which have reopened.

Bridge C is 26 years old and is situated in a coastal area where the tidal river water is saline. This bridge has been inspected on a number of occasions and mild AAR-induced cracking identified in some columns and crossheads with wider cracks in pile caps, which are often submerged. The substructure elements have recently been painted, after patch repair and crack injection, which has masked the previously recorded cracks. However, in addition to AAR-induced cracks, corrosion-induced cracks were also noted at the corners of some columns. These cracks were not

present in 2004. The bases of the columns to about 800 mm above the pile caps have been jacketed with a cement-based product in order to protect against scour (not against chloride ingress). Figure 3 shows some repaired elements in Bridge C.

**Table 1- Details of structures**

Bridge ID	Bridge type	Date Built	Environment	Cracking defects
A	3 spans- simply supported, consisting of pier columns & crossheads, supporting I-beams and deck slabs	1961	Over fresh water creek, carrying freeway lanes	Fine, mild vertical cracking at centre of some columns, and moderate cracking in crossheads varying in different locations from parallel horizontal to random and some vertical (bending) cracks
B	2 spans, continuous box girder T beam supported by central pier wall and abutment piers	1991	Over freeway, dry conditions	Random and oblique to vertical cracking in central pier wall and random cracking in the abutment crossheads.
C	6 spans- simply supported, consisting of pier columns & crossheads, supporting I-beams and deck slabs	1959	Over tidal river, exposed to salt water	Fine map-cracking throughout crossheads, central vertical crack in columns, cracking in pile caps, corrosion-induced cracks at column corners

**Figure 1- Mild cracking in column (left) and crosshead (right) of Bridge A**

**Figure 2- Vertical cracking in pier column of Bridge B, about 0.35- 0.40 mm wide**

**Figure 3- Views of repair in a crosshead and a column in Bridge C. Note jacket at the base of column applied later for scour protection**

### 3. Examination and testing of concrete cores

Each of the bridges was subjected to visual inspection and characterisation of concrete cores, drilled from various elements, by the methods listed below.

- Visual examination of core samples taken from different elements, and
- Petrographic examination
- SEM/EDX examination
- Available alkali content
- Residual expansion potential
- Compressive strength
- Modulus of elasticity
- Volume of permeable voids (VPV)
- Chloride content (Bridge C only)
- Onsite measurement of half-cell potential and corrosion rate of steel (Bridge C only)

These methods were used to assess the extent of AAR and its impact on the mechanical properties of the affected concrete. Table 2 shows the list of cores taken from each bridge. Most cores were of 75mm diameter, except those intended for residual expansion measurements, which were 95mm in diameter.

#### 3.1 Visual features of cores

Figure 4 shows representative photographs of cores from the three bridges. Cores from Bridge A contained uncrushed river gravel with some light and some dark particles. The dark particles exhibit stronger signs of reaction. The cores from the crossheads and columns appeared generally similar, to former has developed somewhat stronger reaction than the columns. Overall, the extent of AAR is considered to be mild in cores from Bridge A.

Bridge B cores exhibited stronger signs of AAR, as seen in Figure 4. A distinct layer of surface coating was present on the outer face of cores, particularly those from the abutment. Well-defined AAR rims and internal aggregate cracking were noted in some cores. Some air voids also appeared to contain AAR products. The extent of AAR in the cores is considered to be moderate to large and greater than those in cores from the other bridges.

Bridge C cores were similar in different elements and contained uncrushed river gravel. AAR signs were stronger in cores from the pile cap and included AAR rims at aggregate periphery and in some air voids. Cores from the jacketed areas of columns showed very weak bonding between the jacket and column, due to no cleaning of the column surface prior to application of jacket concrete. The latter comprised a different (proprietary) type of concrete with maximum aggregate size of 9mm.

**Table 2- List of cores taken from various elements**

Bridge	Location of Core <sup>†</sup>	Core ID
A	Two cores from P1C2	C14/2633-1 and C14/2633-2
	Three cores from P1C1	C14/2633-3, C14/2633-4 and C14/2633-5
	Five cores from south abutment crosshead	C14/2633-6, C14/2633-7, C14/2633-8, C14/2633-9 and C14/2633-10
B	Five cores from Pier wall	C14/ 2634-1 through C14/ 2634-5, inclusive
	Five cores from abutment	C14/ 2634-6 through C14/ 2634-10 inclusive
C	Three cores from Pier 1 Pile-cap	C13/2491-1, C13/2491-2 and C13/2491-3
	Two cores from P1C3	C13/2491-4A (jacket) and C13/2491-4B (behind jacket)
	Two cores from P1C2	C13/2491-5A (jacket) and C13/2491-5B (behind jacket)
	Three cores from east abutment crosshead	C13/2491-6, C13/2491-7 (included a 10 mm later of repair mortar) , and C13/2491-8
	Two cores from P3C3	C13/2491-9 (upper) and C13/2491-10 (lower)
	Two cores from P3C2	C13/2491-11 (upper) and C13/2491-12 (lower)
	Two cores from P3C1	C13/2491-13 (upper) and C13/2491-14 (lower)

<sup>†</sup>P= pier; C= Column, numbering of piers is from South to North.

## 4. Results and discussion

### 4.1 Petrographic examination of cores

**Bridge A:** The coarse aggregate in the cores from columns was predominately gneissic deformed quartz gravel, in which quartz crystals have been highly strained, producing strongly distorted crystal habit and patchy extinction. Some weathered andesite-like particles were also present in the thin section. The quartz gravel is susceptible to AAR, but the reactivity of the andesitic particles is uncertain.

The coarse aggregate from the abutment crosshead contained quartzite, in which the quartz grains appeared to be cemented together by fine micaceous materials. Foliated schist-like particles were also present. The fine aggregate fraction in both elements comprised a mixture of monomineralic quartz and feldspar as well as finer fragments of the same nature as the coarse aggregate, which are potentially reactive.

The cementitious matrix in the core from the column showed a few fine peripheral microcracks around a portion of some coarse aggregate particles, which extended a small distance into the cement paste. The core from crosshead exhibited more definite signs of AAR gel formation around aggregate particles and in parts of some microcracks in the cement paste.

**Bridge B:** The coarse and fine aggregate phases in the pier wall and abutment crosshead were the same. The coarse aggregates was a mixture of metamorphic rock types of schist and gneiss, and all the particles exhibited strong signs of deformation and orientation, as indicated by elongated quartz grains and bands of micaceous minerals in parallel orientation. Some particles comprised a fine matrix of microcrystalline quartz and highly birefringent amphibole type minerals. Particles of quartzite with highly deformed quartz crystals were also present, in which quartz crystals showed sutured boundaries and patchy extinction. These rock types are considered to be susceptible to AAR.

The fine aggregate fraction was a mixture of mono-mineralic quartz and feldspar crystals as well as finer fragments of the coarse aggregate particles. Some of the single quartz crystals also showed moderate undulatory extinction angles. A portion of the fine fraction may be susceptible to AAR.

The cementitious matrix in cores from both elements showed a considerable number of micro-cracks at the aggregate periphery, extending into the cement paste. AAR gel was definitely identified in some micro-cracks around the aggregate and in the paste. The petrographic examination clearly verified AAR is both elements.
